As a consequence, the entries of $\widetilde{\mathbb{L}} = \widetilde{\mathbf{L}}^T\widetilde{\mathbf{U}}$ are solely determined from input/output data using only (time) samples of the subsystem kernels h_1, h_2 and h_3. In a similar way, one can also show that the other matrices in (9) appearing in BT, namely, $\widetilde{\mathbf{L}}^T\mathbf{A}\widetilde{\mathbf{U}}$, $\widetilde{\mathbf{L}}^T\mathbf{M}\widetilde{\mathbf{U}}$, $\widetilde{\mathbf{L}}^T\mathbf{b}$, and $\widetilde{\mathbf{U}}^T\mathbf{c}$ can be also be constructed relying only on kernels' data. Hence, by means of the SVD of $\widetilde{\mathbb{L}}$ as in (8), we are able to compute the matrices $\mathbf{Z}_1$ and $\mathbf{Y}_1$ and construct reduced models quantities in (9) directly from data. We call this framework QuadBT for bilinear balanced truncation. Due to the page limitations in this extended abstract, we have presented our formulation using only 2 quadrature nodes and unity weights. The general case follows immediately and will be included in the full paper.

We outlined our approach above using numerical quadrature in the time-domain but one can use an equivalent frequency-domain representation of the Gramians and consider instead quadrature rules in the frequency domain. Such a frequency-domain formulation would yield data matrices analogous to $\widetilde{\mathbb{L}}$, whose entries would now be derivable from the sampling of the multivariate subsystem transfer functions $H_k(s_1,\dots,s_k)$ defined above (and from associated divided differences).

The recent extensions of the Loewner framework applied to the class of BDS's in Antoulas et al. (2016b); Karachalios et al. (2021) make also use of specific transfer functions corresponding to the the BDS subsystems, i.e., regular transfer functions for the former and symmetric transfer functions for the latter. However, in these works, this is done in order to construct interpolatory models. We showed in Gosea et al. (2021) that our data-driven BT formulation outperforms the classical Loewner framework for LTI systems Mayo and Antoulas (2007) (in terms of the approximation errors). We anticipate a similar conclusion in the bilinear setting as well.

In our description given above, we have only considered the leading two terms of the Volterra series expansion. Although the leading two terms are enough in many cases Flagg and Gugercin (2015); Goyal (2018), we are investigating the impact of including higher-order Gramians, e.g., $\mathbf{P}_3, \mathbf{P}_4$ etc. We anticipate similar extensions that would require sampling of higher order kernels $h_k(t_1,\dots,t_k)$ and/or transfer functions $H_k(s_1,\dots,s_k)$.

3. PRELIMINARY NUMERICAL RESULTS

We consider the viscous Burgers' equation model from Benner and Breiten (2012). After applying a finite difference scheme for approximating the spatial derivatives, the resulting system of ODEs has a quadratic-bilinear nonlinearities with dimension n_q. By means of Carleman's linearization, a bilinear model of the form (1) with dimension $n = n_q^2 + n_q$ is obtained. To enforce positive-definite Gramians as the solutions of the Lyapunov equations (6), we multiply the matrix $\mathbf{M}$ with a positive scalar less than 1; here we choose $\gamma = 1/5 \in (0,1)$, i.e. $\tilde{\mathbf{M}} = \gamma\mathbf{M}$.

For a proof of concept example, we choose $n_q = 3$, leading to a bilinear system of dimension $n = 12$. Note that since the proposed framework is data-driven, the order of the underlying system does not play a role in our approach. We choose 50 linearly spaced time samples t_k in the interval $[0, 100]$s, truncation index $T = 2$, and construct the data-driven Loewner matrix $\widetilde{\mathbb{L}}$ whose singular values are expected to approximate the Hankel singular values. The results displayed in Fig. 1 verifies this expectation. The approximated Hankel singular values (obtained via the data-driven formulation) accurately match the original ones.

The Hankel singular value decay indicates that the underlying bilinear model is of minimal order $r_b = 7$. However, for MOR purposes, we use a slightly lower truncation order and choose $r = 5$. We simulate the full-model, the classical (projection-based) BT reduced model, and the data-driven QuadBT model with a control input $u(t) = 20(\cos(2\pi t) + \sin(12\pi t)e^{-0.4t})$ over $t \in [0, 5]$s. The resulting outputs and the output errors shown in Fig. 2 illustrate that the proposed data-driven QuadBT method closely mimics the performance of the classical BT.

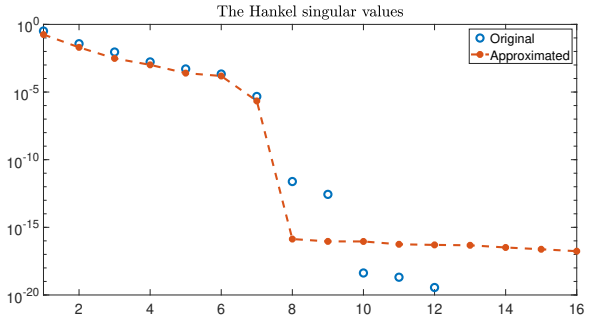

Fig. 1. Hankel singular values (original vs. approximated).

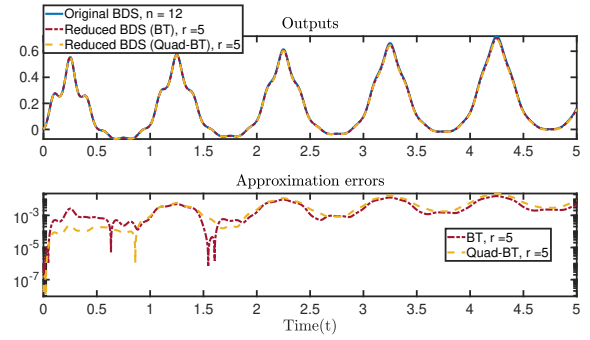

Fig. 2. Outputs (top) and output errors (bottom)

4. CONCLUSIONS

We developed a data-driven formulation for balanced truncation of bilinear systems, which does not require access to a state-space formulation and only works with the samples of subsystems kernels. The numerical results illustrate the potential of the new approach. Even though using a truncation index of $T = 2$ already yielded an accurate approximation, it would be interesting to include higher-order terms in the Volterra expansion, which will require sampling higher-order kernels. Since the Volterra kernels are smooth, we expect that progressively coarser sampling in each dimension will be sufficient for higher-order kernels and we anticipate significant benefits may accrue from sparse grid sampling and related methods.

3D Cues for Human Control of Target Acquisition in Auditory Augmented Reality ⋆

Konstantinos Dadamis, John Williamson, Roderick Murray-Smith

School of Computing Science, University of Glasgow, Scotland.
(e-mail: Roderick.Murray-Smith@glasgow.ac.uk).

Abstract: We compare the effectiveness of different auditory cues for attracting attention to spatial targets around a mobile user, using a commercial 3D audio headset instrumented with GPS and inertial sensors. We compare two approaches to spatial audio feedback with a baseline case that only provides 'on target' feedback: 1. hints as single sounds played from a 3D location and 2. frequency modulation of inter-pulse gaps based on proximity. We illustrate the difference in user control behaviour created by the different forms of feedback with phase plots. Single 3D sound hints provided the best improvement over the baseline case of no hint. Frequency modulation of pulses performed more poorly for larger targets. The choice of sound has a significant effect on targeting performance and there is a significant trade-off between efficient targeting and aesthetically-pleasing audio.

1. INTRODUCTION

Instrumented headsets which can sense orientation, location and bearing can be used to augment the user's experience of the world with a virtual audio layer. Fusing location awareness with orientation sensing allows accurate alignment of the virtual layer with real-world objects. In mobile contexts visual attention is a scarce resource, and navigation systems based on audio and vibrotactile cues Williamson et al. (2010); Holland et al. (2002) have successfully provided spatial guidance without overloading the visual channel. Positional audio could increase the efficiency of these navigation mechanisms.

Aside from the benefits of disengaging from the visual display, the advantages of positional audio cues are twofold. Firstly, audio cues extend the field of awareness of the user, presenting information close to their current location, but out of their current field of view, as discussed in Bolia et al. (1999). Secondly, audio cues function as effective attention management elements. Animation is an essential part of modern interfaces as it directs user attention to key UI components; the audio counterparts of animation cues can apply this attention management for entities out of view. We explore a range of possible solutions for effectively and efficiently informing the user about the location of nearby points of interest.

We used the Jabra Intelligent Headset [1] which includes 3D audio, GPS location, magnetometers, accelerometers and gyroscopes in iOS with the Jabra API. This commercially-available, integrated hardware package simplifies the equipment requirements for spatial audio target acquisition and provides a potential mass market for spatial audio applications.

2. TARGET ACQUISITION

There are several challenges when it comes to designing auditory cues for spatialised content. The cues need to be both efficient and result in a pleasant user experience. Key aspects of auditory target display are informing the user about the nature and number of targets nearby and their bearing and distance from the user. This paper explores different feedback mechanisms for informing users about the bearing of a single given target. The purpose of guidance feedback is to ease (quicker, requiring less effort) aligning head orientation with that of targets around the user. It needs to give a user hints about which direction to turn, and how close the target is. This feedback can be a single event (e.g. a "ping" in the target direction), while in others it is an ongoing process providing gradient information to ease acquisition. For a review of the spatial audio targeting literature see Marentakis (2006); Gröhn et al. (2005); Strachan et al. (2005); Sandberg et al. (2006); Eriksson (2008); McGookin et al. (2009). We explore three feedback conditions:

1. Baseline condition. No Hint In this experiment, the user is given no cue about the target direction, to explore the user's behaviour and performance on the simplest scenario, as a baseline. Instead, she only relies upon the simple feedback when on-target. Consequently, in order to acquire the target, she turns her head until feedback is heard.

2. Single-sound Hint from 3D location For each trial, a 3D pulse sound (with duration of 0.3-1.00s) is played once, from the direction of the target. We experiment with a number of different sounds.

3. Frequency modulation of pulses based on proximity In this case, the feedback given to the user simulated the behaviour of feedback from parking sensors available in many modern cars, where the delay between short pulses represents the distance to another car. Assume that the feedback pulse has a duration of τ, and the angular size of the target is w_t. Within the target area, feedback is played continuously, as in the previous experiments. When the user is in the opposite direction (180° from the target's centre), the pulse's period was set to be $k\tau$, where k is a specified multiplier. Consequently, when the user's distance from the target is $\psi \in (w_t/2, 180°]$, the pulse period is $\frac{\psi - w_t/2}{180° - w_t/2}(k-1)\tau + \tau$. k was set to 20 and the pulse used was a sinusoidal tone of 261Hz of duration $\tau = 0.1$s.

[1] **https://www.jabra.co.uk/supportpages/jabra-intelligent-headset**. Last accessed 25/1/2022.

As a pre-experiment, we investigated the sensitivity of faster cue-based acquisition to the specific sound used by exploring the impact of the types of sounds played on localisation speed. Our baseline was a simple sinusoidal tone (261Hz). When applying filters to white noise sounds, the widest filters (350-8000Hz) give the best localisation results Susnik et al. (2003), so the ideal sound should contain a wide range of frequencies. We tested two "blowing bottle" sounds from Cook (2002), and recorded two voiced vowel sounds. 4 further synthesized sounds were tested, Buzz-0004, Buzz-0035, Buzz-0036 and pulse1sec. 3D positional audio works best with sounds with strong transients and significant high-frequency content, for a clear inter-aural time delay and a perceptible effect of the head-related transfer function, which primarily modulates high-frequency components. As expected, the pure tone sound did not perform well, but surprisingly the richer "blowing bottle" sounds and the voiced sound performed worse. The sounds with fastest responses are Buzz-0004, Buzz-0036, the 'a' vowel recording and 'pulse1sec', which was the overall best. The aesthetic aspect of the sounds is important for the user experience, but the best performing sounds, apart from Buzz-0004, were considered to be somewhat robotic, squeaky or eccentric for a mainstream target acquisition application.

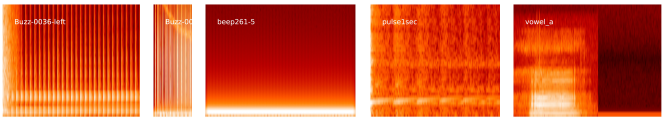

Fig. 1. Spectrograms of sounds used. Clipped to 8KHz max. freq, NFFT=1024, 1000 sample overlap.

3. EXPERIMENTAL SCENARIO

We investigate the impact of feedback choice on user behaviour, in terms of speed of action, nature of movement and user experience. In all cases, a simple 261Hz feedback tone indicates that the user is 'on-target'. The user is considered to be located at a fixed position, so that the GPS location uncertainty does not affect the results. As such the results provide a 'best case' scenario. The experimental task was performed on-campus, and the targets used are parts of the University of Glasgow's Main Building, as shown in Figure 2. Successful acquisition is defined as being achieved when the user looks towards the target bearing ψ_t for 3 seconds consecutively. The target is considered to be missed when the user has not acquired the target within 20 seconds. The targets are considered to be at the same distance d from the user and have the same angular w_t size (in degrees). We consider the user to be looking at the target when the direction is within the angle range $\psi_t \pm \frac{w_t}{2}$.

Fig. 2. Panoramic view of experiment location.

5 users aged between 23-46 and self-declared normal hearing tested the system. Each test for each of 7 target sizes w_t consists of the same ten targets in sequence, and the order of condition was cycled through participants. After acquiring or missing one target, the user was immediately presented with the next target. After all 10 targets at a given size w_t, the user rested for two minutes, then continued with the next sub-test of a different target size. Each experiment consists of 7 tests, for target sizes of w_t = 5, 10, 20, 40, 60, 90 and 180°, ordered from easiest (largest) to smallest, to give users progressively more challenging tasks. Within a particular feedback condition (e.g. frequency modulation of pulses) the order of the targets was kept constant. The users were not able to memorise the sequence. The sequence was varied across conditions. In most trials the users moved their whole body and not just the head in order to acquire the target. The sounds used are shown in the spectrogram plots in Figure 1.

4. ANALYSIS OF RESULTS

We view the user's behaviour from the perspective of a control system minimising the 'error' between the current bearing angle ψ and the reference or target bearing ψ_t, such that error $e = \psi_t - \psi$. The different feedback mechanisms will change the overall control system behaviour, Jagacinski and Flach (2003); Poulton (1974). In the 'no hint' case, feedback is only provided when over the target, so the user has an exploration behaviour. In the '3D hint' case feedback is provided once, at the start, to help the user infer target location so any error minimisation is being done by the user, with respect to the user's inferred target location. In the 'frequency modulation of pulses' method, explicit error feedback is provided in an ongoing fashion.

The experiments are sampled at 20Hz, and the data is smoothed using a Savistky-Golay filter (length 41 samples, order 4 polynomial), equivalent to least-squares polynomial fitting of a quartic polynomial to the last 2.05 seconds of data. This filter structure better preserves edges and transients than standard low-pass filters and can be used to robustly estimate derivatives.

The phase and polar plots shown in Fig. 3 provide a visual summary of acquisition performance. Target overshooting, oscillation and under-damped behaviour are all clearly visible. In contrast to time-series, phase plots make it easier to align and compare the dynamics of multiple acquisitions as time offsets are ignored. An example of an unsuccessful acquisition is illustrated in Figure 3a, where the user receives no hint about the location of the target, and fails to acquire it within the 20s time limit. The user enters and exits the target zone associated with the feedback tone starting and stopping, but continues to overshoot and 'hunt' around the small target.

4.1 No 3D hint

User performances are summarized in Figure 4, where the standard error of the mean time is indicated by error bars. The acquisition time decreases as the target size increases. No hint was slowest for all users apart from User 2 who's slowest condition was frequency modulation of pulses. The users missed significant numbers of targets on the 5 & 10° tests. Figure 3b shows a successful acquisition for a larger, easier target size of 20°. The user was initially close to the target (˜50°), but with no cue, chose the longer, slower way (310°).

4.2 With single sound 3D hint

Figure 4 shows a significant improvement in the acquisition times compared to the baseline case of *no hint*. The 3D hint that the user receives provides the approximate direction of the target and lets the user turn immediately towards that direction. As expected, the 3D audio made it clear whether a target is on the left or right of the user, but it was not as easy to perceive whether it was in front of or behind the user. The user's search for the target became faster on average for all users, with larger improvements for smaller targets.

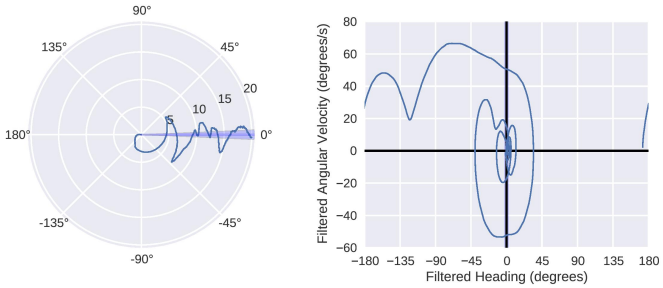
4.3 Frequency modulation of pulses based on proximity

Fig. 4 shows that for small targets (w_t 5-20°), this approach can speed responses over *No 3D hint*, but for larger targets (w_t 40-180°), it adds little, or gets worse. User 2 was slower throughout with this approach. Users had no initial hint of the target's direction, so to find the shortest path, some scanned the area around them, by quickly turning to the left and right (as shown in the edges of Fig. 5f), and then followed the path which increased the pulse frequency. Others went for one direction or the other until they heard the first target cues. The proximity indication of target reduces the velocity near the target.

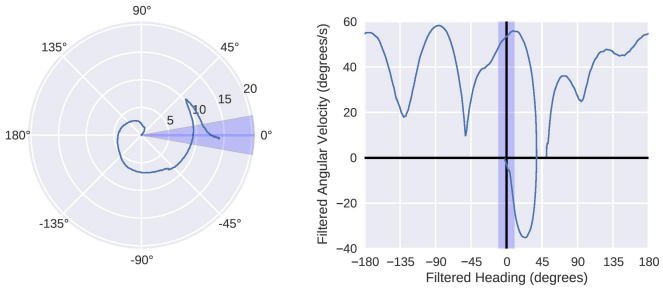
Summarising the statistics, comparing ratios of means for each type of trial, the relative speed up using 3D hints over no hint is 40% ($\mu = 1.40$, $\sigma = 0.55$). The speed up of 3D hints over the Frequency approach is 25% ($\mu = 1.25, \sigma = 0.74$). The No Hint case had most misses ($\mu = 1.39$), followed by Frequency ($\mu = 1.21$) and fewest was 3D hint ($\mu = 0.79$).

4.4 Comparison of Phase plots

The use of phase plots to represent the error convergence allows us to show multiple acquisitions of different time lengths on a single plot which allows us to test for consistent changes in approach depending on the feedback style. We have grouped the responses to small ($w_t = 5°$) targets and large ($w_t = 60°$) targets. Smaller targets in Figure 5 show underdamped responses where the user oscillates around the target, whereas larger targets show overdamped responses where the user hits the target and stays there. For larger initial errors, the velocity decrease slows already before the target zone is reached in Figure 5b, suggesting that the user enters a different control mode (akin to Costello's *Surge Model* Costello (1968)), however for larger targets, in Figure 5e there is less anticipatory change, and no further oscillatory control near the target, leading to larger final errors. The 3D hint led to smoother velocity profiles outside the target zone, suggesting that the user has a good sense of target location, where other feedback mechanisms, especially no feedback and pulse frequency modulation, have more variation in bearing velocity. Oscillation around the target is worst with no hint. Surges from initial conditions to close to the target are larger for the single sound hint (the 3 largest velocities when crossing 0° are for the 3 initial conditions closest to the target) suggesting scope for improving performance for nearby targets.



(a) Unsuccessful acquisition for target of size 5° without 3D hint



(b) Successful acquisition for target of size 20° without 3D hint

Fig. 3. User behaviour without an audio cue, during one target acquisition. Left: evolution of the bearing error angle e on polar axes. The radial part r represents time, the angle e is the user's bearing error. The $0 \pm \frac{w_t}{2}$ target zone is shaded to ease comparison. Right: phase plots of time derivative $\dot{e}$ against the user's bearing error e.

4.5 Movement time and difficulty of task

We investigated the relationship between the movement time and the index of difficulty for the "No 3D hint" and "With single sound 3D hint" systems. Meyer et al. Meyer et al. (1990), developing earlier work Crossman and Goodeve (1983), proposed that the time (MT) to move to a target area is a function of the distance to the target (A) and the size of the target (W), $MT = a + bID$, where the index of difficulty, $ID = (\frac{A}{W})^{\frac{1}{n}}$, where n relates to the upper limit on submovements. $n = 2.6$ minimised the RMS error. Figs. 6a and 6b show the linear relationship between the MT and ID. The circles' radii $r \propto W$. Blue circles indicate that the user did not go past 180°, while red circles indicate the user took the long way round, with higher MT. Large targets have lower ID and lower MT.

5. CONCLUSIONS

We demonstrate auditory targeting behaviour with a commercial, instrumented headset. The headset and API provided a practical development platform for spatial audio systems. Experimental results demonstrate that the use of 3D hints for auditory targeting is an improvement over no feedback. User feedback indicated that this provides a simple, intuitive, aesthetically pleasing way for users to locate targets and required the least mental and physical workload. The pulse-frequency approach was less effective, slowing users for larger targets.

Visualisation of experimental results based on phase plots standard in control applications, can aid the design of bearing-based interaction. Phase plots allow rapid comparison of behaviour from time-series of varying lengths and present a clear visual summary of the dynamics of target acquisition, where the distance cue leads to a ballistic 'surge' phase Costello (1968) where the user moves towards the target zone to the final control phase. The additional 'radar' visualisation approach to time-series representation gives a clear representation of the head movement during the acquisition process, highlighting areas of high activity, which are likely to lead to lower usability results.

Abstract: This extended abstract discusses the role that systems theory plays in unveiling fundamental limitations of learning algorithms and architectures when used to control a dynamical system, and in suggesting strategies for overcoming these limitations. As an example, a feedforward neural network cannot stabilize a double integrator using output feedback. Similarly, a recurrent NN with differentiable activation functions that stabilizes a non-strongly stabilizable system must be itself open loop unstable, a fact that has profound implications for training with noisy, finite data. A potential solution to this problem, motivated by results on stabilization with periodic control, is the use of neural nets with periodic resets, showing that indeed systems theoretic analysis is instrumental in developing architectures capable of controlling certain classes of unstable systems. The abstract finishes by arguing that when the goal is to learn control oriented models, the loss function should reflect closed loop, rather than open loop model performance, a fact that can be accomplished by using gap-metric motivated loss functions.

Keywords: Control Oriented Learning, Neural Nets, Reinforcement Learning.

1. INTRODUCTION AND MOTIVATION.

Despite recent advances in Machine Learning (ML), the goal of designing control systems capable of fully exploiting the potential of these methods remains elusive. Modern ML methods can leverage large amounts of data to learn powerful predictive models, but such models are not designed to operate in a closed-loop environment. Recent results on reinforcement learning offer a tantalizing view of the potential of a rapprochement between control and learning, but so far proofs of performance and safety are mostly restricted to limited cases (e.g. finite horizon LQR/LQG or iterative tasks). Thus, learning elements are often used as black boxes within the loop, with limited interpretability and less than completely understood properties. Further progress hinges on the development of a principled understanding of the limitations of control-oriented machine learning. This extended abstract presents some initial results unveiling the fundamental limitations of some popular learning algorithms and architectures when used to control a dynamical system. For instance, it shows that even though feed forward neural nets are universal approximators, they are unable to stabilize some simple systems. Along these lines we also show that a recurrent neural net with differentiable activation functions that stabilizes a non-strongly stabilizable system must be itself open loop unstable, and discuss the implications of this fact for training with noisy, finite data. On the other hand, this difficulty can be overcome by using either time varying architectures or architectures with periodic resets. We also present some empirical evidence that conventional, off the shelf Reinforcement Learning will fail to stabilize non-strongly stabilizable plants. The extended abstract finishes by arguing that when the goal is to learn stabilizing controllers, the loss function should reflect closed loop performance, a fact that can be accomplished by using gap-metric motivated loss functions.

1.1 Fundamental limitations of Feed Forward NN.

Even though Feed Forward NN (FFNN) are routinely used as controllers, there are fundamental obstructions that may prevent the existence of stabilizing FFNN controllers with continuous activation functions (Sontag and Sussmann (1980)). In this portion of the extended abstract we present some simple examples illustrating these limitations.

Single Hidden Layer FNN. Recall the single hidden layer FNN can approximate arbitrarily well any continuous functions (Cybenko (1989). However, as shown in (Sontag (1992)), there exists an asymptotically controllable system that has the origin as a locally asymptotically stable equilibrium point of the zero input dynamics and yet it cannot be be stabilized on compact sets using a single hidden layer FNN, even with discontinuous activation functions. This limitation arises from the fact that the (one sided) inverse needed to implement a stabilizing controller cannot be generically approximated by a linear combinations of scalar functions of linear combinations, even when the forward mapping is continuous.

Similarly, single hidden layer FNN cannot control nonholonomic systems due to their inability to implement Lie Brackets. On the other hand, since continuous-time

periodic controllers can overcome topological obstructions (Khaneja and Brockett (1980)) we conjecture that if $\dot{x} = f(x) + g(x)u$ is stabilizable, there is a recurrent NN (RNN) with (continuous) activation ReLU, state z, and input x, and a feedback $u = k(z, x)$ so that $\{(0, z)\}$ is asymptotically stable.

The discussion above illustrates the limitations of single hidden layer FFNNs when used as controllers. However, this leaves open the question of whether multi-layer FFNN can be used as universal controllers. In the next section we show that this is not the case.

1.2 Inadequacy of Deep FFNNs for output feedback

In this section we illustrate with a simple example the limitations of FFNNs when used to implement output feedback controllers. To this effect, consider the stabilization of a double integrator using output feedback,

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= f(x_1)\,, \end{aligned} \tag{1}$$

where $f(x_1)$ is implemented by a FFNN. Such a controller can never render the origin a globally asymptotically stable equilibrium point. To see this, consider the "energy" function $V(x_1, x_2) = \frac{1}{2}x_2^2 - \int_0^{x_1} f(\lambda)d\lambda$. Since $dV/dt \equiv 0$, trajectories starting at any $(0, x_2)$,$x_2 \neq 0$ cannot asymptotically approach the origin $(0, 0)$. To be precise, suppose $f(x_1)$ is locally bounded and Lebesgue measurable. Then $F(\xi) := \int_0^{\xi} f(\lambda)d\lambda$ is locally Lipschitz, and $x_1(t)$ is absolutely continuous (a.c.), so also $F(x_1(t))$ is a.c., so V is a.c. Thus, the chain rule can be applied, and V is constant along trajectories. (The a.c. property rules out examples such as the Cantor function, where derivatives can be identically zero yet the function is not constant.)

1.3 RNNs and non-strongly stabilizable systems

This portion of the extended abstract discusses the challenges in using RNNs to control non-strongly stabilizable plants, that is, Linear Time Invariant (LTI) plants that cannot be stabilized by open loop stable LTI controllers. These plants are interesting both on their own and because their relationship to the problem of simultaneous stabilization (Doyle et al. (1992)). Recall that a SISO plant is strongly stabilizable if it satisfies the parity interlacing property Doyle et al. (1992): the number of real poles in the right half plane (RHP) (counted according to their multiplicity) in between every pair of RHP zeros (including those at infinity) is even.

Proposition 1. *If a RNN with differentiable activation functions stabilizes a non-strongly stabilizable plant, then the RNN must be open loop unstable.*

The proof follows by considering the controller obtained by linearizing the input/output (between time series) mapping implemented by the NN.

A more interesting case arises if we allow for recurrent NN that implement non-smooth mappings. To investigate this case, consider an ideal setting where a known, open loop unstable internally stabilizing controller is used to train the neural net (Fig. 1). This scenario arises for instance when seeking to optimize performance. In this situation,

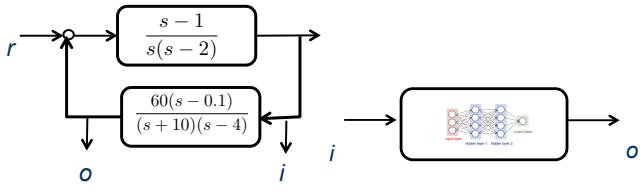

Fig. 1. Using the closed-loop signals generated by a stabilizing controller to train a NN.

one can use this pre-trained NN as an initial controller and then adjust its weights (for instance via gradient descent) to improve performance.

Let $i(t)$ and $o(t)$ denote the input output signals. Since the controller stabilizes the loop, it follows that $i(t), o(t) \in \mathcal{L}_\infty$, so in principle these bounded signals could be used to train a NN. Nevertheless, as we show next, a NN that interpolates all input/ouput pairs generated by an open loop unstable controller, has to be open loop unstable.

Proposition 2. *Consider an unbounded mapping $\mathcal{C}\colon \mathcal{L}_\infty \to \mathcal{L}_{\infty,e}$. Let $\mathcal{I}_b \subseteq \mathcal{L}_\infty$ denote the set of essentially bounded inputs that result in bounded outputs, i.e.*

$$\mathcal{I}_b \doteq \{r \in \mathcal{L}_\infty \colon (s \doteq \mathcal{C}r) \in \mathcal{L}_\infty\}$$

Then, if an operator $\mathcal{NN}$ is such that $\mathcal{NN}r = \mathcal{C}r$ a.e. for all $r \in \mathcal{I}_b$, $\mathcal{NN}$ must be open loop unstable, in the sense that there exists some $r_o \in \mathcal{L}_\infty$ such that $\mathcal{NN}r_o \notin \mathcal{L}_\infty$

From the observation above it follows that the NN can be trained in open-loop using the closed loop signals generated by an open loop controller only in the ideal case that these signals are perfectly known. This is a consequence of the fact that, since the NN is open-loop unstable, a suitably chosen perturbation of the input signal will lead to unbounded outputs. The discussion above leaves open the question of whether the NN can be trained in closed loop. As we show next, if the NN has differentiable activations, closed loop training is also likely to fail, due to the sensitivity of the parameters with respect to the observed outputs. For simplicity, we consider a SISO tracking scenario where the NN implements an LTI controller and the goal is to find the controller parameters θ that minimize some function $\mathcal{L}[e(\theta, u)]$ of the output e corresponding to a given input u, that is:

$$\theta^o = \operatorname*{argmin}_{\theta} \mathcal{L}[e(\theta, u)]$$

where

$$e(\theta) = \frac{u(s)}{1 + P(s)C(s, \theta)}$$

To illustrate the difficulties arising when the controller is open loop unstable, we will compute the gradient of the loss function with respect to the parameters of the controller. Let $C = \frac{N}{D}$ denote a coprime factorization of C, parameterized directly in term of its poles and zeros, that is $D(s) = D_o\Pi(s-\theta_i)$ and $N(s) = N_o\Pi(s-\psi_i)$. Since C is open loop unstable, at least one $\theta_i > 0$ and

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \theta_i} &= \frac{\partial \mathcal{L}}{\partial e}\frac{\partial e}{\partial C}\frac{\partial C}{\partial \theta_i} = \frac{\partial \mathcal{L}}{\partial e}\frac{-P}{(1+PC)^2}\frac{\partial C}{\partial \theta_i}u(s) \\ &= \frac{\partial \mathcal{L}}{\partial e}\frac{P}{(1+PC)^2}\left(\frac{C}{s-\theta_i}\right)u(s) \end{aligned} \tag{2}$$

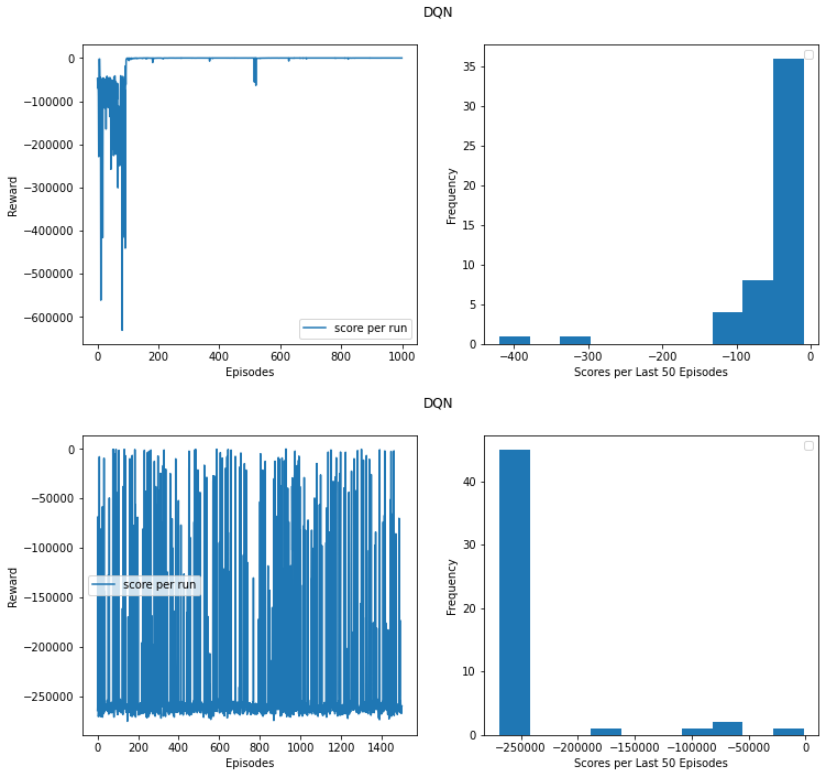

Fig. 2. Deep Reinforcement applied to a double integrator (top) and a non-strongly stabilizable plant (botton).

In the ideal case where $\frac{\partial C}{\partial \theta_i}$ can be exactly computed the poles of $\frac{\partial C}{\partial \theta_i}$ are cancelled by the zeros of $\frac{-P}{(1+PC)^2}$ and the overall system is stable. On the other hand, if only approximate values of the gradient are available (due for instance to finite and/or discrete time approximations), then this exact pole-zero cancellation no longer holds, leading to an unstable mapping $\frac{\partial C}{\partial \theta_i} \to \frac{\partial \mathcal{L}}{\partial \theta_i}$.

The developments above raise the question of whether a non-strongly stabilizable plant can be stabilized by an open loop stable controller. An affirmative answer to this question was given in Savkin and Petersen (1997), showing that this is indeed possible when using linear time varying, infinite dimensional controllers. An alternative, simpler controller is presented below:

Proposition 3. *Consider a non-strongly stabilizable LTI plant P and an LTI stabilizing controller with state space realization: A_c, B_c, C_c, D_c. Then the controller*

$$\mathcal{C}(y) = \begin{cases} \dot{x}_c = A_c x_c + B_c y \\ x_c(t^+) = x_c(t^-),\ t \neq kT \\ x_c(kT) = 0 \\ u = C_c x_c + D_c y \end{cases} \tag{3}$$

is open loop stable and stabilizes P.

Intuitively, the states of the controller are reset every T seconds to prevent them from growing too large. At the same time, since for $t \in (kT, (k+1)T)$ the LTI controller is acting, T can be chosen so that at the end of each cycle the state of the plant satisfies $\|x(kT+T)\| < \|x(kT)\|$. While in principle this avoids the difficulties entailed in training an open-loop unstable controller, at the moment is unclear how to implement and train such a controller using available NN architectures.

1.4 Reinforcement Learning

Next, we present some experiments illustrating the difficulties of using Reinforcement Learning to control non-strongly stabilizable plants. Consider the problem of stabilizing a plant using Deep Reinforcement Learning. To this effect, we considered a neural network architecture consisting of two hidden layers with leaky ReLu activations and a set of discrete actions $\mathcal{U}$. The NN takes an observation (i.e., $y_k = Cx_k$) and outputs a vector $q_k = V_\theta(y_k)$ of the same dimension as the number of actions, where each entry is a prediction of the value from taking the corresponding action. The next control action u_k is selected as the one corresponding to the maximal entry in q, with probability $1 - \epsilon_k$, or a random action with probability ϵ_k, where $\epsilon_k = \max\{\epsilon_{\min}, 0.99 * \epsilon_{k-1}\}$ The reward corresponding to the action u_k at state x_k is set to be $-\|x_k\|_2^2$.

The neural net was trained with Q-learning as follows. Let $u_{\text{taken,k}}$ denote the action taken at step k, and let q_{k+1} be the vector obtained by applying the neural network to the next observation $y_{k+1} = Cx_{k+1}$. We then set $\hat{q}_k$ to be the vector obtained by replacing the entry in q_k corresponding to $u_{\text{taken,k}}$ with $-||x_k||^2 + \gamma \max\{q_{k+1}\}$, where max applied to a vector denotes the largest entry. Finally, we perform a gradient descent step on θ, the weights of the NN, with objective $\|V_\theta(y_k) - \hat{q}_k\|^2$. Note that while knowledge of the true states was used in training (through the reward), the policy here depends only on the observations y_k. We applied this approach on both an "easy" plant (a double integrator with state feedback)

$$\begin{aligned} x(k+1) &= \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix} x(k) + \begin{bmatrix} 1 \\ 0 \end{bmatrix} u(k) \\ y(k) &= x(k) \end{aligned} \tag{4}$$

and a "hard" one (not strongly stabilizable)

$$x(k+1) = \begin{bmatrix} 1.2 & 0 \\ 0.1 & 1 \end{bmatrix} x(k) + \begin{bmatrix} 0.1 \\ 0 \end{bmatrix} u(k) \qquad (5)$$
$$y(k) = [1 \ -1]\, x(k)$$

As shown in Fig. 2 the Deep RL algorithm described above stabilizes the "easy" case but fails to do so for the non-strongly stabilizable one.

1.5 Open Loop vs Closed Loop Distances

In this portion of the extended abstract we argue that when using a NN to model a plant, the loss function used to train it should take into account the closed-loop distance between the the unknown plant and its model, rather than the open loop one. Consider the open-loop unstable plant $G_1 = \frac{100}{2s-1}$. Modelling this plant with a NN such that the open loop distance, measured in terms of the induced norm $\|(G_1 - NN)\|_{\ell_i \to \ell_o}$ is finite, will require an open loop unstable net. On the other hand, when the loop is closed with the simple controller $K = 1$, the original plant G_1 and the open-loop stable plant $G_2 = \frac{100}{2s+1}$ have virtually indistinguishable performance (Fig 3) Thus, if the goal

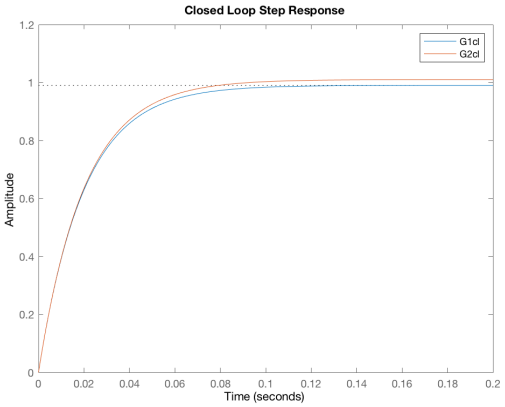

Fig. 3. Closed loop step responses of G_1 and G_2.

is to designing controllers, the stable plant G_2, which is substantially easier to model using a NN, can be used as a proxy for G_1 in the design process. This observation suggests that, when training a NN, one should try to minimize a closed-loop distance, rather than an open loop one. One such metric is the gap metric (see for instance Zhou and Doyle (1998)). Given two plants G_1, G_2 with normalized coprime factorizations $G_i = \frac{N_i}{D_i}$, $i = 1, 2$ the ν-gap δ_ν is defined by

$$\delta_\nu(G_1, G_2) = sup_w | - N_2(jw)M_1(jw) + \\ + M_2(jw)N_1(jw)|$$

Plants with small δ_ν can be stabilized by the same $\mathcal{H}_\infty$ optimal controller and have similar closed loop transfer functions (see Zhou and Doyle (1998) for a formalization of this statement). For instance, for the example above $\delta_\nu(G_1, G_2) = 0.02$, which explains the virtually indistinguishable closed loop responses. This suggest that one should learn coprime factorizations, rather than plants, and then perform a model (in)validation step, as proposed in Steele and Vinnicombe (2001) to estimate the gap between the learned model and the true plant. This approach has the additional advantage that it can handle unstable plants. While learning coprime factors directly from data is an open problem, the results below suggest that, at least in the noiseless case, this can be accomplished by solving two convex Nevanlinna Pick interpolation problems.

Proposition 4. *Given input/output pairs* $\{r(z_i), y(z_i)\}_{i=1}^n$ *there exist stable transfer functions* $N(z), M(z)$ *such that* $y(z_i) = \frac{N(z_i)r(z_i)}{M(z_i)}$ *if and only if there exist* $u(z)$ *such that following conditions hold:*

$$P_N = \left[\frac{r(z_i)r^*(z_j) - u(z_i)u^*(z_j)}{1 - (z_i z_j^*)^{-1}} \right]_{i,j} \succeq 0$$
$$P_M = \left[\frac{y(z_i)y^*(z_j) - u(z_i)u^*(z_j)}{1 - (z_i z_j^*)^{-1}} \right]_{i,j} \succeq 0$$

Using Schur complements, these conditions can be transformed into convex LMIs in u. Once the Pick matrices P_N and P_M have been found, state space realizations for N and M can be obtained using for instance the formulas in Parrilo et al. (1998).

1.6 Conclusions

This extended abstract illustrates the challenges entailed in using ML to control dynamical systems. As shown here, learning stabilizing controllers places additional constraints on the architectures and on the algorithms used to train them. Thus, we argue that control-agnostic ML is unlikely to succeed in controlling challenging systems. Rather, the choice of representations and training has to be guided by systems theory.

Abstract: Variation diminishment – the reduction in the number of sign changes and local extrema in a signal – is an intrinsic system property that lies at the heart of positive systems theory and over- and undershooting analysis in controlled systems. While, for general system operators, this property is difficult to verify, we show that it can be readily verified for the controllability and observability operators of finite-dimensional linear time-invariant systems under an internal k-positivity assumption. This complements earlier results on verifying this property for Hankel and Toeplitz operators, and establishes a bridge to internally positive systems theory. Our results provide a new framework for upper bounding the number of over- and undershoots in step responses, as well as a new realization theory of externally positive systems.

Keywords: positive systems, total positivity, k-positivity, variation diminishing, step response analysis

1. INTRODUCTION

Linear time-invariant (LTI) systems

$$\begin{aligned} x(t+1) &= Ax(t) + bu(t) \\ y(t) &= cx(t), \end{aligned} \tag{1}$$

that map nonnegative inputs u to nonnegative outputs y are characterized by a *nonnegative impulse* response $g(t) := cA^{t-1}b \geq 0$, $t \geq 1$ and are referred to as *externally positive* (Farina and Rinaldi, 2000). A particular property of such systems is the monotonicity of their step response, which motivated several studies on the avoidance of over- and undershooting in closed-loop design (Grussler and Rantzer, 2021; Darbha, 2003; Phillips and Seborg, 1988). Indeed, the number of sign changes of g, denoted by $S(g)$ and also known as the *variation* of g, equals the number of local extrema in the step response (see Section 2.1 for precise definitions).

The first problem addressed in this work is the extension of the positivity framework towards establishing upper bounds on the number of over- and undershoots in the step response of non-externally positive systems. We consider single-input-single-output (SISO) discrete-time systems of the form (1). There exist many lower bounds for this problem (Damm and Muhirwa, 2014; Swaroop and Niemann, 1996; El-Khoury et al., 1993), but only few upper bounds (El-Khoury et al., 1993). In our proposed solution, we express the impulse response of (1) as $g(t) = (\mathcal{O}(A,c)b)(t)$, with the *observability operator* given by

$$(\mathcal{O}(A,c)x_0)(t) := cA^t x_0,\ x_0 \in \mathbb{R}^n,\ t \geq 0 \tag{2}$$

The main idea is to bound $\mathrm{S}(g)$ by deriving a computationally tractable certificate for the largest integer k such that $\mathrm{S}(g) = \mathrm{S}(\mathcal{O}(A,c)b) \leq \mathrm{S}(b)$ for all $\{b : \mathrm{S}(b) \leq k\}$. An (observability) operator verifying this property is said to be *k-variation diminishing*. Although there exists a rich literature on variation diminishing transformations (see, e.g, the monographs by Karlin (1968); Pinkus (2009); Fallat and Johnson (2011)), including many recent contributions to system and control theory (see, e.g., (Grussler and Sepulchre, 2022; Grussler et al., 2021; Margaliot and Sontag, 2019; Wu and Margaliot, 2021)), it is unknown how to efficiently verify this property for $\mathcal{O}(A,c)$. This is not surprising, as the verification of external positivity (i.e., 0-variation diminishment) is computationally challenging in general (Blondel and Portier, 2002).

We therefore build our framework around the celebrated subclass of *internally positive systems*, i.e., systems characterized by nonnegative system matrices A, b and c (Luenberger, 1979), for which external positivity is an immediate consequence. These systems have received considerable interest due to their simplifying, scalable analysis properties (Rantzer and Valcher, 2018; Tanaka and Langbort, 2011; Farina and Rinaldi, 2000), and much effort has been put into the computation of internally positive realizations (Ohta et al., 1984; Farina, 1996; van den Hof, 1997; Farina and Rinaldi, 2000; Benvenuti and Farina, 2004). In fact, if we can find a realization with nonnegative A and c, it is also trivial that $\mathcal{O}(A,c)$ is 0-variation diminishing. Here, similar conditions and generalized realizability results are derived for $k > 0$. Our approach recovers the results of

⋆ This work received support by grants from ONR and NSF as well as under the Advanced ERC Grant Agreement Switchlet n.670645 and by DGAPA-UNAM under the grant PAPIIT RA105518.

El-Khoury et al. (1993) in the special case that k can be chosen arbitrarily large, which is a consequence of El-Khoury et al. (1993) using early results on variation diminishing mappings.

The second problem addressed in this work is the establishment of generalized internally positive realizations. Those are externally positive state-space systems that allow negative elements in b, at the cost of more restrictive assumptions on (A, c). It is envisioned that this will lead to generalizations of recent scalable positive systems analysis methods.

Finally, this work *bridges* recent external (input-output) variation diminishing system theory (Grussler and Sepulchre, 2022; Grussler et al., 2021) with internal (unforced, state-space) developments (see, e.g., Margaliot and Sontag (2019); Wu and Margaliot (2021)). In particular, we arrive at a positive realization theory of systems with variation diminishing Hankel operators, where $k = 0$ corresponds to classical external vs. internal positivity. The former has only recently been characterized in (Grussler and Sepulchre, 2022) in terms of so-called k compound systems, where our results are equivalent to simultaneous internally positive realizability of these k systems.

2. PRELIMINARIES

In this section, we briefly introduce some concepts that are essential for our results.

2.1 Variation diminishing maps

The *variation* of a sequence or vector u is defined as the number of sign-changes in u, i.e.,

$$\mathrm{S}(u) := \sum_{i\geq 1} \mathbb{1}_{\mathbb{R}_{<0}}(\tilde{u}_i\tilde{u}_{i+1}), \quad \mathrm{S}(0) := 0$$

where $\tilde{u}$ is the vector resulting from deleting all zeros in u.

Definition 1. A linear map $u \mapsto Xu$ is said to be *order-preserving k-variation diminishing* (OVD_k), $k \in \mathbb{Z}_{\geq 0}$, if for all u with $\mathrm{S}(u) \leq k$ it holds that

i. $\mathrm{S}(Xu) \leq \mathrm{S}(u)$.
ii. The sign of the first non-zero elements in u and Xu coincide whenever $\mathrm{S}(u) = \mathrm{S}(Xu)$.

If the second item is dropped, then $u \mapsto Xu$ is called *k-variation diminishing* (VD_k). For brevity, we simply say X is (O)VD_k.

2.2 Matrix k-positivity and compound matrices

For generic k, *total positivity theory* (Karlin, 1968) provides algebraic conditions for the OVD_k property by means of compound matrices. To define these, let the i-th elements of the r-tuples in

$$\mathcal{I}_{n,r} := \{v = \{v_1, \dots, v_r\} \subset \mathbb{N} : 1 \leq v_1 < \cdots < v_r \leq n\}$$

be defined by *lexicographic ordering*. Then, the (i, j)-th entry of the *r-th multiplicative compound matrix* $X_{[r]} \in \mathbb{R}^{\binom{n}{r}\times\binom{m}{r}}$ of $X \in \mathbb{R}^{n\times m}$ is defined by $\det(X_{(I,J)})$, where I is the i-th and J is the j-th element in $\mathcal{I}_{n,r}$ and $\mathcal{I}_{m,r}$, respectively. For example, if $X \in \mathbb{R}^{3\times 3}$, then $X_{[2]}$ reads

$$\begin{pmatrix} \det(X_{\{1,2\},\{1,2\}}) & \det(X_{\{1,2\},\{1,3\}}) & \det(X_{\{1,2\},\{2,3\}}) \\ \det(X_{\{1,3\},\{1,2\}}) & \det(X_{\{1,3\},\{1,3\}}) & \det(X_{\{1,3\},\{2,3\}}) \\ \det(X_{\{2,3\},\{1,2\}}) & \det(X_{\{2,3\},\{1,3\}}) & \det(X_{\{2,3\},\{2,3\}}) \end{pmatrix}.$$

Notice a nonnegative matrix verifies $X_{[1]} = X \geq 0$, which is equivalent to X being OVD_0. This can be generalized through the compound matrix as follows (Grussler and Sepulchre, 2022, Proposition 4).

Definition 2. Let $X \in \mathbb{R}^{n\times m}$ and $k \leq \min\{m, n\}$. X is called *k-positive* if $X_{[j]} \geq 0$ for $1 \leq j \leq k$, and *strictly k-positive* if $X_{[j]} > 0$ for $1 \leq j \leq k$. In case $k = \min\{m, n\}$, X is called *(strictly) totally positive*.

Proposition 3. Let $X \in \mathbb{R}^{n\times m}$ with $n \geq m$. Then, X is k-positive with $1 \leq k \leq m$ if and only if X is OVD_{k-1}.

The following is an important property of compound matrices (Horn and Johnson, 2012, Subsection 0.8.1).

Lemma 4. Let $X \in \mathbb{R}^{n\times p}$ and $Y \in \mathbb{R}^{p\times m}$. Then

$$(XY)_{[r]} = X_{[r]}Y_{[r]}$$

2.3 Hankel k-positivity and compound systems

The OVD_k property of LTI systems (1) has been studied by Grussler and Sepulchre (2022), where a distinction is made between LTI systems with OVD_k Toeplitz and Hankel operators. The latter are particularly relevant to this work. For $t \geq 0$, the *Hankel operator*

$$(\mathcal{H}_g u)(t) := \sum_{\tau=-\infty}^{-1} g(t-\tau)u(\tau) = \sum_{\tau=1}^{\infty} g(t+\tau)u(-\tau) \quad (3)$$

describes the evolution of the output y of an LTI system subjected to an input $u(t) = u(t)(1 - s(t))$, where $s(t)$ denotes the Heaviside function. The Hankel operator obeys the factorization

$$\mathcal{H}_g u = \mathcal{O}(A, c)(\mathcal{C}(A, b)u) \quad (4)$$

where

$$x(0) = \mathcal{C}(A, b)u := \sum_{\tau=-\infty}^{-1} A^{-\tau-1}bu(\tau),\ u \in \ell_\infty \quad (5)$$

denotes the *controllability operator*. Throughout this work, A is asymptotically stable, which implies that our operators are well-defined. For $t, j \in \mathbb{Z}_{>0}$, we define the *Hankel matrix*

$$H_g(t, j) := \begin{pmatrix} g(t) & g(t+1) & \dots & g(t+j-1) \\ g(t+1) & g(t+2) & \dots & g(t+j) \\ \vdots & \vdots & \ddots & \vdots \\ g(t+j-1) & g(t+j) & \dots & g(t+2(j-1)) \end{pmatrix} \quad (6a)$$

$$= \mathcal{O}^j(A, c)A^{t-1}\mathcal{C}^j(A, b) \quad (6b)$$

where

$$\mathcal{C}^j(A, b) := \begin{pmatrix} b & Ab & \dots & A^{j-1}b \end{pmatrix} \quad (6c)$$

$$\mathcal{O}^j(A, c) := \mathcal{C}^j(A^\mathsf{T}, c^\mathsf{T})^\mathsf{T}. \quad (6d)$$

Hankel k-positivity is defined as follows.

Definition 5. A system $G(z)$ is called *Hankel k-positive* if $\mathcal{H}_g$ is OVD_{k-1} ($k \geq 1$). If $k = \infty$, $G(z)$ is said to be *Hankel totally positive*.

Notice that Hankel 1-positivity coincides with the familiar property of external positivity (Farina and Rinaldi,

2000). A characterization of Hankel k-positivity is given by (Grussler and Sepulchre, 2022, Lemma 2):

Lemma 6. A system $G(z)$ is Hankel k-positive if and only if for all $j \in \mathbb{Z}_{\geq k}$, $H_g(1,j)$ is k-positive.

Using basic results from total positivity theory (Fallat et al., 2017), it is easy to show that k-positivity of Hankel matrices only requires checking the nonnegativity of consecutive minors. From (6b), each of these consecutive minors is given by

$$g_{[j]}(t) := \det(H_g(t,j)),$$

which is interpreted as the impulse response of an LTI system $G_{[j]}(z)$, called the *j-th compound system*. If (A,b,c) is a realization of $G(z)$, then $G_{[j]}(z)$ can be realized as

$$(A_{[j]}, \mathcal{C}^j(A,b)_{[j]}, \mathcal{O}^j(A,c)_{[j]}). \tag{7}$$

since

$$\det(H_g(t,j)) = H_g(t,j)_{[j]} = \mathcal{O}^j(A,c)_{[j]}(A_{[j]})^{t-1}\mathcal{C}^j(A,b)_{[j]}$$

by (6b) and Lemma 4.

3. INTERNALLY K-POSITIVE SYSTEM OPERATORS

In this section, we present our main results on the characterization of OVD_k observability and controllability operators to (1). The proofs of these results can be found in our full paper (Grussler et al., 2022), where an extension of the results to continuous-time is also studied.

We start with following simple lemma.

Lemma 7. For (A,b,c), the following are equivalent:

i. $\mathcal{C}(A,b)$ and $\mathcal{O}(A,c)$ are OVD_{k-1}, respectively.
ii. For all $t \geq k$, $\mathcal{C}^t(A,b)$ and $\mathcal{O}^t(A,c)$ are k-positive, respectively.

Notice that for $k = 1$ Lemma 7 recovers the well-known characterization of internal positivity in terms of the nonnegativity of (A,b), and (A,c), respectively. Next, we seek a finite-dimensional and computationally tractable characterization as our first main result.

Theorem 8. Let (A,b,c) be a realization of $G(z)$ such that A is k-positive. The following hold:

i. If $\mathcal{C}^j(A,b)_{[j]} \geq 0$ for $1 \leq j \leq k$, then $\mathcal{C}^t(A,b)$ is k-positive for all $t \geq k$.
ii. If $\mathcal{O}^j(A,c)_{[j]} \geq 0$ for $1 \leq j \leq k$, then $\mathcal{O}^t(A,c)$ is k-positive for all $t \geq k$.

The proof of this result involves extending a test for matrix k-positivity based on verifying the positivity of consecutive minors, see (Grussler et al., 2022, Theorem 3.6).

3.1 Impulse response analysis

For LTI systems, the total number of over- and undershoots (in the step response) equals the number of sign changes in the impulse response. Since $g(t) = (\mathcal{O}(A,c)b)(t)$, $\mathcal{O}(A,c)$ being OVD_{k-1} implies that response of (A,b,c) changes its sign at most $\mathrm{S}(b)$ times for all $\mathrm{S}(b) \leq k-1$, and has the same sign-changing order as b in case of an equal number of sign-changes. Since our framework is realization-dependent, we derive

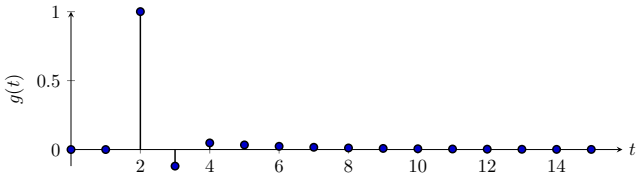

Fig. 1. The impulse response of (8) has two zero crossings, which coincides with our derived upper bound.

the following result, which is similar in spirit to classical positive realization theory (Ohta et al., 1984).

Theorem 9. Let (A,b,c) be a minimal realization of $G(z)$. Then, $G(z)$ admits a realization (A_+,b_+,c_+) such that A_+ and $\mathcal{O}(A_+,c_+)$ are OVD_{k-1} if and only if there exist a k-positive $N \in \mathbb{R}^{K\times K}$ and a $P \in \mathbb{R}^{n\times K}$ with $K \geq n$ such that $AP = PN$ and $\mathcal{O}^j(A,c)_{[j]}^{\mathsf{T}} \in \mathrm{cone}(P_{[j]})^*$ for $1 \leq j \leq k$, where $k \leq n$.

As a consequence of the order preservation in the OVD_k definition, this also provides a first simple result on generalized internally positive realizations.

Theorem 10. Let (A,b,c) be such that $\mathcal{O}(A,c)$ is OVD_1, $\mathrm{S}(b) \leq 1$. Further, assume that the first non-zero element in b is negative and the first non-zero element of the impulse response of (A,b,c) is positive. Then, (A,b,c) is externally positive.

Theorem 10 is a new contribution that has not been published in (Grussler et al., 2022).

Example Consider the following system, previously shown as an example in (El-Khoury et al., 1993):

$$G(z) = \frac{(z-0.22)(z-0.6)}{z^3(z-0.7)}$$

The transfer function $G(z)$ has a realization given by

$$A = \begin{pmatrix} 0.7 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad b = \begin{pmatrix} 0 \\ 1 \\ -0.82 \\ 0.132 \end{pmatrix} \quad c = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}^{\mathsf{T}} \tag{8}$$

It can be verified that this realization has totally positive A and $\mathcal{O}^4(A,c)$. By Lemma 7 and Theorem 8, $\mathcal{O}(A,c)$ is totally positive and the number of sign changes in the impulse response of $G(z)$ (and, hence, the number of extrema in its step response) is upper bounded by $\mathrm{S}(b) = 2$; the same upper bound was previously obtained by (El-Khoury et al., 1993). Figure 1 shows that this bound is tight. However, in contrast to (El-Khoury et al., 1993), our framework does not assume real poles or zeros. In particular, the modified transfer function

$$G_m(z) = \frac{(z-0.5+i)(z-0.5-i)}{z^3(z-0.7)},$$

can be realized with the same A and c as in (8) and with $b = (0\ 1\ -1\ 1.25)^{\mathsf{T}}$. This again provides a tight upper bound on the variation of the impulse response.

Finally, let A be as in (8), but $b = (-1\ 1\ 1\ 1)^{\mathsf{T}}$ and $c = (1\ 1\ 0\ 0)$. By Lemma 7 and Theorem 8, $\mathcal{O}(A,c)$ is OVD_1 (but not OVD_2) and $(g(1)\ g(2)) = (0\ 1.3)$. Applying Theorem 10 proves that (A,b,c) is externally positive without requiring a fully internally positive realization.

3.2 Internally Hankel k-positive systems

Next, we introduce the following subclass of Hankel k-positive systems:

Definition 11. (A, b, c) is called *internally Hankel k-positive* if A, $\mathcal{C}(A, b)$, and $\mathcal{O}(A, c)$ are OVD_{k-1} $(1 \leq k \leq n)$. If $k = n$, we say that (A, b, c) is *internally Hankel totally positive*.

Internally Hankel k-positive systems are thus OVD_{k-1} from past input u to $x(0)$, and from $x(0)$ to all future $x(t)$ and future output y. In particular, by (4), all internally Hankel k-positive systems are also (externally) Hankel k-positive, and setting $u \equiv 0$ recovers the k-positive property of unforced systems as partially studied in (Margaliot and Sontag, 2019; Wu and Margaliot, 2021). Thus, Definition 11 bridges the external and the unforced notions of variation diminishing LTI systems. A combination of Lemma 7 and Theorem 8 gives the following characterization of internal Hankel k-positivity.

Theorem 12. (A, b, c) is internally Hankel k-positive if and only if the realizations of the first k compound systems of (A, b, c) in (7) are (simultaneously) internally positive.

Similar to Theorem 9, we need to address the question of the existence of (minimal) Hankel k-positive realizations.

Theorem 13. A system $G(z)$ with order n and minimal realization (A, b, c) has a minimal internally Hankel k-positive realization, $k \leq n$, if and only if there exists a $P \in \mathbb{R}^{n \times n}$ with $\mathrm{rank}(P) = n$ such that for all $1 \leq j \leq k$

$$AP = PN \text{ for some } k\text{-positive } N \tag{9a}$$

$$\mathcal{C}^j(A, b)_{[j]} \in \mathrm{cone}(P_{[j]}), \tag{9b}$$

$$\mathcal{O}^j(A, c)_{[j]}^{\mathsf{T}} \in \mathrm{cone}(P_{[j]})^*. \tag{9c}$$

Finally, under an irreducibility condition, all unforced k-positive systems give rise to an internally Hankel k-positive system:

Proposition 14. Let $A \in \mathbb{R}^{n \times n}$ be k-positive with irreducible $A_{[j]}$, $1 \leq j \leq k$. Then there exists a $b \in \mathbb{R}^n$ such that $\mathcal{C}^j(A, b)_{[j]} > 0$ for all $1 \leq j \leq k$ and (A, b) is controllable.

1. EXTENDED ABSTRACT

Mean Field Games (MFGs) systems were introduced independently by Huang et al. (2006) and Lasry and Lions (2007) in order to model dynamic differential games with a large number of *indistinguishable small players*. In the model proposed in Lasry and Lions (2007), the asymptotic equilibrium is described by means of a system of two Partial Differential Equations (PDEs). The first equation, together with a final condition, is a Hamilton-Jacobi-Bellman (HJB) equation describing the value function of a *typical player* whose cost function depends on the distribution m of the entire population. The second equation is a Fokker-Planck (FP) equation which, together with an initial distribution m_0, describes the fact that m evolves following the optimal dynamics of the typical player.

In the case where both equations have a nondegenerate second order term, several numerical methods have been proposed to approximate solutions to the MFG system. In this context, convergent finite difference and Semi-Lagrangian (SL) schemes have been proposed in Achdou and Capuzzo-Dolcetta (2010); Achdou et al. (2013), and Carlini and Silva (2018) respectively.

In the case where both equations in the MFG system have no second order terms, we say that the MFG system is of first order. This system characterizes the limit behavior of equilibria of *deterministic* and *symmetric* differential games as the number of players tends to infinity. In this framework, a SL scheme has been proposed in Carlini and Silva (2014), where a convergence result is established when the state dimension is equal to one. We also refer the reader to Chowdhury et al. (2021) for a recent extension of this result to the case where non-local and fractional diffusion terms appear in both equations of the MFG system. To the best of our knowledge, the only convergence result in general state dimension of an approximation of the first order MFG system has been established in Hadikhanloo and Silva (2019). In these aforementioned works, it is supposed that a typical agent in the game controls directly its velocity and minimizes a cost functional whose dependence on the state variable is rather restrictive.

In this talk, we consider deterministic MFGs where the dynamics of a typical agent is non-linear with respect to the state variable and affine with respect to the control variable. Particular instances of this problem are MFGs where the typical agent controls its acceleration (see e.g. Achdou et al. (2020); Cannarsa and Mendico (2020)). We propose a fully discrete scheme that combines a semi-Lagrangian type discretization of the HJB equation, which takes advantage of the particular structure of the dynamics, and a discretization of the FP equation which has a probabilistic interpretation in terms of an underlying discrete time and finite state Markov chain X_n. The scheme that we propose takes then the form of a discrete time an finite state MFG (see Gomes et al. (2010)) which can be solved by the *fictitious play method* (see Hadikhanloo and Silva (2019)). Our main result is the convergence of solutions to this approximation towards MFG equilibria, which is numerically illustrated by several examples dealing with MFGs with control on the acceleration.

Abstract: The problem to reconcile observed marginal distributions with a given prior was posed by E. Schrödinger in 1932/32, and is now known as the Schroödinger Bridge Problem. It represents a stochastic counterpart of the Optimal Mass Transport (OMT). In either setting, the problem to interpolate between "unbalanced" marginals has been approached by introducing source/sink terms into the transport equations, in an adhoc manner, chiefly driven by applications in image registration. In the present work we developed a formalism to interpolate between "unbalanced" marginals in the original spirit of E. Schrödinger, seeking the most likely transport of particles that may vanish along their path between given end points in time. In this, we develop a Schrödinger system of equations that accounts for losses, by allowing particles to "jump" into a coffin state according to a suitable probabilistic law. The solution of the Schrödinger system allows constructing a stochastic evolution that reconciles the given unbalanced marginals.

Keywords: Estimation, Stochastic control, Large deviation theory.

1. EXTENDED SUMMARY

The present extended abstract is based on Chen et al. (2021). The main contribution is an extension of the paradigm of the Schroödinger Bridge Problem that seeks to reconcile marginal distributions with a prior probability law, to the case where the marginal distributions are unbalanced, corresponding to differing total mass that needs to be accounted for via losses. A physical instance that provides motivation for the scenario that we envision can be described as follows.

Consider the problem of estimating the velocity field of ocean currents by releasing into the water a cloud of tracer particles and by sampling their distribution at a later time. The diffusion coefficient is assumed known and the original cloud that is released at time $t = 0$ consists of N particles. These are expected to remain in suspension for a duration of time while they diffuse and drift with the current. At time $t = 1$, their distribution is sampled again. Some of the particles in the meantime have sunk, so that the number of found particles is less than N. Suppose this experiment is performed several times, treating the model originating from previous experiments as a "prior". Is it conceivable to "improve" a prior model in a rational way? More explicitly, by relying on a prior model and the new sampling result, is it possible to determine an updated model that represents the most probable way that the tracer cloud may have been transported?

Further motivation is provided by natural processes that involve micro-organisms that may reproduce or die out along the way between measurements, sediment or pollution transport processes that dissipate or accentuate between observations, or virtual processes where fusion of data or morphing of images call for interpolation between distributions of varying total mass. However, our basic framework appeals to a setting where the mechanism generating losses has a physical origin as highlighted in the example with tracer particles.

At first sight, this problem appears to be of a different nature than those treated in the theory of Large Deviations Varadhan (1966, 1984); Dembo and Zeitouni (2009), in that the sought path-space measure is not a probability measure per se. Nevertheless, in spite of the paucity of the available data, it is possible to solve this inverse problem by a natural embedding technique. A byproduct is a physically motivated framework to interpolate distributions of unequal mass (integrals). The blueprint for the rationale in our work is the celebrated duo of papers by E. Schrödinger in 1931/32 Schrödinger (1931, 1932) where he considered the problem of reconciling (equal-mass) marginal distributions with a prior stochastic evolution.

In our formulation of the unbalanced Schrödinger Bridge Problem (uSBP), the marginals cannot be assumed to be probability distributions as their integrals differ due to losses. To this end, we embed the distributions into a frame that includes a coffin/extinction state, leading to a probability law on a continuum together with a discrete state. Thereupon, we find the updated law and killing rate that minimize the relative entropy to the prior with losses, and are consistent with the two marginals. In the special

case when the marginals are already consistent with the prior, naturally, the solution coincides with the lossy prior, differently from what happens in other formulations of SBP with killing which are based on Feyman-Kac functionals Nagasawa (1990); Wakolbinger (1989); Blaquière (1992); Dawson et al. (1990); Aebi and Nagasawa (1992); Léonard (2011); Chen et al. (2015, 2017), and unbalanced transport Chizat et al. (2018a,b); Chen et al. (2019); Koehl et al. (2021).

We would like to stress the fact that earlier proposals on how to address unbalanced transport Chen et al. (2015); Georgiou et al. (2008); Jiang et al. (2011); Chizat et al. (2018a,b); Chen et al. (2019); Koehl et al. (2021) resorted to ad-hoc regularization to cope with the unequal marginals, where either adjustment at the two ends or the presence of a source/sink contribution dynamically adjusts the differing end-point masses. In contrast, our formulation is cast in terms of prior knowledge and large-deviation theory, advancing a viewpoint that is close in spirit to the original rationale of E. Schrödinger. To this end, we consider below a diffusion process with killing and seek the closest update of the corresponding law that is in agreement with the marginal data. That is, we seek the most likely diffusion process with a suitably updated killing that matches the two marginals of unequal mass. We next summarize the main technical statements of the theory that we will present.

Consider a diffusion process

$$dX_t = b(t, X_t)dt + \sigma(t, X_t)dW_t, \tag{1}$$

over the Euclidean space $\mathbb{R}^n$, with a nonnegative killing rate $V(t, x)$ (assume $V(\cdot, \cdot)$ is jointly continuous with respect to (t, x) and not constantly zero). A thought experiment similar to Schrödinger's, calls for a large number N of trajectories over a time interval $[0, 1]$, that are independently sampled from (1) with initial probability distribution ρ_0, and a recorded empirical distribution for the surviving particles at time $t = 1$ approximated by ρ_1, which is inconsistent with the prior law, that is,

$$\rho_1(\cdot) \neq \int_{\mathbb{R}^n} q(0, x, 1, \cdot)\rho_0(x)dx.$$

The kernel $q(0, x, 1, y)$ is no longer a probability kernel in that

$$\int_{\mathbb{R}^n} q(0, x, 1, y)dy \neq 1,$$

in general, and thus, neither $\int_{\mathbb{R}^n} q(0, x, 1, \cdot)\rho_0(x)dx$ nor ρ_1 are necessarily probability densities, due to killing. In particular, $\int \rho_1(x)dx = N_s/N \leq 1$ where N_s denotes the number of survival particles at time 1. Just as in the standard SBP, we consider continuous distributions, assuming that N is large, and seek to identify the most likely behavior of the particles. By behavior we mean the most likely evolution of the particles along with the most likely times that the particles may have gotten killed (or, absorbed by an underlying medium).

As in the standard Schrödinger bridge, the problem arising from the above thought experiment can be formally stated using the theory of *large deviations* Dembo and Zeitouni (2009). However, in this case, the space of trajectories needs to be modified to accommodate for possible killing of particles. To this end, we augment the state space of the diffusion $\mathbb{R}^n$ with a "coffin state" $\mathfrak{c} \notin \mathbb{R}^n$, see (Øksendal, 2000, Subsection 8.2), resulting in the state space

$$\mathcal{X} = \mathbb{R}^n \cup \{\mathfrak{c}\}.$$

Let $\Omega = D([0, 1], \mathcal{X})$ be the Skorokhod space over $\mathcal{X}$, that is, each element in Ω is a càdlàg over $\mathcal{X}$ (Billingsley, 1999, page 121). Denote by $\mathcal{P}(\Omega)$ and $\mathcal{P}(\mathcal{X})$ the spaces of probability distributions over Ω and $\mathcal{X}$, respectively. Each diffusion process X_t $(t \in [0, 1])$ on $\mathbb{R}^n$ with killing corresponds to a process $\mathbf{X}_t$ taking values in $\mathcal{X}$, and therby, to a law in $\mathcal{P}(\Omega)$.

In our unbalanced SBP setting, the set of probability laws over path space $\mathcal{P}(\Omega)$ that are in alignment with the observations is

$$\{\mathbf{P} \in \mathcal{P}(\Omega) \mid \mathbf{P}_0 = p_0,\ \mathbf{P}_1 = p_1\},$$

where p_0, p_1 are the natural augmentation of ρ_0, ρ_1 so that they belong in $\mathcal{P}(\mathcal{X})$, respectively. Specifically, assuming that $\int_{\mathbb{R}^n} \rho_1(x)dx \leq 1$, we set

$$p_0 = (\rho_0(\cdot), 0) \tag{2a}$$

and

$$p_1 = (\rho_1(\cdot), 1 - \int_{\mathbb{R}^n} \rho_1(x)dx), \tag{2b}$$

and arrive at the following.

Unbalanced Schrödinger Bridge Problem (uSBP): Determine

$$\mathbf{P}^\star := \arg \min_{\mathbf{P} \in \mathcal{P}(\Omega)} \{\mathbb{D}(\mathbf{P}\|\mathbf{R}) \ \mid \ \mathbf{P}_0 = p_0, \mathbf{P}_1 = p_1\}. \tag{3}$$

Here, with the notation $\mathbf{R}(\cdot) = \int_{\mathcal{X}^2} \mathbf{R}^{xy}(\cdot)\mathbf{R}_{01}(dxdy)$, and $\mathbf{P}(\cdot) = \int_{\mathcal{X}^2} \mathbf{P}^{xy}(\cdot)\mathbf{P}_{01}(dxdy)$ we denote path measures, whereas $\mathbf{R}_{01}$ $(\mathbf{P}_{01})$ denotes the joint marginal distribution of $\mathbf{R}$ $(\mathbf{P})$ over the marginal $\mathbf{X}_{0,1}$, and $\mathbf{R}^{xy}$ $(\mathbf{P}^{xy})$ denotes the law conditioned on $\mathbf{X}_0 = x \in \mathcal{X}$ and $\mathbf{X}_1 = y \in \mathcal{X}$. Then, also, $\mathbb{D}(\mathbf{P}\|\mathbf{R})$ denotes the Kullback-Leibler divergence. A relation with a static SBP emerges.

Static uSBP: Determine

$$\boldsymbol{\pi}^\star := \arg \min_{\boldsymbol{\pi} \in \mathcal{P}(\mathcal{X}^2)} \{\mathbb{D}(\boldsymbol{\pi}\|\mathbf{R}_{01}) \ \mid \ \boldsymbol{\pi}_0 = p_0, \boldsymbol{\pi}_1 = p_1\}. \tag{4}$$

The two formulations can be seen to be equivalent, as follows from the identity

$$\mathbb{D}(\mathbf{P}\|\mathbf{R}) = \mathbb{D}(\mathbf{P}_{01}\|\mathbf{R}_{01}) + \int_{\mathcal{X}^2} \mathbb{D}(\mathbf{P}^{xy}\|\mathbf{R}^{xy})\mathbf{P}_{01}(dxdy).$$

The equivalence is highlighted in the following theorem.

Theorem 1. (see Chen et al. (2021)). Suppose $\mathbf{P}^\star$ solves the dynamic uSBP (3), then $\mathbf{P}^\star_{01}$ also solves the static uSBP (4). On the other hand, if $\boldsymbol{\pi}^\star$ solves (4), then setting $\mathbf{P}^\star = \int_{\mathcal{X}^2} \mathbf{R}^{xy}(\cdot)\boldsymbol{\pi}^\star(dxdy)$ solves (3), while $\mathbf{P}^\star_{01} = \boldsymbol{\pi}^\star$.

The solutions to (3) and (4) are of the form

$$\mathbf{P}^\star = f(\mathbf{X}_0)g(\mathbf{X}_1)\mathbf{R}, \text{ and} \tag{5}$$

$$\boldsymbol{\pi}^\star = f(\mathbf{X}_0)g(\mathbf{X}_1)\mathbf{R}_{01}, \tag{6}$$

respectively. Explicit solution that includes an update on the prior killing rate as well as determining the change of measure effected by f, g, can be computed as follows.

The Fokker-Planck equation for a diffusion (1) with killing rate $V(t, x)$ is

$$\partial_t R_t + \nabla \cdot (bR_t) + VR_t = \frac{1}{2} \sum_{i,j=1}^{n} \frac{\partial^2 (a_{ij} R_t)}{\partial x_i \partial x_j}. \tag{7}$$

Throughout we assume that $a(t,X)=\sigma(t,X)\sigma(t,X)'$ is a positive definite matrix. A corresponding Schrödinger system and its relation to the law of $\mathbf{P}^\star$ can be expressed after reparametrizing the pair (f,g) of functions on $\mathcal{X}$ as follows

$$f(x)\mathbf{R}_0(x)=\begin{cases}\hat\varphi(0,x) & \text{if } x\in\mathbb{R}^n\\ \hat\psi(0) & \text{if } x=\mathfrak{c},\end{cases} \tag{8a}$$

$$g(y)=\begin{cases}\varphi(1,y) & \text{if } y\in\mathbb{R}^n\\ \psi(1) & \text{if } y=\mathfrak{c}.\end{cases} \tag{8b}$$

A generalized Schrödinger system along with the nonlinear coupling constraints then takes the form

$$\partial_t\hat\varphi=-\nabla\cdot(b\hat\varphi)-V\hat\varphi+\frac{1}{2}\sum_{i,j=1}^n\frac{\partial^2(a_{ij}\hat\varphi)}{\partial x_i\partial x_j} \tag{9a}$$

$$\frac{d\hat\psi}{dt}=\int V\hat\varphi(t,x)dx \tag{9b}$$

$$\partial_t\varphi=-b\cdot\nabla\varphi+V\varphi-\frac{1}{2}\sum_{i,j=1}^n a_{ij}\frac{\partial^2\varphi}{\partial x_i\partial x_j}-V\varphi \tag{9c}$$

$$\frac{d\psi}{dt}=0 \tag{9d}$$

$$\rho_0=\varphi(0,\cdot)\hat\varphi(0,\cdot) \tag{9e}$$

$$\rho_1=\varphi(1,\cdot)\hat\varphi(1,\cdot) \tag{9f}$$

$$\hat\psi(0)=0 \tag{9g}$$

$$\psi(1)\hat\psi(1)=1-\int\rho_1. \tag{9h}$$

The solvability of this Schrödinger system is claimed in the next theorem.

Theorem 2. (see Chen et al. (2021)). Let R be the law of a diffusion (1) with nontrivial killing rate $V(t,x)$ and $a(t,x)=\sigma(t,x)\sigma(t,x)'$ being positive definite for all $(t,x)\in\mathbb{R}\times\mathbb{R}^n$, and assume that ρ_0,ρ_1 are absolutely continuous with respect to the Lebesgue measure. There exists a unique (up to a constant scaling) 4-tuple $(\hat\varphi(t,x),\hat\psi(t),\varphi(t,x),\psi(t))$ of non-negative functions that satisfies the Schrödinger system (9).

Discretization of the Schrödinger system (9) leads to an efficient algorithm to compute $(\hat\varphi(t,x),\hat\psi(t),\varphi(t,x),\psi(t))$, and thereby, $\mathbf{P}^\star$ as well as the corresponding Fokker-Planck equation for the corresponding marginals. This will be discussed in the talk and is detailed in Chen et al. (2021). Further, a dynamic formulation of the updated law is possible in the form of a corresponding diffusion process as we explain next.

We denote by P_t the marginal of $\mathbf{X}_t$ restricted to the first component in $\mathcal{X}$, and by q_t the probabilty of the coffin state. Thus, we use the vectorial notation

$$\mathbf{P}_t=:(P_t,q_t).$$

Accordingly, for the marginals $\mathbf{R}_t=(R_t,s_t)$ of the prior, R_t satisfies the Fokker-Planck equation (7) while $s_t=1-\int_{\mathbb{R}^n}R_t(x)dx$. The solution $\mathbf{P}^\star$ to (3) is then characterized by the following theorem.

Theorem 3. (see Chen et al. (2021)). The solution $\mathbf{P}^\star$ to (3) corresponds to a diffusion process

$$dX_t=(b(t,X_t)+a(t,X_t)\nabla\log\varphi(t,X_t))dt+\sigma(t,X_t)dW_t \tag{10}$$

with killing rate $\psi V/\varphi$, where φ is obtained from the solution of the generalized Schrödinger system (9). Accordingly,

$$\partial_tP_t+\nabla\cdot((b+a\nabla\log\varphi)P_t)=\frac{1}{2}\sum_{i,j=1}^n\frac{\partial^2(a_{ij}P_t)}{\partial x_i\partial x_j}-\frac{\psi}{\varphi}VP_t. \tag{11}$$

The original Schrödinger bridge problem, when there is no killing, is known to be equivalent to the stochastic control problem of minimizing control energy subject to the marginal two end-point constraints Chen et al. (2016), or equivalently, to a fluid dynamic formulation whereby the velocity field $u(t,\cdot)$ effecting the flow minimizes this action integral, namely,

$$\min_{P_t(\cdot),u(t,\cdot)}\int_0^1\int_{\mathbb{R}^n}\frac{1}{2}\|u(t,x)\|^2P_tdxdt \tag{12a}$$

$$\partial_tP_t+\nabla\cdot((b+\sigma u)P_t)-\frac{1}{2}\sum_{i,j=1}^n\frac{\partial^2(a_{ij}P_t)}{\partial x_i\partial x_j}=0 \tag{12b}$$

$$P_0=\rho_0,\quad P_1=\rho_1. \tag{12c}$$

The optimization takes place over the *feedback control policy-flow field* $u(t,x)$ together with the corresponding density flow $P_t(x)$. Below, we present an analogous formulation for the Schrödinger bridge problems with unbalanced marginals.

Along the flow, the killing rate may deviate from the prior V and is to be determined. To quantify the deviation of the posterior killing rate from the prior, we introduce an entropic cost inside the action integral, to penalize changes in the ratio $\alpha(t,x)$ between the posterior and the prior killing rate. That is, α is an added optimization variable which is $\alpha(t,x)\geq 0$, and with the posterior killing rate being αV. To penalize differences between the posterior and the prior killing rates we introduce the factor

$$\alpha\log\alpha-\alpha+1 \tag{13}$$

inside the action integral, which is convex and achieves the minimal value 0 at $\alpha=1$. This entropy cost has been used in Léonard (2014, 2016) to study Schrödinger bridge problem over graphs. It is associated with the large deviation principle for continuous-time Markov chain with discrete state. Combining this entropic cost term for the ratio of killing rates with (12) we arrive at

$$\min_{P,u,\alpha}\int_0^1\int_{\mathbb{R}^n}\left[\frac{1}{2}\|u(t,x)\|^2P_t+(\alpha\log\alpha-\alpha+1)VP_t\right]dxdt \tag{14a}$$

$$\partial_tP_t+\nabla\cdot((b+\sigma u)P_t)+\alpha VP_t-\frac{1}{2}\sum_{i,j=1}^n\frac{\partial^2(a_{ij}P_t)}{\partial x_i\partial x_j}=0 \tag{14b}$$

$$P_0=\rho_0,\quad P_1=\rho_1. \tag{14c}$$

Note that the control strategy has now two components, a drift term $u(t,x)$ and a correcting term $\alpha(t,x)$ for the killing rate. We conclude with the existence and form of solutions to (14).

Theorem 4. Let $(\hat{\varphi}(t,x), \hat{\psi}(t), \varphi(t,x), \psi(t))$ be the solution to the Schrödinger system (9), then the solution to (14) is given by the choice

$$u^\star(t,x) = \sigma(t,x)' \nabla \log \varphi(t,x) \tag{15a}$$

$$\alpha^\star(t,x) = \frac{\psi(t)}{\varphi(t,x)} \tag{15b}$$

$$P_t(x) = \varphi(t,x)\hat{\varphi}(t,x). \tag{15c}$$

In summary, the key contribution in this work is to address in a rigorous manner the needed update of prior evolution and killing mechanism, through large deviation theory, that extends Schrödinger's dictum of seeking the most likely law that reconciles given marginal distributions. The solution that emerges differs in an essential way from earlier approaches to do the same via Feynman-Kac multiplicative reweighing Nagasawa (1990); Wakolbinger (1989); Blaquière (1992); Dawson et al. (1990); Aebi and Nagasawa (1992); Léonard (2011); Chen et al. (2015, 2017). It is important to underscore that in these earlier approaches, when the prior is consistent with the given marginals, the solution fails to coincide with the prior as one would expect and want. Such a natural requirement for the solution is inherent in our large deviation formulation of the unbalanced Schrödinger Bridge Problem.

Abstract: The fact that further constructions often don't bring breakthrough results motivates us to combine designs to be particles of other combinatorial structures. One of them are mosaics of designs, where instead of having a matrix presenting incidences of a design, one might fill the matrix with incidences of more than one design. Another way of combining designs are design cubes. They can be thought of as 3-dimensional incidence 0-1 matrices, such that each 2-dimensional incidence submatrix satisfies the properties of a design. In this paper we shall be concentrated on designing and combining t-designs although we are aware of the fact that the ideas presented here might work and be interesting for other sorts of combinatorial designs.

Keywords: t-design, mosaic of designs, design cube, difference set
AMS subject classification: 05B05, 05B30

1. INTRODUCTION AND PRELIMINARIES

Combinatorial designs are *set systems* (a collection of subsets of a given set) and consist of two types of objects, *points* (elements of the given set) and *blocks* (subsets of the given set, e.g. members of the given collection), satisfying some additional properties. There are different kinds of combinatorial designs; a good overview of most of them can be found in Colbourn et al. (2007). They are often represented with an *incidence matrix*, which is a 0-1 matrix with rows labelled by points and columns labelled by blocks, where its (i, j)-th entry indicates whether a point lies in a block or not.

In this paper we shall construct and combine t-designs, but it is worth mentioning that the main ideas of combining designs presented here would work for some other types of designs as well. A t-design with parameters (v, k, λ) is a collection $\mathcal{B}$ of k-element subsets (blocks) of a v-element set X (of points), such that every t-element subset of X is contained in exactly λ blocks. In such a case we speak sometimes of a t-(v, k, λ) design. It is known that t, v, k and λ must satisfy a number of more or less complicated (necessary) divisibility conditions, whereas for $t \geq 2$ the existence of a t-design with parameters (v, k, λ) is known only for particular cases which are not described by any general set of sufficient conditions. The number of blocks b can be calculated as $b = \lambda \cdot \binom{v}{t} / \binom{k}{t}$. A design is called *symmetric* if $b = v$. Each point of a t-design is incident with the same number of blocks, usually denoted by $r = \lambda \cdot \binom{v-1}{t-1} / \binom{k-1}{t-1}$.

Example 1. The most prominent and cited example in combinatorial design theory is the Fano plane, having parameters 2-$(7, 3, 1)$. Its incidence matrix can be chosen to be cyclic and given as

$$M = \begin{bmatrix} 0&1&1&0&1&0&0 \\ 0&0&1&1&0&1&0 \\ 0&0&0&1&1&0&1 \\ 1&0&0&0&1&1&0 \\ 0&1&0&0&0&1&1 \\ 1&0&1&0&0&0&1 \\ 1&1&0&1&0&0&0 \end{bmatrix}$$

Where are the borders of knowledge considering the existence of t-designs? For $t = 2$, it is not known whether 2-$(51, 6, 1)$, 2-$(40, 10, 3)$ or 2-$(39, 13, 6)$ exist. If you add the condition for the design to be symmetric, then the smallest examples with non-determined existence are 2-$(157, 13, 1)$ (the projective plane of order 12) or 2-$(81, 16, 3)$. The smallest 3-design with existence in question is 3-$(16, 7, 5)$ and the smallest 4-design 4-$(13, 6, 6)$. Let us point out that at the first glance these parameter sets look rather small.

2. CONSTRUCTION METHODS

A design is given when the blocks are known. Therefore, the size of the search space is $\binom{\binom{v}{k}}{b}$. It explains immediately the difficulty of finding designs by explicit constructions. To reduce the search space, additional constraints might be taken into account. If an automorphism group acts on a design, it acts on the set of points X and on the set of blocks $\mathcal{B}$, partitioning them into orbits. It acts on the set $\binom{X}{k}$ from which we choose our blocks as well, partitioning it into orbits of k-subsets. Clearly, only complete orbits of blocks can be chosen to keep the automorphism group acting on the design. That fact reduces the search space size enormously.

The chosen orbits form a tactical decomposition of the incidence matrix. Out of that fact one can determine

⋆ This work has been supported by the Croatian Science Foundation under the projects 6732 and 9752.

additional necessary conditions for the existence of such a decomposition and reduce the search space further (for details, see Krčadinac et al. (2014)). The most general and successfully widely used method for constructing t-designs by computer goes back to Kramer et al. (1976), where the problem is set as an integer system of linear equations.

3. MOSAICS OF DESIGNS

The rather unsatisfactory fact that a systematic approach towards constructing and classifying designs is often not possible due to the size of the search space, we came to the idea of combining designs together. Looking at Example 1, if we treat the 0's as incidences, we can interprete the $v \times b$ incidence matrix as filled with incidences of two (here complementary) designs. There is place for generalization.

Example 2. Here the matrix of order 7 is filled with 3 different numbers

$$M = \begin{bmatrix} 0&1&1&2&1&2&2\\ 2&0&1&1&2&1&2\\ 2&2&0&1&1&2&1\\ 1&2&2&0&1&1&2\\ 2&1&2&2&0&1&1\\ 1&2&1&2&2&0&1\\ 1&1&2&1&2&2&0 \end{bmatrix}$$

and if we interpret them as incidences, we can clearly write this decomposition as

$$2\text{-}(7,1,0) \oplus 2\text{-}(7,3,1) \oplus 2\text{-}(7,3,1).$$

It is namely obvious that this matrix "consists" of the following three incidence matrices

$$M_0 = \begin{bmatrix} 1&0&0&0&0&0&0\\ 0&1&0&0&0&0&0\\ 0&0&1&0&0&0&0\\ 0&0&0&1&0&0&0\\ 0&0&0&0&1&0&0\\ 0&0&0&0&0&1&0\\ 0&0&0&0&0&0&1 \end{bmatrix}, \quad M_1 = \begin{bmatrix} 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0 \end{bmatrix},$$

$$M_2 = \begin{bmatrix} 0&0&0&1&0&1&1\\ 1&0&0&0&1&0&1\\ 1&1&0&0&0&1&0\\ 0&1&1&0&0&0&1\\ 1&0&1&1&0&0&0\\ 0&1&0&1&1&0&0\\ 0&0&1&0&1&1&0 \end{bmatrix},$$

where $M_0 + M_1 + M_2 = J$, J, being the all-one matrix.

In Gnilke et al. (2018) we have introduced the following combinatorial object. Let c be a positive integer and let $\mathcal{B}_i$ be designs with parameters t_i-(v, k_i, λ_i), $i = 1, \ldots, c$ with the same number of points v and blocks b. A *c-mosaic of designs* $\mathcal{B}_1, \mathcal{B}_2, \ldots, \mathcal{B}_c$ is a $(v \times b)$ matrix $M = [m_{pq}]$, $m_{pq} \in \{l_1, l_2, \ldots, l_c\}$ for which holds that matrices M_i defined as

$$[M_i]_{pq} = \begin{cases} 1, & m_{pq} = l_i \\ 0, & otherwise \end{cases}$$

are incidence matrices of designs $\mathcal{B}_i$.

Once having defined mosaics of designs as a tiling of a $(v \times b)$ matrix, the next task is again to find explicit constructions of these objects.

A design $\mathcal{B}$ on a set X is called *resolvable* if there exists a partition of the set of blocks $\mathcal{B}$ into so called parallel classes, such that every class itself is a partition of the set of points X. Note that for a resolvable t-(v, k, λ) design the number of parallel classes is $p = \lambda \binom{v-1}{t-1} \binom{k-1}{t-1}^{-1}$ and each class contains $\frac{v}{k}$ blocks.

Theorem 1. Let D be the incidence matrix of a resolvable t-(v, k, λ) design, where the columns have been arranged by parallel classes. Let L be a latin square of order $\frac{v}{k}$ with entries $l_1, \ldots, l_{\frac{v}{k}}$. Then $M := D(I_p \otimes L)$ is a $\frac{v}{k}$-mosaic.

Corollary 2. Let F be the field with q elements. Then there is a q-mosaic of affine planes of order q:

$$2\text{-}(q^2, q^2, q^2 + q) = 2\text{-}(q^2, q, 1) \oplus \cdots \oplus 2\text{-}(q^2, q, 1).$$

Open question. Is there a mosaic of a matrix of order 31 of the following form (with the following parameters):

$$2\text{-}(31, 15, 7) \ \oplus \ 2\text{-}(31, 10, 3) \ \oplus \ 2\text{-}(31, 6, 1)?$$

We are still unable to answer this question because of the number of combinatorial possibilities and at the same time couldn't find an argument against the existence.

Nice application of mosaics of designs have been described in Wiese et al. (2022).

4. DESIGN CUBES

Another idea how to combine designs together is looking at 3-dimensional incidence matrices $A = [a_{ijk}]$, $i, j, k = 1, \ldots, v$, $a_{ijk} \in \{0, 1\}$. We will not introduce a third kind of objects (although this might be possible and find its applications), but we want for each 2-dimensional submatrix to be incidence matrix of a design. Hence, for a given A, take a fixed i (from 1 to v), and observe the $v \times v$ matrix $A^i_{jk} = [a_{ijk}]$, $j, k = 1, \ldots, v$ which needs to be an incidence matrix of a (symmetric) design. Do the same for a fixed $j = 1, \ldots, v$ and fixed $k = 1, \ldots, v$. If all $3v$ matrices A^i_{jk}, A^j_{ik} and A^k_{ij} are incidence matrices of a design, we shall call such a 3-dimensional matrix A a *design cube*. If the parameters of the symmetric design are 2-(v, k, λ), we shall assign this parameter triple to the design cube as well.

Example 3. We continue with combining the incidence matrix of the Fano plane from Example 1 in order to get a design cube. The first matrix below is just a copy of it, and the six others are row-shifts of that matrix.

$$\begin{bmatrix} 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0 \end{bmatrix} \begin{bmatrix} 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0 \end{bmatrix} \begin{bmatrix} 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0 \end{bmatrix}$$

$$\begin{bmatrix} 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1 \end{bmatrix} \begin{bmatrix} 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0 \end{bmatrix} \begin{bmatrix} 1&0&1&0&0&0&1\\ 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1 \end{bmatrix}$$

$$\begin{bmatrix} 1&1&0&1&0&0&0\\ 0&1&1&0&1&0&0\\ 0&0&1&1&0&1&0\\ 0&0&0&1&1&0&1\\ 1&0&0&0&1&1&0\\ 0&1&0&0&0&1&1\\ 1&0&1&0&0&0&1 \end{bmatrix}$$

Imagine putting these matrices one above the other, playing the role of $A^1_{ij}, \ldots, A^7_{ij}$ (the third index fixed) from the definition above. We get a cube of order 7. We need to check that all 2-dimensional (sub)matrices of order 7 are incidence matrices of a 2-$(7, 3, 1)$ design. This is trivial if we fix the 3. dimension "k": all the matrices listed above are incidence matrices of the Fano plane. If we fix the first dimension (index) i, we see that the i-th rows are simply shifts of the previous row. Finally, if we fix the second dimension (index) j, we see that columns are shifts as well, but in the opposite direction.

Theorem 3. If there exists a (v, k, λ) difference set, then there exists a design cube with parameters 2-(v, k, λ).

The proof of this theorem follows facts listed in Example 3 and can be generalized easily. Namely, the incidence matrix of the Fano plane in our example is presented as a cyclic matrix hence it can be seen as the *development* of a $(7, 3, 1)$ *difference set* (Colbourn et al. (2007)) in the cyclic group of order 7.

For the moment we are not aware of any examples not coming from difference sets and finding such an example would be the first task in continuing the research on design cubes. Furthermore, it would be interesting to define and find generalizations of design cubes in higher dimensions.

Abstract: The fundamental lemma by Willems and coauthors facilitates a parameterization of all trajectories of a linear time-invariant system in terms of a single, measured one. This result plays an important role in data-driven simulation and control. Under the hood, the fundamental lemma works by applying a persistently exciting input to the system. This ensures that the Hankel matrix of resulting input/output data has the "right" rank, meaning that its columns span the entire subspace of trajectories. However, such binary rank conditions are known to be fragile in the sense that a small additive noise could already cause the Hankel matrix to have full rank. Therefore, in this extended abstract we present a robust version of the fundamental lemma. The idea behind the approach is to guarantee certain lower bounds on the singular values of the data Hankel matrix, rather than mere rank conditions. This is achieved by designing the inputs of the experiment such that the minimum singular value of a deeper input Hankel matrix is sufficiently large. This inspires a new quantitative and robust notion of persistency of excitation. The relevance of the result for data-driven control will also be highlighted through comparing the predictive control performance for varying degrees of persistently exciting data.

Keywords: Identification, linear systems, data-driven control

1. INTRODUCTION

The fundamental lemma from Willems et al. (2005) is a powerful result that enables the characterization of the subspace of all possible trajectories of a linear time-invariant (LTI) system using raw time series data sorted into a Hankel matrix. The result has inspired many methods for data-driven analysis and control; see (Markovsky and Rapisarda, 2008; van Waarde et al., 2020; van Waarde, 2021; Coulson et al., 2019; De Persis and Tesi, 2019; Berberich et al., 2020), and the survey by Markovsky and Dörfler (2021) and references therein.

At its core, the fundamental lemma requires applying an input sequence to the system that is persistently exciting of sufficient order such that the resulting input/output data Hankel matrix spans the entire subspace of possible trajectories of the system. In other words, if a deeper input data Hankel matrix is full row rank, the resulting input/output data Hankel matrix spans the admissible trajectory subspace. This input/output data Hankel matrix can then be used as a non-parametric system model.

One major drawback of the fundamental lemma is that it only holds for noise-free data. Indeed, when the data are corrupted by noise, rank conditions are no longer sufficient for the data matrix to span the admissible trajectory subspace leading to poor performance when used for data-driven analysis and control. This demonstrates that these binary rank conditions can no longer indicate suitable data when in the presence of noise. This motivates defining a new *quantitative* notion of persistency of excitation that gives a measure of *how* persistently exciting the inputs are. In adaptive control, such quantitative notions are studied (Åström and Wittenmark, 2008, Remark 1, pg. 64), but not in the context of the fundamental lemma.

In this extended abstract we propose a robust fundamental lemma that relies on a new *quantitative* notion of persistency of excitation. The result informs the input selection such that the minimum singular value of the input/output data matrix is lower bounded by a user specified parameter. This results in a data matrix that is more robust to noise leading to better performance when used for data-driven analysis and control.

The rest of the extended abstract is organized as follows. We begin with notation. Section 2 formalizes the problem of interest. Section 3 contains the main result whose relevance is illustrated through a data-driven control case study in Section 4. We conclude in Section 5.

Notation: Let $m, n \in \mathbb{Z}_{>0}$. Given a matrix $M \in \mathbb{R}^{m\times n}$ and integer $i \in \mathbb{Z}_{>0}$ we denote the i-th singular value of M by $\sigma_i(M)$ with the ordering $0 \leq \sigma_1(M) \leq \sigma_2(M) \leq \cdots \leq \sigma_{\min\{m,n\}}$. When $m = n$ and $M = M^\top$, we denote the i-th eigenvalue of M by $\lambda_i(M)$ with the ordering $\lambda_1(M) \leq \lambda_2(M) \leq \cdots \lambda_n(M)$. We use $\|M\| = \sigma_{\min\{m,n\}}$ to denote the spectral norm of a matrix M, $\|M\|_F$ the Frobenius norm, and $\|x\|$ to denote the 2-norm of a vector

x. The Moore-Penrose pseudo inverse of M is denoted by $M^\dagger$. Given $i, j, T \in \mathbb{Z}_{\geq 0}$ with $i \leq j$ and a sequence $\{z(t)\}_{t=0}^{T-1} \subset \mathbb{R}^n$ define

$$z_{[i,j]} := [z(i)^\top \; z(i+1)^\top \cdots z(j)^\top]^\top.$$

Given an integer $k \in \mathbb{Z}_{>0}$ with $k \leq j - i + 1$, define the *Hankel matrix of depth* k associated with $z_{[i,j]}$ as

$$\mathcal{H}_k(z_{[i,j]}) := \begin{bmatrix} z(i) & z(i+1) & \cdots & z(j-k+1) \\ z(i+1) & z(i+2) & \cdots & z(j-k+2) \\ \vdots & \vdots & \ddots & \vdots \\ z(i+k-1) & z(i+k) & \cdots & z(j) \end{bmatrix}.$$

2. PROBLEM STATEMENT

Consider the discrete-time LTI system

$$x(t+1) = Ax(t) + Bu(t), \tag{1}$$

where $x(t) \in \mathbb{R}^n$ is the state, and $u(t) \in \mathbb{R}^m$ is the control input. Throughout this extended abstract we will focus on a special case of full state measurements. We recall the definition of persistency of excitation.

Definition 2.1. Let $T \in \mathbb{Z}_{>0}$. The input sequence $u_{[0,T-1]}$ is called persistently exciting of order $k \in \mathbb{Z}_{>0}$ if $\mathcal{H}_k(u_{[0,T-1]})$ has full row rank.

We now state a version of the fundamental lemma (Willems et al., 2005) for the special case of input/state data.

Theorem 2.1. Let (A, B) be controllable and $T \in \mathbb{Z}_{>0}$. Let $(u_{[0,T-1]}, x_{[0,T-1]})$ be an input/state trajectory of (1) such that $u_{[0,T-1]}$ is persistently exciting of order $n+1$. Then the data matrix

$$\begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix} = \begin{bmatrix} x(0) & x(1) & \cdots & x(T-1) \\ u(0) & u(1) & \cdots & u(T-1) \end{bmatrix} \tag{2}$$

has rank $n + m$.

As a result, the matrix (2) along with $x(T)$ fully capture the behaviour of (1) and can be used for data-driven analysis and control or system identification (Markovsky and Dörfler, 2021). However, the above rank condition on the data matrix (2) is not always a valid indicator that the data is suitable for characterizing the behaviour of (1). In fact, when the data is corrupted by noise, (2) may have full rank, but can lead to poor performance when used for data-driven analysis or control. We present a motivating example outlining precisely how we can improve on such rank conditions.

Example 2.1. Suppose we wish to identify matrices A, B of the system

$$x(t+1) = Ax(t) + Bu(t) + w(t), \tag{3}$$

where $w(t) \in \mathbb{R}^n$ is a noise term. Let $(u_{[0,T-1]}, x_{[0,T-1]})$ be an input/state trajectory of the noisy system such that $u_{[0,T-1]}$ is persistently exciting of order $n+1$. To identify A, B, we consider the least squares problem

$$\min_{A,B} \quad \left\| \mathcal{H}_1(x_{[1,T]}) - [A \; B] \begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix} \right\|_F$$

with solution given by

$$\begin{bmatrix} \hat{A} & \hat{B} \end{bmatrix} := \mathcal{H}_1(x_{[1,T]}) \begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix}^\dagger. \tag{4}$$

The data satisfies

$$\mathcal{H}_1(x_{[1,T]}) = [A \; B] \begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix} + \mathcal{H}_1(w_{[0,T-1]}).$$

Hence, the error of our estimate is given by

$$\begin{aligned} \left\| \begin{bmatrix} \hat{A} & \hat{B} \end{bmatrix} - [A \; B] \right\| &= \left\| \mathcal{H}_1(w_{[0,T-1]}) \begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix}^\dagger \right\| \\ &\leq \frac{\sigma_n(\mathcal{H}_1(w_{[0,T-1]})}{\sigma_1\left(\begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix} \right)}. \end{aligned}$$

Note that the estimation error can be arbitrarily large, regardless of whether (2) is full row rank. What is important instead is the smallest singular value of (2). Indeed, if we wish to identify A, B to within some specified error, we require that the smallest singular value of the data matrix (2) is bounded below by some threshold depending on the noise term w. •

This example motivates us to develop a robust fundamental lemma that moves away from rank conditions by defining a quantitative notion of persistency of excitation which guarantees a lower bound on the minimum singular value of the data matrix (2). More formally, the goal of this extended abstract is to solve the following problem.

Problem 2.1. Let $\delta > 0$. Design an input sequence $u_{[0,T-1]}$ such that the resulting data matrix satisfies

$$\sigma_1\left(\begin{bmatrix} \mathcal{H}_1(x_{[0,T-1]}) \\ \mathcal{H}_1(u_{[0,T-1]}) \end{bmatrix} \right) \geq \delta. \tag{5}$$

3. MAIN RESULT

The two main ingredients of the fundamental lemma are controllability and persistency of excitation. To establish a robust fundamental lemma, we must develop quantitative notions of these two main ingredients. We start with persistency of excitation.

Definition 3.1. Let $T \in \mathbb{Z}_{>0}$, $\alpha > 0$. The input sequence $u_{[0,T-1]}$ is called α-persistently exciting of order $k \in \mathbb{Z}_{>0}$ if $\sigma_1(\mathcal{H}_k(u_{[0,T-1]})) \geq \alpha$.

This is a natural generalization of persistency of excitation since for any $\alpha > 0$ an α-persistently exciting signal of order k is necessarily persistently exciting of order k.

We now focus on the second main ingredient of the fundamental lemma: controllability. Define matrix $M \in \mathbb{R}^{(n+m+nm)\times(n+m+nm)}$ and vector $z \in \mathbb{R}^{n+m+nm}$ as

$$M := \begin{bmatrix} A & B & 0 & \cdots & 0 \\ 0 & 0 & I_m & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & I_m \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad z = \begin{bmatrix} \xi \\ \eta \\ 0_{nm} \end{bmatrix} \tag{6}$$

where $\xi \in \mathbb{R}^n$, $\eta \in \mathbb{R}^m$, and I_m and 0_{nm} denote the $m \times m$ identity matrix and the zero vector of length nm, respectively. Define for any z of the form (6)

$$\Theta_z := \begin{bmatrix} z & M^\top z & \cdots & (M^\top)^n z \end{bmatrix}^\top. \tag{7}$$

Note that $\Theta_z^\top$ can be viewed as an extended controllability matrix of the pair $(M^\top, z)$. We make the following quantitative controllability assumption on this pair.

Assumption 3.1. Let $\rho > 0$. For all z of the form (6) with $\|z\| = 1$, assume

$$\sigma_1(\Theta_z) \geq \rho. \tag{8}$$

This assumption can be thought of as ensuring that the finite horizon controllability Gramian $\Theta_z^\top \Theta_z = \sum_{j=0}^{n} (M^\top)^j z z^\top M^j$ has lower bounded eigenvalues. This assumption is not restrictive since for any controllable (A, B), there exists uniform $\rho_0 > 0$ that lower bounds $\sigma_1(\Theta_z)$ for all z with $\|z\| = 1$, by the following lemma.

Lemma 3.1. Let (A, B) be controllable. Then

(i) $\operatorname{rank}(\Theta_z) = n + 1$, and
(ii) there exists $\rho_0 > 0$ such that $\sigma_1(\Theta_z) \geq \rho_0$,

for all z be of the form (6) with $\|z\| = 1$.

Proof. We begin by proving (i). Assume on the contrary that the rows of Θ_z are linearly dependent. From the structure of Θ_z, we must have that $\eta = 0$ and thus $z = (\xi, 0_{(n+1)m})$. Likewise, we must have that $\xi^\top B = \xi^\top AB = \cdots = \xi^\top A^{n-1} B = 0$. By controllability of (A, B), this implies that $\xi = 0$, and hence $z = 0$. This contradicts the fact that $\|z\| = 1$, proving the claim. We now prove (ii). Assume on the contrary that $\forall \rho_0 > 0$, $\exists\ z$ with $\|z\| = 1$ such that $\sigma_1(\Theta_z) < \rho_0$. Let $\{\rho_j\}_{j=1}^{\infty} \subset \mathbb{R}$ be a sequence such that $\lim_{j\to\infty} \rho_j = 0$. By assumption, for each ρ_j, there exists z_j with $\|z_j\| = 1$ and $\sigma_1(\Theta_{z_j}) < \rho_j$. Since the set $\{z \mid \|z\| = 1\}$ is compact, $\{z_j\}_{j=1}^{\infty}$ has a convergent subsequence converging to some $\bar{z}$ with $\|\bar{z}\| = 1$. Thus, $\sigma_1(\Theta_{\bar{z}}) \leq 0$. However, by part (i), $\Theta_{\bar{z}}$ has full row rank and hence, there exists $\bar{\rho} > 0$ such that $\sigma_1(\Theta_{\bar{z}}) > \bar{\rho}$ which is a contradiction, proving the result. ■

We now state the main theorem which solves Problem 2.1.

Theorem 3.1. Let $T \in \mathbb{Z}_{>0}$, (A, B) be controllable, and $\delta > 0$. Suppose that Assumption 3.1 holds and $(u_{[0,T-1]}, x_{[0,T-1]})$ is an input/state trajectory of (1) such that $u_{[0,T-1]}$ is $\delta\frac{\sqrt{n+1}}{\rho}$-persistently exciting of order $n+1$. Then

$$\sigma_1\left(\begin{bmatrix}\mathcal{H}_1(x_{[0,T-1]})\\ \mathcal{H}_1(u_{[0,T-1]})\end{bmatrix}\right) \geq \delta.$$

Proof. Denote the minimum singular value of the input/state data matrix (2) by $\sigma \geq 0$ with corresponding left and right singular vectors $(\xi, \eta) \in \mathbb{R}^{n+m}$ and $v \in \mathbb{R}^T$, respectively. Then, $\|(\xi, \eta)\| = \|v\| = 1$ and

$$[\xi^\top\ \eta^\top] \begin{bmatrix}\mathcal{H}_1(x_{[0,T-1]})\\ \mathcal{H}_1(u_{[0,T-1]})\end{bmatrix} = \sigma v^\top.$$

Let $z = (\xi, \eta, 0_{nm})$. By definition of Θ_z in (9) and the dynamics (1), we have

$$\Theta_z \begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix} = \sigma \mathcal{H}_{n+1}(v_{[0,T-1]}). \tag{9}$$

By Cauchy's interlacing theorem (Horn and Johnson, 1994, Corollary 3.1.3),

$$\sigma_1\left(\mathcal{H}_{n+1}(u_{[0,T-1]})\right) \leq \sigma_{n+1}\left(\begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix}\right). \tag{10}$$

By the Courant-Fischer-Weyl max-min principle (Horn and Johnson, 1994, Theorem 3.1.2),

$$\sigma_{n+1}\left(\begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix}\right) = \min_{\substack{\mathcal{U}\\ \dim(\mathcal{U})=n+1}} \max_{\substack{y\in\mathcal{U}\\ \|y\|=1}} \left\| \begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix}^\top y \right\|.$$

By Lemma 3.1, $\operatorname{rank}(\Theta_z) = n + 1$, and hence

$$\begin{aligned}
&\sigma_{n+1}\left(\begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix}\right)\\
&\leq \max_{\substack{y\in\operatorname{im}\Theta_z^\top\\ \|y\|=1}} \left\| \begin{bmatrix}\mathcal{H}_1(x_{[0,T-n-1]})\\ \mathcal{H}_{n+1}(u_{[0,T-1]})\end{bmatrix}^\top y \right\|\\
&= \max_{\|\Theta_z^\top q\|=1} \left\|\sigma \mathcal{H}_{n+1}(v_{[0,T-1]})^\top q\right\|\\
&\leq \sigma \left\|\mathcal{H}_{n+1}(v_{[0,T-1]})^\top\right\| \max_{\|\Theta_z^\top q\|=1} \|q\|\\
&\leq \sigma\sqrt{n+1} \max_{\|\Theta_z^\top q\|=1} \|q\|,
\end{aligned} \tag{11}$$

where the equality comes from (9) and the last inequality holds because the rows of $\mathcal{H}_{n+1}(v_{[0,T-1]})$ have norm at most 1. Without loss of generality, write $q = \sum_{j=1}^{n+1} \alpha_j \mu_j$ where $\alpha_j \in \mathbb{R}$ and $\mu_j \in \mathbb{R}^{n+1}$ are orthonormal eigenvectors of $\Theta_z \Theta_z^\top$ corresponding to eigenvalues $\lambda_j(\Theta_z \Theta_z^\top)$. Then

$$\max_{\|\Theta_z^\top q\|=1} \|q\|^2 = \max_{\sum_{j=1}^{n+1} \alpha_j^2 \lambda_j(\Theta_z\Theta_z^\top)=1} \sum_{j=1}^{n+1} \alpha_j^2.$$

We see the maximum is achieved for $\alpha_1 = \pm\frac{1}{\sqrt{\lambda_1(\Theta_z\Theta_z^\top)}}$, and $\alpha_j = 0$ for $j \in \{2, \ldots, n+1\}$. Hence,

$$\max_{\|\Theta_z^\top q\|=1} \|q\| = \frac{1}{\sqrt{\lambda_1(\Theta_z\Theta_z^\top)}}.$$

Combining the above with (10) and (11), we obtain

$$\sigma \geq \sigma_1\left(\mathcal{H}_{n+1}(u_{[0,T-1]})\right) \sqrt{\frac{\lambda_1(\Theta_z\Theta_z^\top)}{n+1}}.$$

Substituting $\sqrt{\lambda_1(\Theta_z\Theta_z^\top)} = \sigma_1(\Theta_z) \geq \rho$ by Assumption 3.1 and using the fact that $u_{[0,T-1]}$ is $\delta\frac{\sqrt{n+1}}{\rho}$-persistently exciting of order $n+1$ yields the result. ■

The theorem tells us how the inputs should be chosen such that *for any* user defined parameter δ, the smallest singular value of the data matrix (2) is lower bounded by δ. The degree of persistency of excitation needed depends on ρ which is assumed to be a prior in our setting. However, Lemma 3.1 shows that, for any controllable system (1), there exists $\rho_0 > 0$ such that $\sigma_1(\Theta_z) \geq \rho_0$ for all z. To design an input sequence so that (5) holds, we only require a lower bound on ρ_0 since any input that is $\delta\frac{\sqrt{n+1}}{\rho_0}$-persistently exciting of order $n+1$ yields the desired result.

4. NUMERICAL EXAMPLE

In this section we compare the performance of several data sets with varying degrees of persistency of excitation for a data-driven control task. Our hypothesis is that data sets whose inputs have a larger degree of persistency excitation will perform better when the data is corrupted by noise. Consider a controllable system (3) with

$$A = \begin{bmatrix}1 & 1\\ 0 & 1\end{bmatrix},\ B = \begin{bmatrix}0\\ 1\end{bmatrix}.$$

We generated 3 input data sequences of length $T = 50$ with varying degrees of persistency of excitation. We denote

the i-th input data sequence by $u^{(i)}_{[0,T-1]}$. The inputs for each input data sequence were chosen as $u^{(1)}(t) \sim \mathcal{N}(0, 10^{-2}), u^{(2)}(t) = 0.05u^{(1)}(t), u^{(3)}(t) = 0.01u^{(1)}(t)$ for all $t \in \{0, \dots, T-1\}$. As a result, we obtained 3 input sequences that were $\alpha^{(i)}$-persistently exciting of order $n+1$, with $\alpha^{(1)} = 0.48$, $\alpha^{(2)} = 0.024$, $\alpha^{(3)} = 0.0048$. The corresponding state data $x^{(i)}_{[0,T]}$ was generated by (3) where the noise $w(t) \sim \mathcal{N}(0, 10^{-4}I_n)$ was the same across all data sets. Using the data, we constructed 3 different data-driven one-step predictors as in (4)

$$x(t+1) = \mathcal{H}_1\left(x^{(i)}_{[1,T]}\right) \begin{bmatrix} \mathcal{H}_1\left(x^{(i)}_{[0,T-1]}\right) \\ \mathcal{H}_1\left(u^{(i)}_{[0,T-1]}\right) \end{bmatrix}^{\dagger} \begin{bmatrix} x(t) \\ u(t) \end{bmatrix}. \quad (12)$$

We then used the predictor equations (12) for a predictive control reference tracking task by solving the following optimization problem in a receding horizon fashion:

$$\begin{aligned} \min_{x,u} \quad & \sum_{k=0}^{T_\mathrm{f}-1} \|x_k - r\|^2 + \|u_k\|^2 \\ \text{s.t.} \quad & x_0 = x(t) \\ & x_{k+1} = \mathcal{H}_1\left(x^{(i)}_{[1,T]}\right) \begin{bmatrix} \mathcal{H}_1\left(x^{(i)}_{[0,T-1]}\right) \\ \mathcal{H}_1\left(u^{(i)}_{[0,T-1]}\right) \end{bmatrix}^{\dagger} \begin{bmatrix} x_k \\ u_k \end{bmatrix} \\ & k \in \{0, \dots, T_\mathrm{f} - 1\} \end{aligned} \quad (13)$$

where $x(t)$ denotes the current state at time t, $r \in \mathbb{R}^n$ is the reference, and $T_\mathrm{f} = 10$ is the prediction horizon. System (3) was simulated for each data set with noise $w(t) \sim \mathcal{N}(0, 10^{-4}I)$ the same across all simulations and inputs obtained by solving (13) in receding horizon. Figure 1 depicts the performance of the three data-driven one-step predictors for the reference tracking task.

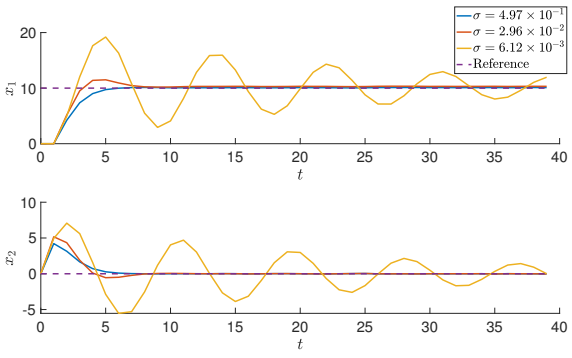

Fig. 1. State trajectories $x(t) = (x_1(t), x_2(t))$ controlled by solving (13) in a receding horizon fashion for three data sets with varying degrees of persistency of excitation. The legend indicates the minimum singular value of the data matrices (2) used for prediction in (13).

For this example, we approximated ρ_0 for which Lemma 3.1 holds. By randomly sampling vectors z with $\|z\| = 1$, we obtained $\rho_0 \approx 0.105$. Thus, Assumption 3.1 should hold for any $\rho \leq \rho_0$. Based on ρ_0 and the degree of persistency of excitation of each input sequence, we can compute the value $\delta^{(i)}$ for which (5) holds for the i-th input/state data. Theorem 3.1 guarantees that (5) holds for each data set with $\delta^{(1)} = 2.9 \times 10^{-2}$, $\delta^{(2)} = 1.4 \times 10^{-3}$, and $\delta^{(3)} = 2.9 \times 10^{-4}$. As we see from Figure 1, the performance of the data-driven predictors decreases as the minimum singular value of the data matrix (2) decreases. This can be attributed to the fact that the one-step predictor in (12) becomes more accurate as the smallest singular value of the data matrix decreases (as seen in Example 2.1), leading to better performance.

5. CONCLUSION

In this extended abstract, we defined a new quantitative notion of persistency of excitation by analyzing the minimum singular value of an input Hankel matrix. Based on this notion, we specified to what degree the inputs should be persistently exciting to ensure that the smallest singular value of the resulting input/state matrix is larger than a user defined threshold, thus generalizing the celebrated fundamental lemma. As a result, we are able to move away from classical rank conditions and give a quantitative notion of data suitability. A comparison of the control performance of several data sets with varying degrees of persistently exciting input data suggested that data being generated by inputs with a larger degree of persistency of excitation are better suited to control tasks. Future work includes extending these results to the general input/output case.

Abstract: We propose a novel fully decentralized energy management scheme for aggregating distributed energy resources for grid flexibility services in wholesale electricity market. We model this problem as a multi-leader-multi-follower noncooperative game. Then a fully distributed algorithm in discrete-time is proposed to solve the problem and find the Nash Equilibrium(NE). In this algorithm, each aggregator only needs to exchange its estimate of the aggregate and an auxiliary variable with its neighbours. This scheme shows the scalability and efficiency in aggregating flexibility services from a large number of prosumers.

Keywords: Game theory, Smart grid, Flexibility service, Nash equilibrium seeking.

1. INTRODUCTION

In recent years, the growing climate and environmental concerns have led to a rapid increase of the contribution of renewable energy capacities in electricity generation. However, the variability and uncertainty of renewable generation bring potential challenges in the operation of power systems and influence the performance and outcome of electricity market. Designing energy management mechanisms for Distributed Energy Resources(DERs) in the smart grid has been considered as a potential solution for a renewable-power future. The smart grid is typically composed of a variety of new participants, such as microgrids, aggregators, and prosumers. Each of them is self-interested and has different capabilities and objectives. This heterogeneous nature of the smart grid motivates the adoption of game theory as an analytical tool to study the interactions among them.

In particular, managing DERs to response to the system's overall condition is a powerful solution to increasing grid flexibility and facilitating the integration of renewable generations. This will enable end-consumers to take up an unprecedented proactive role(i.e. prosumers) and reap financial benefits through leveraging their flexibility by providing services to system operators. However, it is difficult to imagine that all these individual prosumers directly participate in the wholesale electricity market, thus a market participant, the aggregator, has been introduced to manage these DERs locally and ensure no distribution constraints are violated (Gkatzikis et al. (2013)). There are two main approaches which an aggregator can employ to steer the prosumers to the optimal operation point. One is the fully centralized scheme, where the aggregator has access to all parameters of the prosumers (Parvania et al. (2013)). The other one is pricing based methods, where the aggregator is treated as a leader and proposes some prices to the following prosumers (see e.g. Zugno et al. (2013)).

Competition among participating agents can be incoporated in a game theoretic setup, where the aggregator aims to steer the prosumers to a desired setpoint, often taken to be the Nash equilibrium of the game. Designing algorithms for equilibrium-seeking problems has attracted substantial research interest in the last decades. These algorithms can be roughly divided into two categories in terms of methods used: gradient-based algorithms (Franci and Grammatico (2020), Pavel (2019)) and proximal-point algorithms (Belgioioso and Grammatico (2019), Yi and Pavel (2018)). In these works, each player is required to know or estimate the overall information of all the other players. The algorithm in (Koshal et al. (2016)) only requires each player maintains an estimate of the true aggregate, but it requires diminishing step-sizes for exact convergence. The work (Gadjov and Pavel (2020)) proposes a single-layer distributed algorithm that reaches a variational generalized NE under constant step sizes while the initial values of aggregate estimations must be same with those of actions. In (De Persis and Grammatico (2019), Shakarami et al. (2019)), continuous-time algorithms for aggregative games are proposed. While discrete-time algorithms are in general more suited for implementations in energy-domain applications, their design requires additional care, e.g. a careful choice of step sizes is needed.

This work consists of two parts: network modeling and game-theoretic algorithms. In the first part, we consider a fully decentralized energy management scheme for aggregating distributed energy resources for grid flexibility services in wholesale electricity market. We explicitly model

this scheme as a multi-leader-multi-follower game. In the upper level, the aggregators aim to maximize their profits by incentivizing the prosumers to utilize their flexible resources and providing these services to the transmission network. In the lower level, the prosumers act as price takers and change their supplies or demands based on the incentivizing prices sent by the aggregators.

The dominant scenario in the literature of game-theoretic algorithms in energy management systems is to consider a single aggregator and study the competition among different prosumers. In this work, on the other hand, we consider a multi-aggregator scheme in which the aggregators compete among each other to increase their profit in the market. A system operator aims to steer the aggregators towards the NE of the game. The challenge here is that the profit of an aggregator itself depends on the cost functions of all of its prosumers. The latter cost functions are unknown to the aggregator due to privacy reasons.

After carefully modeling the competition among aggrgeators and their coupling with the prosumers, we propose a fully distributed algorithm in discrete-time to solve the resulting optimization problem and steer the aggregators towards the NE of the game. Each aggregator only needs to exchange its estimate of the aggregate and an auxiliary variable with its neighbours.

Notation We use $\mathbf{1}$ to denote a vector of all ones. We use $\|A\|$ to denote the maximum singular value of A. For a differentiable scalar function f, we use f' and f^{-1} to denote its derivative and inverse function respectively.

Operator theoretic definitions We use $\mathrm{Id}(\cdot)$ to denote the identity operator. For a closed set $\Omega \in \mathbb{R}^n$, the mapping Proj_Ω denotes the projection onto Ω. The set-valued mapping N_Ω denotes the normal corn operator for the set $\Omega \in \mathbb{R}^n$. For a non-differentiable function f, ∂f denotes its subdifferential set-valued mapping, defined as $\partial f = \{v \in \mathbb{R}^n | f(z) \geq f(x) + v^\top (z - v)\}$ for all $z \in \mathrm{dom}(f)$. A set-valued mapping F is ℓ-Lipschitz continuous, with $\ell > 0$, if $\|u - v\| \leq \ell \|x - y\|$ for all $x, y \in \mathbb{R}^n$, $u \in \mathrm{F}(x)$, $v \in \mathrm{F}(y)$. The mapping F is μ-strongly monotone, with $\mu > 0$, if $(u - v)^\top)(x - y) \geq \mu \|x - y\|^2$ for all $x, y \in \mathbb{R}^n$, $u \in \mathrm{F}(x)$, $v \in \mathrm{F}(y)$. The mapping F is η-averaged, with $\eta \in (0, 1)$, if $\|u - v\|^2 \leq \ell \|x - y\|^2 - \frac{1-\eta}{\eta} \|(\mathrm{Id} - (F)(x)) - (\mathrm{Id} - (F)(y))\|^2$, for all $x, y \in \mathbb{R}^n$, $u \in \mathrm{F}(x)$, $v \in \mathrm{F}(y)$. The mapping F is β-cocoercive, with $\beta > 0$, if βF is $\frac{1}{2}$-averaged.

2. PROBLEM FORMULATION

We consider a scenario where there is an energy supply deficit in the wholesale electricity market. This can be due to a decrease in power generation from a wind or solar farm because of a change in weather conditions and power demand. The Transmission System Operator can procure energy flexibility services to complement this deficit from Distributed Energy Resources (DERs) connected at the distribution level. We design a fully decentralized energy management scheme for aggregating these DERs to freely participate in the wholesale market and introduce a group of aggregators to manage a population of prosumers, as shown in Fig.1. The case of an excess in energy supply can be treated analogously.

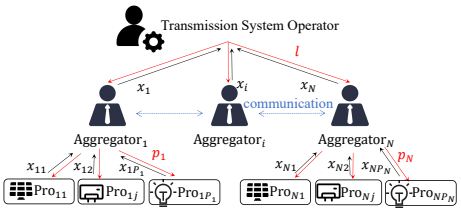

Fig. 1. The decentralized energy management scheme

2.1 Aggregator/Prosumer Model

The set of aggregators is denoted by $\mathcal{I} = \{1, 2, ..., N\}$ and aggregator i provides flexibility x_i by incentivizing the prosumers to consume less or generate more energy. Each aggregator aims to maximize its net revenue J_i, and we employ the following optimization problem,

$$\max_{0 \leq x_i \leq \bar{x}_i} J_i(x_i, p_i, s(\mathbf{x})) = -x_i p_i + l\big(s(\mathbf{x})\big) x_i \qquad (1)$$

where p_i and $l(\cdot)$ are the unit prices for buying and selling flexibility services respectively, $l : \mathbb{R} \to \mathbb{R}$, $s : \mathbb{R}^N \to \mathbb{R}$, and $\bar{x}_i$ is the maximum available flexibility due to the line capacity constraint. We assume that the selling price $l(\cdot)$ affinely depends on the aggregated flexibility, namely

$$l(s(\mathbf{x})) = l_0 - \lambda s(\mathbf{x}), \qquad (2)$$

where λ is a positive parameter corresponding to price elasticity and l_0 is a basic price for unit flexibility; $\mathbf{x} = \mathrm{col}(x_i)_{i \in \mathcal{I}}$, $s(\mathbf{x}) = \frac{1}{N} \mathbf{1}_N^\top \mathbf{x}$ and the coefficient $\frac{1}{N}$ is included for convenience. We note that the individual optimization problems are coupled with each other through the selling price l.

We denote the the prosumer ij's flexibility by x_{ij} for each $j \in \mathcal{P}_i = \{1, 2, ..., P_i\}$, where $\mathcal{P}_i$ is the set of prosumers assosiated with aggregator i. So the total flexibility $x_i := \sum_{j \in \mathcal{P}_i} x_{ij}$. The prosumer ij's goal is to maximize its revenue by altering its demand or supply based on the incentivizing price p_i. This results in the following optimization problem,

$$\max_{x_{ij} \geq 0} U_{ij}(x_{ij}) = x_{ij} p_i - g_{ij}(x_{ij}) \qquad (3)$$

where $U_{ij}(\cdot)$ denotes the utlitiy function of prosumer ij, and $g_{ij}(\cdot)$ accounts for the cost/inconvenience for providing the flexibility x_{ij}. We note that the first term in (3) is the payment received from aggregator i in return for the provided flexibility.

The model (1)-(3) for the aggregator i and its prosumers gives rise to a bilevel optimization problem. In the reminder of this section, we transfer this model into an equivalent convex problem by imposing a few assumptions.

Assumption 1. For each $j \in \mathcal{P}_i$ and $x_{ij} \geq 0$, the cost function g_{ij} is twice continuously differentiable and strictly convex with $g'_{ij}(0) \geq 0$. Moreover, we assume that g'_{ij} is convex, μ_{ij}-strongly monotone and ℓ_{ij}-Lipschitz continuous, for some constant $\mu_{ij}, \ell_{ij} > 0$.

The most common cost function, linear quadratic function $g_{ij} = \frac{1}{2} a_{ij} x_{ij}^2 + b_{ij} x_{ij}$, $a_{ij} > 0$, $b_{ij} > 0$, satisfies Assumption 1 with $\mu_{ij} = \ell_{ij} = a_{ij}$.

The prosumer maximization problem (3) admits the following well-known solution descending from the KKT condition.

Lemma 1. Let Assumption1 hold. Then, (3) admits a unique solution given by:

$$x_{ij} = \pi_{ij}(p_i) = \begin{cases} g_{ij}'^{-1}(p_i) & if\ p_i \geq g_{ij}'(0) \\ 0 & if\ p_i < g_{ij}'(0) \end{cases} \tag{4}$$

Then we can build the relationship between p_i and x_i by the following Lemma.

Lemma 2. Let Assumption 1 hold and let $\bar{\mathcal{P}}_i \subseteq \mathcal{P}_i$ denote the set of prosumers providing flexibility, i.e., $x_{ij} > 0$ for all $j \in \bar{\mathcal{P}}_i$. Then, there exits a continuous function u_i satisfying

$$p_i = u_i(x_i) \tag{5}$$

with the following properties: (i) $u_i \geq \max_{j\in M}\{g_{ij}'(0)\}$; (ii) u_i is continuous, strictly increasing and convex; (iii) μ_i-strongly monotone and ℓ_i-Lipschitz continuous, with $\mu_i = 1/\sum_{j\in\bar{\mathcal{P}}_i}\frac{1}{\mu_{ij}}$ and $\ell_i = 1/\sum_{j\in\bar{\mathcal{P}}_i}\frac{1}{\ell_{ij}}$.

To obtain more explicit expressions for optimal flexibility response x_i and price p_i, we take linear-quadratic function as an example for cost function and consider all prosumers entering the market. In this case, we have

$$u_i(x_i) = \beta_i + \alpha_i x_i \tag{6}$$

where $\alpha_i = 1/\sum_{j\in\mathcal{P}_i}\frac{1}{a_{ij}}$ and $\beta_i = \sum_{j\in\mathcal{P}_i}\frac{b_{ij}}{a_{ij}}/\sum_{j\in\mathcal{P}_i}\frac{1}{a_{ij}}$.

2.2 Game Theoretic Formulation

Following Lemma 2, we can substiute $p_i = u_i(x_i)$ in (5) to obtain

$$\min_{\underline{x}_i \leq x_i \leq \overline{x}_i} J_i(x_i, s(\mathbf{x})) = x_i u_i(x_i) - l\big(s(\mathbf{x})\big)x_i, \tag{7}$$

where $l\big(s(\mathbf{x})\big)$ is given by (2) and $\underline{x}_i := u_i^{-1}(\max_{j\in M}\{g_{ij}'(0)\})$.

We now write the noncooperative game among aggregators in a compact form as a triple

$$\mathcal{G} = \{\mathcal{I}, (\Omega_i)_{i\in\mathcal{I}}, (J_i(x_i, s(\mathbf{x})))_{i\in\mathcal{I}}\},$$

where $\mathcal{I}$ is the set of the aggregators participating in the game,

$$\Omega_i = \{x_i \in \mathbb{R} | \underline{x}_i \leq x_i \leq \overline{x}_i\}$$

is the set of possible strategies that aggregator i can take, and $J_i(x_i, s(\mathbf{x}))$ is the objective function. For this aggregative game, we obtain the subdifferential of the objective function with respect to x_i as

$$\begin{aligned} &f_i(x_i, s) = \partial_{x_i} J_i(x_i, s(\mathbf{x})) = \\ &u_i + (\partial_{x_i} u_i(x_i) + \lambda)x_i + N\lambda s - l_0. \end{aligned} \tag{8}$$

The following property plays a crucial role for our NE seeking algorithm design.

Lemma 3. Let Assumption 1 hold. Then, for all $i \in \mathcal{I}$, $x_i \in \Omega_i$ and $s \in \mathbb{R}$, the mapping $x_i \to f_i(x_i, s)$ is $\bar{\mu}_i$-strongly monotone with $\bar{\mu}_i := 2\mu_i + \lambda$ and $\bar{\ell}_i$-Lipschitz continuous with $\bar{\ell}_i := 2\ell_i + \lambda$.

The following lemma demonstrates the existence and uniqueness of the NE.

Lemma 4. Let Assumption 1 hold and $2\mu_i + \lambda > N\lambda$. Then, the aggregative game $\mathcal{G}$ has a unique NE $\mathbf{x}^*$, which satisfy

$$0 \in F(\mathbf{x}^*, s(\mathbf{x}^*)) + N_\Omega(\mathbf{x}^*) \tag{9}$$

where, $F(\mathbf{x}, s(\mathbf{x})) := \mathrm{col}(f_i(x_i, s(\mathbf{x}))_{i\in\mathcal{I}}$, $\Omega := \prod_{i\in\mathcal{I}}\Omega_i$.

We consider the aggaregators communicate only locally with their neighbours, over a communication graph G.

Assumption 2. The communication graph G is undirected and connected.

3. ALGORITHM

3.1 Algorithm Design

In this section we present our proposed algorithm. To offset the lack of full information, each aggregator i maintains a local estimate σ_i of the aggregate $s(\mathbf{x})$ and an additional auxiliary variable ψ_i to reach consensus of the local estimate, and exchanges them with its neighbours over G. The goal is that over time each aggregator will have the same aggregate estimate, equal to the average of the aggregators' actions, and its decision will correspond to NE. The proposed distributed algorithm is given below.

Algorithm 1 Distributed algorithm 1

Initialization: for all $i \in \mathcal{I}$, set $x_i(0) \in \Omega_i$, $\sigma_i(0) \in \mathbb{R}$, $\psi_i(0) \in \mathbb{R}$

Iterate until convergence: For all $i \in \mathcal{I}$, aggregator i exchanges $\sigma_i(k)$, $\psi_i(k)$ with its neighbours $\mathcal{N}_i$.

Local variable update:

$$\begin{aligned} x_i(k+1) &= \mathrm{Proj}_{\Omega_i}(x_i(k) - \tau_i\kappa_i f_i(x_i(k), \sigma_i(k))) \\ \psi_i(k+1) &= \psi_i(k) + v_i(\sum_{j\in\mathcal{N}_i}(\sigma_i(k) - \sigma_j(k))) \\ \sigma_i(k+1) &= \sigma_i(k) + \rho_i(-\sigma_i(k) + x_i(k) \\ &\quad - \sum_{j\in\mathcal{N}_i}(2\psi_i(k+1) - \psi_i(k))) \end{aligned}$$

where $\kappa_i > 0$ is a designed parameter, τ_i, v_i and ρ_i are positive step sizes.

To write the algorithm more compactly, let $\boldsymbol{\psi} = \mathrm{col}(\psi_i)_{i\in\mathcal{I}}$, $\boldsymbol{\sigma} = \mathrm{col}(\sigma_i)_{i\in\mathcal{I}}$, $K = \mathrm{diag}(\kappa_i)_{i\in\mathcal{I}}$, $\boldsymbol{\tau} = \mathrm{diag}(\tau_i)_{i\in\mathcal{I}}$, $\mathbf{v} = \mathrm{diag}(v_i)_{i\in\mathcal{I}}$, $\boldsymbol{\rho} = \mathrm{diag}(\rho_i)_{i\in\mathcal{I}}$, $F(\mathbf{x}, \boldsymbol{\sigma}) = \mathrm{col}(f_i(x_i, \sigma_i))_{i\in\mathcal{I}}$. Consequently, we can write the dynamics in Algorithm 1 as,

$$\begin{aligned} &\mathbf{x}(k+1) = \mathrm{Proj}_\Omega(\mathbf{x}(k) - \boldsymbol{\tau}KF(\mathbf{x}(k), \boldsymbol{\sigma}(k))) \\ &\boldsymbol{\psi}(k+1) = \boldsymbol{\psi}(k) + \mathbf{v}L\boldsymbol{\psi}(k) \\ &\boldsymbol{\sigma}(k+1) = \boldsymbol{\sigma}(k) + \boldsymbol{\rho}(\mathbf{x}(k) - \boldsymbol{\sigma}(k) - L(2\boldsymbol{\psi}(k+1) - \boldsymbol{\psi}(k))) \end{aligned} \tag{10}$$

where L is the Laplacian matrix of G.

3.2 Steady-State Analysis

Before we provide a convergence analysis, we show that the steady state of the dynamics in (10) yields the NE of the game. To this end, we define

$$\Gamma([\mathbf{x}; \boldsymbol{\psi}; \boldsymbol{\sigma}]) := \begin{bmatrix} KF(\mathbf{x}, \boldsymbol{\sigma}) + N_\Omega(\mathbf{x}) \\ -L\boldsymbol{\sigma} \\ \boldsymbol{\sigma} - \mathbf{x} + L\boldsymbol{\psi} \end{bmatrix} \tag{11}$$

In what follows, we show that (10) can be written as the following preconditioned forward-backward iteration:

$$\begin{aligned} \boldsymbol{\omega}(k+1) &= (\mathrm{Id} + \Phi^{-1}\mathcal{B})^{-1} \circ (\mathrm{Id} - \Phi^{-1}\mathcal{A})(\boldsymbol{\omega}(k)) \\ &= \mathcal{V}_\Phi \circ \mathcal{U}_\Phi \end{aligned} \tag{12}$$

where $\boldsymbol{\omega} = \text{col}(\mathbf{x}, \boldsymbol{\psi}, \boldsymbol{\sigma})$, $\mathcal{U}_\Phi = (\text{Id} - \Phi^{-1}\mathcal{A})$, $\mathcal{V}_\Phi = (\text{Id} + \Phi^{-1}\mathcal{B})^{-1}$, two operators $\mathcal{A}$ and $\mathcal{B}$ are split from Γ

$$\mathcal{A} := \begin{bmatrix} KF(\mathbf{x}, \boldsymbol{\sigma}) \\ 0 \\ -\mathbf{x} + \boldsymbol{\sigma} \end{bmatrix}, \mathcal{B} := \begin{bmatrix} N_\Omega(\mathbf{x}) \\ -L\boldsymbol{\sigma} \\ L\boldsymbol{\psi} \end{bmatrix} \tag{13}$$

and

$$\Phi = \begin{bmatrix} \boldsymbol{\tau}^{-1} & 0 & 0 \\ 0 & \mathbf{v}^{-1} & L \\ 0 & L & \boldsymbol{\rho}^{-1} \end{bmatrix}. \tag{14}$$

The main result of this subsection is provided below.

Proposition 1. Let Assumption 1 and 2 hold. Assume that $2\mu_i + \lambda > N\lambda$, τ_i, v_i and ρ_i are all positive, and let $\boldsymbol{\beta}$ and $\mathbf{v}$ be chosen such that

$$\max\{\rho_i\}_{i\in\mathcal{I}} < (\|L\|^2\mathbf{v})^{-1}. \tag{15}$$

Then, dynamics (10) is equivalent to the forward-backward iteration (12), hence the steady state $\overline{\boldsymbol{\omega}} = \text{col}(\overline{\mathbf{x}}, \overline{\boldsymbol{\psi}}, \overline{\boldsymbol{\sigma}})$ of (10) coincides with the fix point of iteration (12) and the zero of the mapping Γ in (11). Moreover, $\overline{\mathbf{x}}$ is the NE $\mathbf{x}^*$ of game $\mathcal{G}$.

3.3 Convergence Analysis

In this subsection, we show the convergence of Algorithm 1 to NE under suitable choices of step sizes.

We state several results which we will use to claim the convergence of Algorithm 1.

Lemma 5. Let Assumption1 and 2 hold, $2\mu_i + \lambda > N\lambda$ and

$$\kappa_i \in \left(\frac{(\sqrt{\bar{\mu}_i} - \sqrt{\bar{\mu}_i - N\lambda})^2}{\bar{\ell}_i^2}, \frac{(\sqrt{\bar{\mu}_i} + \sqrt{\bar{\mu}_i - N\lambda})^2}{\bar{\ell}_i^2} \right) \tag{16}$$

for $i \in \mathcal{I}$, the mapping $\widetilde{\mathcal{A}}$ is cocoercive,

$$\widetilde{\mathcal{A}} := \begin{bmatrix} KF(\mathbf{x}, \boldsymbol{\sigma}) \\ -\mathbf{x} + \boldsymbol{\sigma} \end{bmatrix} \tag{17}$$

Using the fact that $\tilde{\mathcal{A}}$ is cocoercive, we can now show properties for the operators $\mathcal{A}$ and $\mathcal{B}$, $\mathcal{U}_\Phi$, $\mathcal{V}_\Phi$ in the Φ-induced norm.

Lemma 6. Let Assumption1 and 2 hold, $2\mu_i + \lambda > N\lambda$, κ_i satisfies (16), τ_i, v_i and ρ_i are all positive and satisfy (15). Then, $\Phi^{-1}\mathcal{A}$ is ξ-cocoercive, $\mathcal{U}_\Phi$ is $\frac{1}{2\xi}$-averaged, $\Phi^{-1}\mathcal{B}$ is maximally monotone, $\mathcal{V}_\Phi$ is $\frac{1}{2}$-averaged in the Φ-induced norm.

Next we show the operator $\mathcal{V}_\Phi \circ \mathcal{U}_\Phi$ is averaged if the step sizes are chosen small enough.

Lemma 7. The forward-backward iteration in (12), is θ-averaged, with $\theta = \frac{1}{2-1/(2\xi)} \in (0, 1)$, if

$$\tau_i < \frac{2\epsilon}{\tilde{\ell}^2}, \rho_i < \frac{2\epsilon}{\tilde{\ell}^2}, v_i < \frac{1}{\|L\|^2}\left(\frac{1}{\rho_i} - \frac{\tilde{\ell}^2}{2\epsilon}\right) \tag{18}$$

where $\tilde{\ell} = \max\{\max\{\bar{\ell}_i\}_{i\in\mathcal{I}}, N\lambda\} + 1$, $\epsilon = \min\{\epsilon_i\}_{i\in\mathcal{I}}$ and $\epsilon_i = -\frac{\sqrt{(N\lambda\kappa_i+1)^2+(\kappa_i\bar{\mu}_i-1)^2}}{2} + \frac{\kappa_i\bar{\mu}_i+1}{2}$.

Now we can show the convergence of Algorithm 1.

Theorem 1. Let Assumption1 and 2 hold, $2\mu_i+\lambda > N\lambda$, κ_i satisfies (16), $\boldsymbol{\tau}$, $\boldsymbol{\beta}$ and $\mathbf{v}$ are chosen as in Lemma 7. Then, the iteration (12) is θ-averaged, with $\theta \in (0, 1)$, thus the sequence defined by Algorithm 1 converges to the zero of the mapping Γ, $\overline{\boldsymbol{\omega}} = \text{col}(\overline{\mathbf{x}}, \overline{\boldsymbol{\psi}}, \overline{\boldsymbol{\sigma}})$.

Proof of Theorem 1(sketch): It follows by Proposition 1 that Algorithm 1 corresponds to the fix point of iteration (12) of the mapping $\mathcal{V}_\Phi \circ \mathcal{U}_\Phi$, which is θ-averaged, with $\theta \in (0, 1)$, by Lemma 7, if the step sizes satisfy (18). Then the convergence of the sequence generated by the iteration (12) to $\overline{\boldsymbol{\omega}} = \text{col}(\overline{\mathbf{x}}, \overline{\boldsymbol{\psi}}, \overline{\boldsymbol{\sigma}})$ follows by (Bauschke et al. (2011), Prop. 15.5).

Abstract: We construct a structure-preserving finite element method and time-stepping scheme for inhomogeneous, incompressible magnetohydrodynamics (MHD). The method preserves energy, cross-helicity (when the fluid density is constant), magnetic helicity, mass, total squared density, pointwise incompressibility, and the constraint $\operatorname{div} B = 0$ to machine precision, both at the spatially and temporally discrete levels.

Keywords: Structure-preserving discretization, magnetohydrodynamics, finite element method, variational formulation, conservation laws.

1. INTRODUCTION

We construct a structure-preserving finite element method for solving the inhomogeneous, incompressible magneto-hydrodynamic (MHD) equations on a bounded domain $\Omega \subset \mathbb{R}^3$. These equations seek a velocity field u, magnetic field B, pressure p, and density ρ satisfying

$$\rho(\partial_t u + u \cdot \nabla u) - (\nabla \times B) \times B = -\nabla p, \text{ in } \Omega \times (0,T), \quad (1)$$
$$\partial_t B - \nabla \times (u \times B) = 0, \text{ in } \Omega \times (0,T), \quad (2)$$
$$\partial_t \rho + \operatorname{div}(\rho u) = 0, \text{ in } \Omega \times (0,T), \quad (3)$$
$$\operatorname{div} u = \operatorname{div} B = 0, \text{ in } \Omega \times (0,T), \quad (4)$$
$$u \cdot n = B \cdot n = 0, \text{ on } \partial\Omega \times (0,T), \quad (5)$$
$$u(0) = u_0,\ B(0) = B_0,\ \rho(0) = \rho_0, \text{ in } \Omega. \quad (6)$$

The method we construct exactly preserves energy $\frac{1}{2}\int_\Omega \rho u \cdot u + B \cdot B\, dx$, cross-helicity $\int_\Omega u \cdot B\, dx$ (when $\rho \equiv 1$), magnetic helicity $\int_\Omega A \cdot B\, dx$, mass $\int_\Omega \rho\, dx$, total squared density $\int_\Omega \rho^2\, dx$, and the constraints $\operatorname{div} u = \operatorname{div} B = 0$ at the spatially and temporally discrete level. Here, A denotes the magnetic potential; that is, A is any vector field satisfying $\nabla \times A = B$ and $A \times n|_{\partial\Omega} = 0$.

Our method, developed in Gawlik and Gay-Balmaz (2022), builds upon a growing body of literature on structure preservation in incompressible MHD simulations. Much of this literature focuses on the setting of constant density. In that setting, researchers have constructed energy-stable schemes that preserve $\operatorname{div} B = 0$ Hu et al. (2017); energy-stable schemes that preserve $\operatorname{div} u = \operatorname{div} B = 0$ Hiptmair et al. (2018); schemes that preserve energy, cross-helicity, and $\operatorname{div} u = \operatorname{div} B = 0$ Liu and Wang (2001); Gawlik et al. (2011); and schemes that preserve energy, cross-helicity, $\int A\, dx$, and $\operatorname{div} u = \operatorname{div} B = 0$ in two dimensions Kraus and Maj (2017). More recently, Hu, Lee, and Xu Hu et al. (2021) constructed a finite element method for homogeneous, incompressible MHD that preserves energy, cross-helicity, magnetic helicity, and $\operatorname{div} B = 0$.

2. WEAK FORMULATION AND CONSERVED QUANTITIES

For every pair of smooth vector fields v and C satisfying $v \cdot n|_{\partial\Omega} = C \cdot n|_{\partial\Omega} = 0$ and every pair of smooth scalar fields σ and q, the solution (u, B, ρ, p) of (1-6) satisfies

$$\langle \partial_t(\rho u), v\rangle + a(\rho u, u, v) - a(B, B, v) + b(u \cdot u/2, \rho, v) = \langle \widetilde{p}, \operatorname{div} v\rangle, \quad (7)$$
$$\langle \partial_t B, C\rangle + a(C, B, u) = 0, \quad (8)$$
$$\langle \partial_t \rho, \sigma\rangle + b(\sigma, \rho, u) = 0, \quad (9)$$
$$\langle \operatorname{div} u, q\rangle = 0, \quad (10)$$

where $\widetilde{p} = p + \rho u \cdot u$ and

$$a(w, u, v) = \langle w, \nabla \times (u \times v)\rangle,$$
$$b(f, g, w) = -\langle w \cdot \nabla f, g\rangle.$$

The structure of equations (7-10) is made even more transparent if one introduces the Lagrangian $\ell(u, B, \rho) = \frac{1}{2}\langle \rho u, u\rangle - \frac{1}{2}\langle B, B\rangle$ of inhomogeneous, incompressible MHD. In terms of $\frac{\delta \ell}{\delta u} = \rho u$, $\frac{\delta \ell}{\delta B} = -B$, and $\frac{\delta \ell}{\delta \rho} = \frac{1}{2} u \cdot u$, equations (7-10) take the form

$$\Big\langle \partial_t \frac{\delta \ell}{\delta u}, v\Big\rangle + a\Big(\frac{\delta \ell}{\delta u}, u, v\Big) + a\Big(\frac{\delta \ell}{\delta B}, B, v\Big) + b\Big(\frac{\delta \ell}{\delta \rho}, \rho, v\Big) = \langle \widetilde{p}, \operatorname{div} v\rangle, \quad (11)$$
$$\langle \partial_t B, C\rangle + a(C, B, u) = 0, \quad (12)$$
$$\langle \partial_t \rho, \sigma\rangle + b(\sigma, \rho, u) = 0, \quad (13)$$
$$\langle \operatorname{div} u, q\rangle = 0. \quad (14)$$

It is this variational structure that inspired the numerical method we propose, see Gawlik and Gay-Balmaz (2021a,b, 2022).

The formulation (7-10) allows one to easily deduce its invariants of motion from basic properties of the trilinear forms a and b. Namely, a and b satisfy:

$$a(w,u,v) = -a(w,v,u), \tag{15}$$
$$a(w,u,v) = 0 \text{ if } u\cdot n|_{\partial\Omega} = v\cdot n|_{\partial\Omega} = 0, \nabla\times w = u, \tag{16}$$
$$b(f,g,w) = -b(g,f,w) \text{ if } \operatorname{div} w = 0,\ w\cdot n|_{\partial\Omega} = 0. \tag{17}$$

These properties give rise to the following conservation laws. Taking $\sigma = 1$ in (9) gives:

$$\frac{d}{dt}\int_\Omega \rho\,dx = \langle \partial_t\rho, 1\rangle = -b(1,\rho,u) = 0.$$

Taking $\sigma = \rho$ in (9) and using (17) gives:

$$\frac{d}{dt}\frac{1}{2}\int_\Omega \rho^2\,dx = \langle \partial_t\rho,\rho\rangle = -b(\rho,\rho,u) = 0.$$

Taking $v = u$ in (7) and $C = B$ in (8) gives:

$$\begin{aligned}&\frac{1}{2}\frac{d}{dt}\int_\Omega \rho u\cdot u + B\cdot B\,dx\\ &\quad= \langle\partial_t(\rho u), u\rangle - \langle\partial_t\rho, u\cdot u/2\rangle + \langle\partial_t B, B\rangle\\ &\quad= \langle\widetilde{p}, \operatorname{div} u\rangle - a(\rho u,u,u) + a(B,B,u)\\ &\qquad - b(u\cdot u/2,\rho,u) - \langle\partial_t\rho, u\cdot u/2\rangle - a(B,B,u) = 0,\end{aligned}$$

where we used $\operatorname{div} u = 0$, (15), and (9). If A satisfies $\nabla\times A = B$ and $A\times n|_{\partial\Omega} = 0$, then:

$$\begin{aligned}&\frac{d}{dt}\int_\Omega A\cdot B\,dx = \langle\partial_t A, B\rangle + \langle A,\partial_t B\rangle\\ &\quad= \langle\partial_t A, \nabla\times A\rangle + \langle A,\partial_t B\rangle = \langle\nabla\times(\partial_t A), A\rangle + \langle A,\partial_t B\rangle\\ &\quad= \langle\partial_t B, A\rangle + \langle A,\partial_t B\rangle = -2a(A,B,u) = 0,\end{aligned}$$

from (8) and (16). Finally, if $\rho\equiv 1$, then taking $v = B$ in (7) and $C = u$ in (8) gives:

$$\begin{aligned}\frac{d}{dt}\int u\cdot B\,dx &= \langle\partial_t u, B\rangle + \langle\partial_t B, u\rangle\\ &= \langle\widetilde{p}, \operatorname{div} B\rangle - a(u,u,B) + a(B,B,B)\\ &\quad - b(u\cdot u/2, 1, B) - a(u,B,u) = 0,\end{aligned}$$

where we used $\operatorname{div} B = 0$, $b(u\cdot u,1,B) = -b(1,u\cdot u,B) = 0$, and (15).

3. SPATIAL DISCRETIZATION

To construct a spatial discretization of (7-10) that preserves all the invariants discussed in Section 2, we will design discretizations of the trilinear forms a and b that satisfy analogues of (15), (16), and (17). By a careful choice of finite element spaces, the method we construct will also preserve the constraints $\operatorname{div} u = 0$ and $\operatorname{div} B = 0$ pointwise.

We make use of the following function spaces:

$$\begin{aligned}H_0^1(\Omega) &= \{f\in L^2(\Omega)\mid \nabla f\in L^2(\Omega)^3,\ f = 0 \text{ on } \partial\Omega\},\\ H_0(\operatorname{curl},\Omega) &= \{u\in L^2(\Omega)^3\mid \operatorname{curl} u\in L^2(\Omega)^3,\ u\times n = 0 \text{ on } \partial\Omega\}\\ H_0(\operatorname{div},\Omega) &= \{u\in L^2(\Omega)^3\mid \operatorname{div} u\in L^2(\Omega),\ u\cdot n = 0 \text{ on } \partial\Omega\},\\ \mathring{H}(\operatorname{div},\Omega) &= \{u\in H_0(\operatorname{div},\Omega)\mid \operatorname{div} u = 0\},\\ L^2_{\int=0}(\Omega) &= \{f\in L^2(\Omega)\mid \textstyle\int_\Omega f\,dx = 0\}.\end{aligned}$$

Let $\mathcal{T}_h$ be a triangulation of Ω, and let $\mathcal{E}_h$ denote the set of interior 2-dimensional faces in $\mathcal{T}_h$. For each integer $s\geq 0$ and each simplex $K\in\mathcal{T}_h$, we denote by $P_s(K)$ the space of polynomials of degree at most s on K. On a face $e = K_1\cap K_2\in\mathcal{E}_h$, we denote the jump and average of a piecewise smooth scalar function f by

$$[\![f]\!] = f_1 n_1 + f_2 n_2,\quad \{f\} = \frac{f_1+f_2}{2},$$

where $f_i = f|_{K_i}$, n_1 is the normal vector to e pointing from K_1 to K_2, and similarly for n_2.

Our numerical method will make use of four approximation spaces: a space $U_h^{\operatorname{div}}\subset H_0(\operatorname{div},\Omega)$ for the velocity u and magnetic field B, a space $F_h\subset L^2(\Omega)$ for the density ρ, a space $Q_h\subset L^2_{\int=0}(\Omega)$ for the pressure $\widetilde{p}$, and an auxiliary space $U_h^{\operatorname{curl}}\subset H_0(\operatorname{curl},\Omega)$. For the velocity and magnetic field, we use the Raviart-Thomas space

$$\begin{aligned}RT_s(\mathcal{T}_h) = \{&u\in H_0(\operatorname{div},\Omega)\mid\\ &u|_K\in P_s(K)^3 + xP_s(K), \forall K\in\mathcal{T}_h\},\end{aligned}$$

where $s\geq 0$ is an integer. For the pressure, we use the zero-mean subspace of the discontinuous Galerkin space

$$DG_s(\mathcal{T}_h) = \{f\in L^2(\Omega)\mid f|_K\in P_s(K),\ \forall K\in\mathcal{T}_h\}.$$

For the density, we use $DG_m(\mathcal{T}_h)$, where $m\geq 0$ is an integer (not necessarily equal to s). For the auxiliary space $U_h^{\operatorname{curl}}$, we use the space of Nedelec elements of the first kind,

$$\begin{aligned}NED_s(\mathcal{T}_h) = \{&u\in H_0(\operatorname{curl},\Omega)\mid\\ &u|_K\in P_s(K)^3 + x\times P_s(K)^3,\ \forall K\in\mathcal{T}_h\}.\end{aligned}$$

In summary,

$$U_h^{\operatorname{div}} = RT_s(\mathcal{T}_h),\qquad Q_h = DG_s(\mathcal{T}_h)\cap L^2_{\int=0}(\Omega),$$
$$U_h^{\operatorname{curl}} = NED_s(\mathcal{T}_h),\qquad F_h = DG_m(\mathcal{T}_h).$$

We define trilinear forms $a_h : L^2(\Omega)^3\times L^4(\Omega)^3\times L^4(\Omega)^3\to\mathbb{R}$ and $b_h : L^2(\Omega)\times L^2(\Omega)\times U_h^{\operatorname{div}}\to\mathbb{R}$ by

$$a_h(w,u,v) = \int_\Omega w\cdot\nabla\times\pi_h^{\operatorname{curl}}(\pi_h^{\operatorname{curl}}u\times\pi_h^{\operatorname{curl}}v)\,dx, \tag{18}$$

$$b_h(f,g,u) = -\sum_{K\in\mathcal{T}_h}\int_K (u\cdot\nabla\pi_h f)\pi_h g\,dx \tag{19}$$

$$+\sum_{e\in\mathcal{E}_h}\int_e u\cdot[\![\pi_h f]\!]\{\pi_h g\}\,ds, \tag{20}$$

where $\pi_h^{\operatorname{curl}} : L^2(\Omega)^3\to U_h^{\operatorname{curl}}$ and $\pi_h : L^2(\Omega)\to F_h$ denote the L^2-orthogonal projectors onto $U_h^{\operatorname{curl}}$ and F_h, respectively. Note that b_h (restricted to $F_h\times F_h\times U_h^{\operatorname{div}}$) is a standard discontinous Galerkin discretization of the scalar advection operator Brezzi et al. (2004).

These trilinear forms possess two important properties that mimic (15-17). The trilinear form a_h is alternating in its last two arguments:

$$a_h(w,u,v) = -a_h(w,v,u), \tag{21}$$

for all $(w,u,v)\in L^2(\Omega)^3\times L^4(\Omega)^3\times L^4(\Omega)^3$. Second, using integration by parts, one checks that b_h is alternating in its first two arguments if its last argument is divergence-free:

$$b_h(f,g,u) = -b_h(g,f,u), \tag{22}$$

for all $(f,g,u)\in L^2(\Omega)\times L^2(\Omega)\times(U_h^{\operatorname{div}}\cap\mathring{H}(\operatorname{div},\Omega))$. The additional property of a_h is shown as follows.

Lemma 3.1. The trilinear form (18) satisfies

$$a_h(w,u,v) = 0 \text{ if } \nabla\times w = u. \tag{23}$$

Proof. If $\nabla\times w = u$, then we can integrate (18) by parts and use the fact that $n\times\pi_h^{\operatorname{curl}}(\pi_h^{\operatorname{curl}}u\times\pi_h^{\operatorname{curl}}v)\big|_{\partial\Omega} = 0$ to obtain

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$$\begin{aligned} a_h(w,u,v) &= \langle w, \nabla \times \pi_h^{\mathrm{curl}}(\pi_h^{\mathrm{curl}} u \times \pi_h^{\mathrm{curl}} v)\rangle \\ &= \langle \nabla \times w, \pi_h^{\mathrm{curl}}(\pi_h^{\mathrm{curl}} u \times \pi_h^{\mathrm{curl}} v)\rangle \\ &= \langle u, \pi_h^{\mathrm{curl}}(\pi_h^{\mathrm{curl}} u \times \pi_h^{\mathrm{curl}} v)\rangle \\ &= \langle \pi_h^{\mathrm{curl}} u, \pi_h^{\mathrm{curl}} u \times \pi_h^{\mathrm{curl}} v\rangle = 0. \quad \blacksquare \end{aligned}$$

We define our semidiscrete numerical method as follows. We seek $u, B \in U_h^{\mathrm{div}}$, $\rho \in F_h$, and $p \in Q_h$ such that

$$\begin{aligned} \langle \partial_t(\rho u), v\rangle + a_h(\rho u, u, v) - a_h(B,B,v) \\ + b_h(u \cdot u/2, \rho, v) = \langle p, \operatorname{div} v\rangle, \quad (24) \\ \langle \partial_t B, C\rangle + a_h(C, B, u) = 0, \quad (25) \\ \langle \partial_t \rho, \sigma\rangle + b_h(\sigma, \rho, u) = 0, \quad (26) \\ \langle \operatorname{div} u, q\rangle = 0, \quad (27) \end{aligned}$$

for all $v \in U_h^{\mathrm{div}}, C \in U_h^{\mathrm{div}}, \sigma \in F_h, q \in Q_h$.

Proposition 3.2. (Gawlik and Gay-Balmaz (2022)). The numerical method (24-27) exactly preserves $\int_\Omega \rho\, dx$, $\int_\Omega \rho^2\, dx$, $\int_\Omega \rho u \cdot u + B \cdot B\, dx$, $\int_\Omega A \cdot B\, dx$, and (if $\rho \equiv 1$) $\int_\Omega u \cdot B\, dx$. Furthermore, $\operatorname{div} u(t) \equiv 0$ and $\operatorname{div} B(t) \equiv 0$ for every t.

Proof. We only prove the conservation of magnetic helicity, see Gawlik and Gay-Balmaz (2022) for the other ones. From (23), if A is any vector field satisfying $\nabla \times A = B$ and $A \times n|_{\partial\Omega} = 0$, then

$$\begin{aligned} \frac{d}{dt}\langle A, B\rangle &= \langle \partial_t A, B\rangle + \langle A, \partial_t B\rangle \\ &= \langle \partial_t A, \nabla \times A\rangle + \langle A, \partial_t B\rangle \\ &= \langle \nabla \times \partial_t A, A\rangle + \langle A, \partial_t B\rangle \\ &= 2\langle \partial_t B, A\rangle = 2\langle \partial_t B, \pi_h^{\mathrm{div}} A\rangle \\ &= -2a_h(\pi_h^{\mathrm{div}} A, B, u) = -2a_h(A,B,u) = 0. \quad (28) \end{aligned}$$

Above, we used (25) with $C = \pi_h^{\mathrm{div}} A$, and we used the fact that $a_h(\pi_h^{\mathrm{div}} A, B, u) = \langle \pi_h^{\mathrm{div}} A, \nabla \times \pi_h^{\mathrm{curl}}(\pi_h^{\mathrm{curl}} B \times \pi_h^{\mathrm{curl}} u)\rangle = a_h(A,B,u)$ since $\nabla \times U_h^{\mathrm{curl}} \subseteq U_h^{\mathrm{div}}$. $\blacksquare$

4. UPWINDING

To incorporate upwinding into the density advection equation (26), one can replace (26) by

$$\langle \partial_t \rho, \sigma\rangle + \widetilde{b}_h(u; \sigma, \rho, u) = 0, \forall \sigma \in F_h, \quad (29)$$

where we introduced the u-dependent trilinear form

$$\begin{aligned} &\widetilde{b}_h(u; f, g, v) \\ &= b_h(f,g,v) + \sum_{e \in \mathcal{E}_h} \int_e \beta_e(u) \left(\frac{v \cdot n}{u \cdot n}\right) [\![\pi_h f]\!] \cdot [\![\pi_h g]\!]\, ds. \quad (30) \end{aligned}$$

Here $\{\beta_e\}_{e \in \mathcal{E}_h}$ are nonnegative parameters which may depend on u. A standard choice for β_e is

$$\beta_e(u) = c|u \cdot n|,$$

Brezzi et al. (2004), where $c \in [0, \frac{1}{2}]$, although we have found that the smooth approximation

$$\beta_e(u) = \frac{2c}{\pi}(u \cdot n) \arctan\left(\frac{u \cdot n}{\varepsilon}\right) \quad (31)$$

with $\varepsilon > 0$ small (e.g. $\varepsilon = 0.01$) tends to give better numerical performance in our experiments. Full upwinding corresponds to the choice $c = \frac{1}{2}$ Brezzi et al. (2004). When $c > 0$, this modification of the density advection equation interferes with conservation of $\int_\Omega \rho^2\, dx$ and $\int_\Omega \rho u \cdot u + B \cdot B\, dx$, but not $\int_\Omega \rho\, dx$ since $\sum_{e \in \mathcal{E}_h} \int_e \beta_e(u) [\![1]\!] \cdot [\![\rho]\!]\, ds = 0$. However, there is a simple way to restore energy conservation. As suggested in Gawlik and Gay-Balmaz (2020), one replaces the momentum equation (24) by

$$\langle \partial_t(\rho u), v\rangle + \langle \alpha, v\rangle + \widetilde{b}_h(u; \theta, \rho, v) = \langle p, \operatorname{div} v\rangle, \quad (32)$$

for all $v \in U_h^{\mathrm{div}}$.

Proposition 4.1. (Gawlik and Gay-Balmaz (2022)). With the exception of $\int_\Omega \rho^2\, dx$, all of the invariants listed in Proposition 3.2 are preserved by (24-27) if one replaces (24) and (26) by (29) and (32), respectively.

5. TEMPORAL DISCRETIZATION

We now describe a temporal discretization of (the upwinded version of) (24-27) that exactly preserves all of the original invariants of (the upwinded version of) (24-27).

We use a time step $\Delta t > 0$, and we write u_k to denote the value of the discrete solution u at time $t_k = k\Delta t$. We denote $u_{k+1/2} = (u_k + u_{k+1})/2$, with similar notation for p, B, ρ, and

$$(\rho u)_{k+1/2} = \frac{\rho_k u_k + \rho_{k+1} u_{k+1}}{2}.$$

We consider the time discretization

$$\begin{aligned} \langle D_{\Delta t}(\rho u), v\rangle + a_h(\rho u, u, v) - a_h(B,B,v) \\ + \widetilde{b}_h(u; u_k \cdot u_{k+1}/2, \rho, v) - \langle p_{k+1}, \operatorname{div} v\rangle = 0, \quad (33) \\ \langle D_{\Delta t} B, C\rangle + a_h(C, B, u) = 0, \quad (34) \\ \langle D_{\Delta t}\rho, \sigma\rangle + \widetilde{b}_h(u; \sigma, \rho, u) = 0, \quad (35) \\ \langle \operatorname{div} u_{k+1}, q\rangle = 0, \quad (36) \end{aligned}$$

for all $v \in U_h^{\mathrm{div}}$, $C \in U_h^{\mathrm{div}}$, $\sigma \in F_h$, $q \in Q_h$, where we abbreviate $u_{k+1/2}$, $B_{k+1/2}$, $\rho_{k+1/2}$, and $(\rho u)_{k+1/2}$ as u, B, ρ, and ρu, respectively, and use the notation $D_{\Delta t}(\rho u) = \frac{\rho_{k+1} u_{k+1} - \rho_k u_k}{\Delta t}$, $D_{\Delta t} B = \frac{B_{k+1} - B_k}{\Delta t}$, etc.

Proposition 5.1. (Gawlik and Gay-Balmaz (2022)). If B_0 satisfies $\operatorname{div} B_0 \equiv 0$, then the solution of (33-36) satisfies

$$\begin{aligned} \int_\Omega \rho_{k+1}\, dx &= \int_\Omega \rho_k\, dx, \quad (37) \\ \int_\Omega \rho_{k+1}^2\, dx &\le \int_\Omega \rho_k^2\, dx, \ (= \text{if } \beta_e = 0, \forall e \in \mathcal{E}_h), \quad (38) \\ \int_\Omega \rho_{k+1} u_{k+1} \cdot u_{k+1} + B_{k+1} \cdot B_{k+1}\, dx & \quad (39) \\ = \int_\Omega \rho_k u_k \cdot u_k + B_k \cdot B_k\, dx, & \quad (40) \\ \int_\Omega u_{k+1} \cdot B_{k+1}\, dx &= \int_\Omega u_k \cdot B_k\, dx, \ \text{if } \rho_0 \equiv 1, \quad (41) \\ \int_\Omega A_{k+1} \cdot B_{k+1}\, dx &= \int_\Omega A_k \cdot B_k\, dx, \quad (42) \end{aligned}$$

as well as $\operatorname{div} u_k \equiv 0$ and $\operatorname{div} B_k \equiv 0$, for every k. Here, A_k denotes any vector field satisfying $\nabla \times A_k = B_k$ and $A_k \times n|_{\partial\Omega} = 0$.

6. NUMERICAL EXAMPLE

We simulated a magnetohydrodynamic rotor on $\Omega = [0,1] \times [0,1]$ with initial conditions

$$\begin{aligned} u(x,y,0) &= g(r)\,(5 - 10y, 10x - 5)\,, \quad (43) \\ B(x,y,0) &= \left(\frac{5}{4\sqrt{\pi}}, 0\right), \quad (44) \\ \rho(x,y,0) &= 1 + 9g(r), \quad (45) \end{aligned}$$

where $r = \sqrt{(x-0.5)^2 + (y-0.5)^2}$ and

$$g(r) = \begin{cases} 1, & \text{if } r \leq 0.1, \\ (23 - 200r)/3, & \text{if } 0.1 < r < 0.115, \\ 0, & \text{if } r \geq 0.115. \end{cases}$$

This setup, which leads to the development of torsional Alfven waves, was considered in (Hiptmair and Pagliantini, 2018, Section 4.3.4) to test a numerical scheme for compressible MHD; here we test our scheme for inhomogeneous, incompressible MHD.

We imposed periodic boundary conditions in the x-direction and $u \cdot n = B \cdot n = 0$ along $y = 0$ and $y = 1$. We used (33-36) with a time step $\Delta t = 0.005$, polynomial degree $s = 0$, and a uniform triangulation of Ω with maximum element diameter $h = 2^{-6}\sqrt{2}$. We used upwinding for both the density and momentum.

Plots of the computed solution at time $t = 0.5$ are shown in Figure 1. Torsional Alfven waves are seen propagating away from the center of the domain in the horizontal direction. One can compare Figure 1 loosely with Figure 4.12 in Hiptmair and Pagliantini (2018), bearing in mind that the fluid considered there is compressible, and the solutions computed there are plotted at different times.

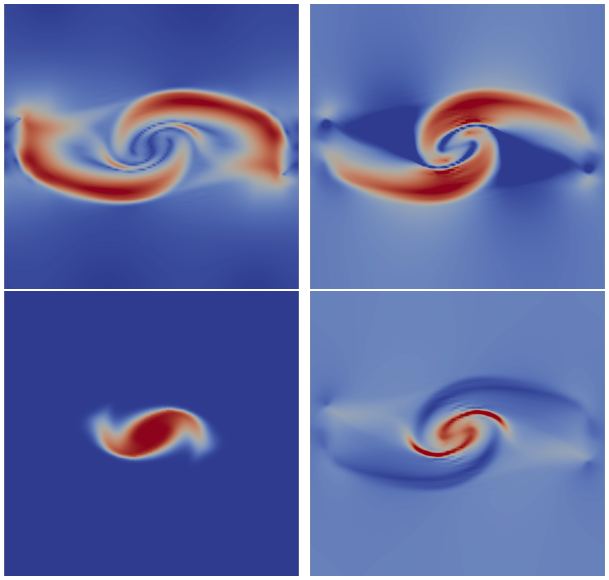

Fig. 1. Contours of $|u|$ (top left), $|B|$ (top right), ρ (down left), and p (down right) at time $t = 0.5$ in the magnetohydrodynamic rotor simulation.

Keywords: deep neural network, curse of dimensionality, compositional function, control lyapunov function, nonlinear control system

1. INTRODUCTION

Control Lyapunov functions are a commonly used tool for studying stability and for constructing stabilizing feedback laws in systems and control theory. Since in most cases there is no analytic method to compute control Lyapunov functions, we are interested in the numerical computation of such functions. However, common numerical methods often suffer from the curse of dimensionality, i.e., an exponential growth of the computational effort in the state dimension. These approaches are thus limited to low-dimensional systems.

It is known that functions with certain beneficial structures can be approximated by deep neural networks without suffering from the curse of dimensionality. In this talk, we discuss the use of deep neural networks for an efficient approximation of control Lyapunov functions. To this end, we extend the approach for computing Lyapunov functions via deep neural networks that has been presented in Grüne (2021).

Our study is inspired by results concerning the approximation of solutions of partial differential equations and optimal value functions, see, e.g., Han et al. (2018); Darbon et al. (2020). These references rely on ideas from reinforcement learning. Alternatively, in Kang et al. (2021) a supervised learning based method is discussed, where an external algorithm provides values of a Lyapunov function that are then used for the training process. We note that while in our numerical examples we also use ideas from reinforcement learning, the complexity analysis presented in this talk is independent of the concrete learning method.

There exist several algorithmically orientated papers that use neural networks for the computation of control Lyapunov functions, see, e.g., Long and Bayoumi (1993); Khansari-Zadeh and Billard (2014); Richards et al. (2018). Moreover, the authors in Gaby et al. (2021) propose a training algorithm for a neural network that is based on a preliminary chosen Lyapunov function candidate. However, these papers do not provide an analytical investigation concerning the curse of dimensionality.

2. PROBLEM FORMULATION

We consider a nonlinear control system of the form

$$\dot{x}(t) = f(x(t), u(t)), \tag{1}$$

where $u \in L_\infty(\mathbb{R}, U)$ with $U \subset \mathbb{R}^m$ and $f\colon \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ is continuous and Lipschitz continuous in x. We assume that the system (1) has an equilibrium at the origin, i.e., $f(0,0) = 0$.

Definition 1. Let $0 \in D \subset \mathbb{R}^n$ be open. A $\mathcal{C}^1$-function $V : D \to \mathbb{R}$ is called (smooth) control Lyapunov function if there exist $\alpha_1, \alpha_2, \alpha_3 \in \mathcal{K}_\infty$ [1] such that

$$\alpha_1(\|x\|) \le V(x) \le \alpha_2(\|x\|), \tag{2}$$

$$\inf_{u \in U} DV(x) f(x,u) \le -\alpha_3(\|x\|) < 0 \tag{3}$$

for all $x \in D \setminus \{0\}$.

In the following, we assume that such a smooth control Lyapunov function exists for the system (1). Note that this is a sufficient condition for asymptotic null-controllability of (1) (cf. Sontag (1983)) and is in fact equivalent to the existence of a (possibly discontinuous) stabilizing feedback that is robust with respect to perturbations in the state (cf. Ledyaev and Sontag (1999)).

It is our goal to construct a neural network architecture that computes a control Lyapunov function avoiding the curse of dimensionality.

3. DEEP NEURAL NETWORKS

We want to briefly recall the concept of deep neural networks and compare the well-known universal approximation theorem to an approximation result for compositional functions.

Neural networks take an input vector and process it through a certain number of layers in order to produce an output. For our purpose of representing a control Lyapunov function, we use the input vector $x \in \mathbb{R}^n$ and a one-dimensional output $W(x;\theta) \in \mathbb{R}$. This means that the input layer possesses $N_0 = n$ neurons and the output layer consists of only one neuron. The numbers N_l of neurons in the remaining layers (called hidden layers) may vary.

[1] We define $\mathcal{K}_\infty$ as the space of all continuous and strictly increasing functions $\alpha\colon [0,\infty) \to [0,\infty)$ with $\alpha(0) = 0$ and $\lim_{\tau\to\infty} \alpha(\tau) = \infty$.

The vector $\theta \in \mathbb{R}^p$ represents parameters that determine the output of the neural network and have to be learned during the training process. Denote with $y_k^l \in \mathbb{R}$ the value of the neuron at position k in layer l. It is determined by the values of the neurons at the previous layer via

$$y_k^l = \sigma^l \left(\sum_{i=1}^{N_{l-1}} w_{k,i}^l \, y_i^{l-1} + b_k^l \right),$$

where $\sigma^l \colon \mathbb{R} \to \mathbb{R}$ is the so-called activation function of the l-th layer and $w_{k,i}^l$, $b_k^l \in \mathbb{R}$ are parameters that are comprised in θ. The activation function of the output layer is usually chosen to be an affine function. Figure 1 shows a neural network with one hidden layer, where the activation of the neuron y_1^1 is highlighted. Note that in our setting we have $y_i^0 = x_i$ for $i = 1, \dots, n$ and $y_1^2 = W(x; \theta)$.

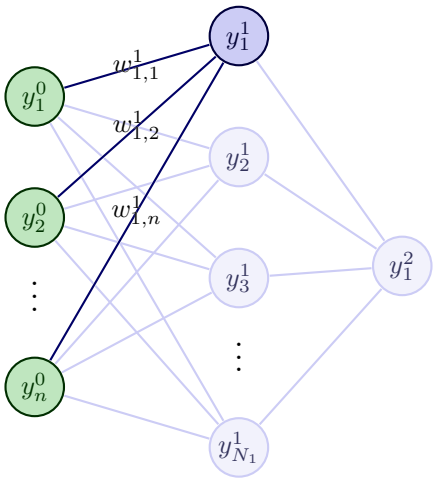

Fig. 1. Neural network with one hidden layer

Based on Mhaskar (1996), the following universal approximation theorem for single-layer neural networks has been proven in Poggio et al. (2017).

Theorem 2. Let $C > 0$ and $K_n \subset [-C, C]^n \subset \mathbb{R}^n$ be compact. Define

$$W_r^n := \left\{ g \in \mathcal{C}^r(K_n, \mathbb{R}) \,\middle|\, \sum_{1 \le |\alpha| \le r} \|D_\alpha g\|_{\infty, K} \le 1 \right\},$$

where for a continuous $g \colon K_n \to \mathbb{R}$ we set

$$\|g\|_{\infty, K} := \max_{x \in K_n} |g(x)|.$$

Moreover, let $\sigma^1 \colon \mathbb{R} \to \mathbb{R}$ be a $\mathcal{C}^\infty$-function that is not a polynomial. Then for any $\epsilon > 0$ there exists a number $N_\epsilon \in \mathbb{N}$ such that a neural network with one hidden layer that has at least N_ϵ neurons satisfies for all $g \in W_r^n$

$$\inf_\theta \|W(x; \theta) - g(x)\|_{\infty, K_n} \le \epsilon.$$

For the number of neurons it holds that

$$N_\epsilon = \mathcal{O}(\epsilon^{-\frac{n}{r}})$$

and this is best possible.

Theorem 2 states that neural networks with one hidden layer are capable of approximating $\mathcal{C}^1$-functions on compact sets. However, the required size of neurons still grows exponentially in the state dimension. For the class of compositional functions, the curse of dimensionality can be avoided.

Definition 3. A function $g \colon \mathbb{R}^n \to \mathbb{R}$ is called compositional of degree $K \in \mathbb{N}$ and level $L \in \mathbb{N}$, if there are functions $h_{lj} \colon \mathbb{R}^K \to \mathbb{R}$, $1 \le l \le L, 1 \le j \le n$, such that

$$g(x) = \sum_{j=1}^n \beta_j z_j^L,$$

where

$$z_j^l = h_{lj}(\alpha_{lj1} z_{i_{lj1}}^{l-1}, \dots, \alpha_{ljK} z_{i_{ljK}}^{l-1}),$$

for $l = 1, \dots, L$, $z_i^0 = x_i$, $i_{ljk} \in \{1, \dots, n\}$ and α_{ljk}, $\beta_j \in \mathbb{R}$.

Let us once again consider the setting of Theorem 2 and define $\Omega_{K,L}^n$ as the set of compositional functions with degree K and level L such that $h_{lj} \in W_r^n$, $1 \le l \le L$, $1 \le j \le n$. Then we can construct a neural network with L hidden layers, where each activation function is a $\mathcal{C}^\infty$-function and not a polynomial, that is able to represent functions in $\Omega_{K,L}^n$ efficiently. More precisely, under certain regularity assumptions on the functions approximated in the single layers, it can be shown that for all $g \in \Omega_{K,L}^n$ it holds that

$$\inf_\theta \|W(x; \theta) - g(x)\|_{\infty, K_n} \le \epsilon,$$

with a number N_ϵ of neurons that satisfies

$$N_\epsilon = \mathcal{O}(n^{1 + \frac{K}{r}} \epsilon^{-\frac{K}{r}}). \tag{4}$$

In total, we observe that for compositional functions with fixed degree K and level L, the required number of neurons grows only polynomially in the state dimension n, whence the curse of dimensionality is avoided.

Thus, in this talk, we discuss conditions regarding the system (1) such that this result can be applied for approximating a control Lyapunov function. To this end, we focus on ensuring compositionality of control Lyapunov functions. Furthermore, we present a corresponding network architecture that enables us to overcome the curse of dimensionality for control Lyapunov functions.

4. COMPUTING LYAPUNOV FUNCTIONS USING DEEP NEURAL NETWORKS

Let us first consider the particular case, where f in (1) does not depend on u, i.e., we have an ordinary differential equation and want to compute a Lyapunov function. For this case, we briefly present the approach from Grüne (2021) that is extended in this talk. There a small-gain condition (see, e.g., Dashkovskiy et al. (2010)) has been used to establish the existence of a Lyapunov function of the form

$$V(x) = \sum_{i=1}^s \hat{V}_i(z_i), \tag{5}$$

where $\hat{V}_i \colon \mathbb{R}^{d_i} \to \mathbb{R}$ and $z_i \in \mathbb{R}^{d_i}$ such that $x = (z_1, \dots, z_s)$. Note that V is a compositional function of level 1 and degree $K = \max_{1 \le i \le s} d_i$.

Let $K \in \mathbb{N}$ and $c > 0$ be fixed and define $\mathcal{F}_K$ as the set of Lipschitz functions $f \colon \mathbb{R}^n \to \mathbb{R}^n$, $n \in \mathbb{N}$, such that the ordinary differential equation $\dot{x}(t) = f(x(t))$ possesses a Lyapunov function of the form (5) with $\max_{1 \le i \le s} d_i \le K$. We can then construct a neural network that approximates

for every $f \in \mathcal{F}_K$ such a Lyapunov function and has a complexity of

$$N_\epsilon = \mathcal{O}(n^{1+K}\epsilon^{-K}),$$

see (4). However, for the construction of the neural network, the separation of the state space into subsystems $x = (z_1, \dots, z_s)$ would have to be known beforehand. It is shown in Grüne (2021) that this can be circumvented by appending an additional layer to the neural network that represents a linear transformation of the original system into the desired form.

For the approximation of a Lyapunov function, our network has to satisfy the conditions (2) and (3) adapted to the uncontrolled case, i.e.,

$$\begin{aligned}&\alpha_1(\|x\|) \le W(x;\theta) \le \alpha_2(\|x\|),\\ &\inf_{u\in U} DW(x;\theta)f(x) \le -\alpha_3(\|x\|) < 0.\end{aligned}$$

To this end, we formulate a cost function L that depends on the output $W(x,\theta)$ as well as on its derivative in direction of the vector field $DW(x,\theta)f(x)$:

$$\begin{aligned}&L(x, W(x;\theta), DW(x;\theta)f(x))\\ &:= ([W(x;\theta) - \alpha_1(\|x\|)]_-)^2 + ([W(x;\theta) - \alpha_2(\|x\|)]_+)^2\\ &\quad +\mu\left([DW(x;\theta)f(x) + \alpha_3(\|x\|)]_+\right)^2,\end{aligned}$$

where $[\cdot]_+ := \max(\cdot, 0)$, $[\cdot]_- := \min(\cdot, 0)$ and $\mu > 0$ is a weighting factor. Using this cost function, the corresponding neural network can be trained towards a Lyapunov function via reinforcement learning.

5. COMPUTING CONTROL LYAPUNOV FUNCTIONS

In order to extend the approach discussed in Section 4 to the controlled case, we investigate structural properties for (1) that yield the existence of a compositional control Lyapunov function. On the other hand, we also construct a suitable network architecture and cost function. In particular, we deal with the appearance of the infimum in our cost function through equation (3).

For establishing compositionality of control Lyapunov functions, we discuss the use of methods from nonlinear control theory. These methods serve the purpose of decoupling problems by decomposing them into smaller subproblems. In our context, such a decomposition into subproblems can be used to obtain a compositional form of the respective control Lyapunov function.

Consider a system of the form

$$\dot{z} = f(z, \xi), \tag{6}$$

$$\dot{\xi} = g(z, \xi) + u \tag{7}$$

and assume that V_0 is a control Lyapunov function for (6) with input ξ and that γ is a stabilizing $\mathcal{C}^2$-feedback for the same system. Then the backstepping procedure (cf. Section 6.1 in Sepulchre et al. (1997)) yields that

$$V(z, \xi) := V_0(z) + \frac{1}{2}\|\xi - \gamma(z)\|^2$$

is a control Lyapunov function for the whole system (6) - (7). In this talk, we discuss how an iterative application of backstepping for a lower triangular system yields a compositional control Lyapunov function. Furthermore, we construct a neural network that approximates this function. Similar to Section 4, we cannot only handle systems that are already given in the desired lower triangular structure, but allow for all systems that have this form after a suitable linear transformation that is learned by the deep neural network.

Next to the network architecture, we also have to formulate a suitable cost function for our purpose of reinforcement learning. To this end, we distinguish two cases. Firstly, we consider the case where the expression

$$\inf_{u\in U} DW(x;\theta)f(x,u) \tag{8}$$

can be evaluated directly. This enables us to implement condition (3) into the cost function analogously to Section 4. For example, if the system (1) is of the form

$$\dot{x}(t) = f(x(t), u(t)) = h(x(t)) + g(x(t))u(t)$$

with $U = [-c, c]^m$ for some $c > 0$, we have

$$\begin{aligned}\inf_{u\in U} DW(x;\theta)f(x,u) =& DW(x;\theta)h(x)\\ &-c\|DW(x;\theta)g(x)\|_1.\end{aligned}$$

Secondly, for the cases where such an explicit calculation of the expression (8) is not possible, we discuss methods for learning an approximation of the respective control values alongside the control Lyapunov function. This also leads to the question, under which conditions a compositional control Lyapunov function implies the existence of a compositional stabilizing feedback.

Further, in this talk we demonstrate how these and similar approaches perform in practice.

Abstract: This paper is concerned with the development of a general scheme for box particle filtering, in which the likelihood computation is shown to be the most crucial step for the estimation strategy. An overview on Box Particle Filters and discussions about from assumptions used in the literature to the filters performance evaluation approach are in the scope of the paper. From this, we aim to produce a filter taking advantages from strong aspects of various existing box particle filters. A class of nonlinear L^2 functions is concerned. Also, a comparative study via an illustration example to highlight the efficiency of the proposed method is investigated.

Keywords: State filtering and Estimation, Nonlinear System, Box Particle Filter, Interval Analysis; 93E10, 93E11.

1. INTRODUCTION

In State Estimation or Filtering problems, when dealing with a linear Gaussian state-space model, analytical expressions computing the state estimates according to posterior distributions can be derived by the well known and widespread Standard Kalman Filter (SKF) (Kalman, 1960). Many extension of SKF are then provided by numerous researches in different contexts (Mohamed and Nahavandi, 2012, Combastel, 2015, Chen et al., 1997, Lu et al., 2019). For nonlinear model without Gaussian measurement assumption, Particle Filters (PF) have been applied successfully to a variety of state estimation problems (Gordon et al., 1993, Doucet et al., 2001). The PF efficiency and accuracy depend mostly on the number of particles used in the estimation which may require a large computation time.

One of the famous extensions of PF to set membership approach is the Box Particle Filter (BPF) (Abdallah et al., 2008). BPF handles box (interval vector of) states and bounded errors by using interval computation and constraint satisfaction techniques. This method has been shown to control quite efficiently the number of required particles, hence reducing the computational cost and providing good results in several experiments.

Since then, numerous variants of BPF are developed (Nassreddine et al., 2010, Blesa et al., 2015, Tran et al., 2018) to deal with measurements bounded uncertainty, measurements stochastic uncertainty or measurements mixed uncertainty. Various techniques and theories have been proposed to address the diversity of requirements in these contexts, e.g. weight updating using Bayesian filtering technique extending to box particle case (Blesa et al., 2015) or belief function theory with different methods (Nassreddine et al., 2010, Tran et al., 2018).

In the present work, regarding this large variety of BPF, a scheme is proposed to give a generalized description that highlights the specificity of this class of filters. An analysis of the likelihood computation methodology is investigated. Furthermore, the system under consideration is nonlinear and concerned a concrete class of functions which is the L^2 space. Throughout these developments, we aim to produce a novel filter benefiting the advantages of existing methods with a number of reinforcement techniques.

2. PROBLEM FORMULATION

2.1 Notations and definitions

A real interval matrix $[X]$ of dimension $p \times q$ is a matrix with real interval components $[x_{ij}]$, $i \in \{1, ..., p\}$, $j \in \{1, ..., q\}$. Write $X \in [X]$ to indicate a point matrix $X = (x_{ij})$ belonging element-wise to $[X]$. Define:

$$\overline{X} \equiv \sup([X]) \triangleq (\sup([x_{ij}])),$$
$$\underline{X} \equiv \inf([X]) \triangleq (\inf([x_{ij}])),$$

as element-wise operators applying to $[X]$ and then $\text{mid}([X]) \triangleq (\overline{X} + \underline{X})/2$, $\text{rad}([X]) \triangleq (\overline{X} - \underline{X})/2$, $\text{width}([X]) \triangleq \overline{X} - \underline{X}$. Define also the (convex) hull of two interval matrices $[X_1]$, $[X_2]$ of the same dimension as $\text{hull}\{[X_1], [X_2]\} \triangleq [\min\{\underline{X}_1, \underline{X}_2\}, \max\{\overline{X}_1, \overline{X}_2\}]$.

Basic interval operators $\diamond \in \{+, -, \times, \div\}$ defined in Jaulin et al. (2001) can be used to compute directly all operations $[u] \diamond [v]$ and $\alpha \diamond [u]$, for real intervals $[u]$, $[v]$ and $\alpha \in \mathbb{R}$, without any further approximation algorithm. Then, interval matrix computations are defined similarly to matrix computations using the basic operators while more general operators are constructed by meant of inclusion function $[f]$ (Jaulin et al., 2001). In practice, the package Intlab developed for Matlab is used for computations.

2.2 Assumptions and discussions

Consider the following dynamical system:

$$(\Sigma): \quad \begin{cases} x_k = f(x_{k-1}, u_k, w_k) \\ y_k = h(x_k, u_k, v_k) \end{cases}, \quad k \in \mathbb{N}^*, \tag{1}$$

where $x_k \in \mathbb{R}^{n_x}$ and $y_k \in \mathbb{R}^{n_y}$ are respectively state and output measurement, $u_k \in \mathbb{R}^{n_u}$ input, $w_k \in \mathbb{R}^{n_w}$ state dynamic disturbance and $v_k \in \mathbb{R}^{n_y}$ measurement noise.

***Assumption (A)*: State Process Uncertainty**
u_k and w_k are unknown and belong to known intervals $[u_k]$ and $[w_k]$ respectively.

***Assumption (B)*: Measurement Bounded Uncertainty**
(B1) v_k (unknown) belongs to known interval $[v_k]$.
(B2) The measurements are intervals $[y_k]$.
(B3) The measurements are assumed to be accurate in the sense that $[y_k] \ni h(x_k, u_k) \equiv h(x_k, u_k, 0)$ (the zero noise case), where x_k is the real state .

***Assumption (C)*: Measurement Stochastic Uncertainty**
(C1) v_k are additive noises with known density p_v.
(C2) The measurements are point values y_k.

***Assumption (D)*: Measurement Mixed Uncertainty**
(D1) v_k are additive Gaussian noises with unknown mean $\mu_k \in \mathbb{R}^{n_y}$ and covariance $\Sigma_k \in \mathbb{R}^{n_y \times n_y}$.
(D2) μ_k, Σ_k belong to known intervals $[\mu_k]$, $[\Sigma_k]$.
(D3) The measurements are point values y_k.

Assumption (A) is used in Abdallah et al. (2008), Nassreddine et al. (2010), Blesa et al. (2015), Tran et al. (2018).

Assumptions (B) are under study in Abdallah et al. (2008), Nassreddine et al. (2010). In Abdallah et al. (2008), the BPF is introduced and becomes standard for many extensions or variants with essential steps: *initialization, box propagation, contraction, likelihood (weight) computation, state estimation and resampling*. In Nassreddine et al. (2010), the Belief State Estimation algorithm is developed using the belief function theory. It may require some techniques for the construction and computation of masses, but after being normalized, these masses become likelihoods in the probability sense. Therefore, we also call likelihood computation as an essential step of this method.

Assumptions (C) are used in Blesa et al. (2015). The method proposed therein includes a different approach to weight the box particles as well as a resampling procedure based on repartitioning the box enclosing the propagated states. There is no contraction step in this method.

Assumptions (D) are used in Tran et al. (2018), in which (D1) is a special case of (C1) with a slight relaxation by adding bounded uncertainties to Gaussian parameters μ_k and Σ_k. In Tran et al. (2018), the belief function theory is used with continuous mass functions to represent these kinds of uncertainties and to compute box particle likelihoods. The proposed approach therein leads to the so-called Evidential Box Particle Filter (EBPF) including all essential steps of the standard BPF.

Remark 1. (B3) is the implicit assumption deriving the consistency between the predicted measurement boxes $[h]([x_k^i], [u_k])$, $i \in \{1, ..., M\}$ (M the number of partitioned boxes), and the real measurement box $[y_k]$. This consistency is used in the contraction step and the likelihood computation by penalizing all particle boxes with which the intersections $[h]([x_k^i], [u_k]) \cap [y_k]$ are empty.

Remark 2. Assumptions (D3) and (C2) are coincided. They can be transformed into (B2) with a slight relaxation of (B3). That is, knowing the density of v_k, we deduce its confidence intervals $[v_k]$ with some significant level α and define $[y_k] \triangleq y_k - [v_k]$. Then (B3) is relaxed in the sense that the observed measurements $[y_k]$ do not contain $h(x_k, u_k)$ with certainty but with only a high probability $(1 - \alpha)$.

3. GENERAL SCHEME OF BOX PARTICLE FILTER

3.1 Scheme

Although applying different background theories, the proposed methods in Abdallah et al. (2008), Nassreddine et al. (2010), Blesa et al. (2015), Tran et al. (2018) study State Estimation in a framework of stochastic uncertainties and/or bounded uncertainties with two main objectives:

Objective 1: Reduce as much as possible the width of box particles to penalize the conservatism due to interval computations (the wrapping effect).

Objective 2: Quantify (compute) box particle likelihoods as well as possible to enhance the accuracy of the estimates.

The methods used in these references can be considered as variants of BPF and be summarized by Scheme 1 which is applied in a mostly similar manner across them.

Remark 3. In this Scheme, for a general presentation, the observed measurements are denoted as intervals since the point values are considered as special cases of intervals. N_{k_0} in the initialization step takes value in $\{1, ..., M\}$ and is the number of box particles obtained at the end of the likelihood computation step at the previous time instant $(k_0 - 1)$. For $k_0 = 0$, the initialization concerns only the partition of $[x_0]$ and not the resampling. The Condition C in the while loop is different from method to method.

Remark 4. BPFs often use a non large (small) number of particles to gain computation time and reduce the loss of a guaranteed estimation. Consequently, the resampling or repartition step happens almost always, at every or only after a few iterations. Therefore, the fact that we hold previous weights and update them afterward has no significant effect while this effect might not be quantified easily. Furthermore, conditions under which the resampling or repartition is implemented base usually on some heuristic choice of a threshold. This is also an issue of discussion.

3.2 Performance evaluation of BPFs sharing Scheme 1

In order to evaluate how the computed likelihoods bring efficiency to the estimation, it must compare the result of a BPF with that of the basic scenarios of Scheme 1:

- **Scenario 1**: Using the contraction step without partition (1 box particle);
- **Scenario 2**: Using equi-likelihood $1/M$ and without contraction step (M box particles);
- **Scenario 3**: Using equi-likelihood $1/M$ and with contraction step (M box particles).

The reason is that, in some applications, using solely the contraction step, the algorithm performance has been rather good and the efficiency brought by the computed

Scheme 1 General Scheme of Box Particle Filtering

STEP 1. Initialization. At a time step $k_0 \geq 0$, (re)partition the interval $[x_{k_0}]$ or resample the set $\{[x^j_{k_0}], w_j\}_{j=1:N_{k_0}}$ into M disjoints equal-volume sub-boxes with the same weights: $\{[x^i_{k_0}], w_i = 1/M\}_{i=1:M}$.

while $\{[x^i_{k_0}], w_i\}_{i=1,...,M}$ still satisfies a predetermined Condition C **do**

STEP 2. Propagation. Get a new set of box particles $\{[x^i_{k_0+1}] = [f]([x^i_{k_0}], [u_{k_0}])\}_{i=1,...,M}$ estimating the box containing the real state $x_{k_0+1} = f(x_{k_0}, u_{k_0})$ with or without a contraction step.

STEP 3. Likelihood computation

a) Compute (and normalize) the likelihoods of box particles $\{[x^i_{k_0+1}]\}_{i=1,...,M}$ being the box containing the real state x_{k_0+1}. This computation bases on the consistency between the estimated measurement $[h]([x^i_{k_0+1}], [u_{k_0}])$'s and the obtained measurement $[y_{k_0+1}]$ using different criteria and methods.

By this step, the following set of box particles with updated weights is obtained : $\{[x^i_{k_0+1}], w_i\}_{i=1,...,M}$.

b) Some techniques can be applied at this step to get a more "efficient" set of box particles, e.g. discarding the boxes with small weights (smaller than some predetermined threshold) and with or without replicating the box associated with the greatest weight,... From this, the set of box particles becomes $\{[x^i_{k_0+1}], w_i\}_{i=1,...,N_{k_0+1}}$, $1 \leq N_{k_0+1} \leq M$.

STEP 4 : Estimation

Interval estimate:

$$[x_{k_0+1}] = \sum_{i=1}^{M} w_i.[x^i_{k_0+1}] \tag{2}$$

Point estimate:

$$x_{k_0+1} = \sum_{i=1}^{M} w_i.\text{mid}([x^i_{k_0+1}]) \tag{3}$$

STEP 5 : $k_0 = k_0 + 1$

end while

STEP 6 : Restarting at STEP 1.

likelihoods might be insignificant. The same manner might happen for the other scenarios.

Following indexes, proposed in Tran et al. (2018), will be used for performance evaluations:

$$\overline{RMSE}_j = \sup \sqrt{\sum_{k=1}^{N} (x_{k,j} - [\hat{x}_{k,j}])^2 / N},$$

$$E_j = \sum_{k=1}^{N} \text{width}([\hat{x}_{k,j}])/N,$$

$$O_j = \left(\sum_{k=1}^{N} \mathbf{1}(x_{k,j} \in [\hat{x}_{k,j}])/N \right) \times 100,$$

where $j \in \{1, ..., n_x\}$, $\overline{RMSE}$ is the root mean squared error upper bound, $\mathbf{1}(x)$ equal 1 (element-wise) if the condition x holds true (element-wise) and vanishes otherwise.

3.3 Likelihood computation methodology

In the next, the diagram in Fig.1 is used to discuss the methodology of Likelihood Computation Methods (LCM) using in Scheme 1.

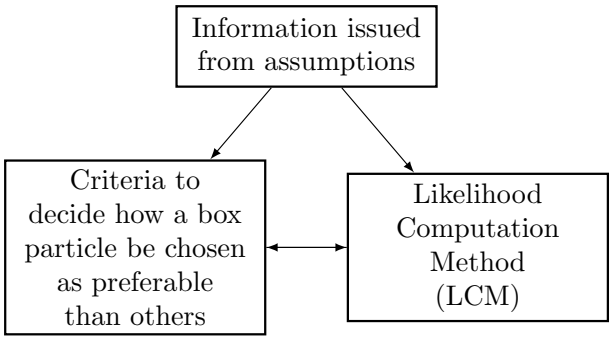

Fig. 1. Likelihood computation methodology diagram

First of all, that is the assumptions of the system under consideration supply the information needed to build the likelihood. For instance, the information may be:

- **Information (a)**: The intersection between $[y_k]$ and the box $[h]([x^i_k], [u_k])$ containing the real value y_k must be non empty,
- **Information (b)**: The distribution of v_k and hence of $r_k = y_k - h(x_k, u_k)$ is Gaussian (for additive measurement noise),
- (or more other piece of information)...

The information can be directly an assumption or a deduction of the later. In bounded-error context, only **Information (a)** is treated (Abdallah et al., 2008) while in the mixed uncertainty case, both **Information (a)** and **Information (b)** are taken into account (Tran et al., 2018).

Criteria and methods are then chosen to exploit the information. On the one hand, once a criterion is chosen, different methods can be used to calculate the likelihood. On the other hand, a calculation method may correspond to one or many criteria. There are also calculation methods that exploit better the supplied information than others.

4. CONCLUSION

Thanks to the initialized investigations aforementioned, we go to the essential of this class of BPF methods which helps to produce an enhancing method. Furthermore, the additional assumption that f and h of (1) belonging to L^2 space enlarges the problem with many theoretical and applied aspects to be solved.

Abstract: We state necessary and sufficient conditions for one finite length input-output trajectory to determine uniquely (modulo state-space isomorphisms) a minimal linear, deterministic input-state-output system, given an upper bound on the state dimension.

Keywords: Time-series modelling, time-invariant systems, nonparametric methods

1. INTRODUCTION

Given a *minimal* linear input-state-output (i-s-o) system

$$\begin{aligned} x(t+1) &= A_{\text{true}}x(t) + B_{\text{true}}u(t) \\ y(t) &= C_{\text{true}}x(t) + D_{\text{true}}u(t)\ , \end{aligned} \tag{1}$$

where $A_{\text{true}} \in \mathbb{R}^{n_{\text{true}}\times n_{\text{true}}}$, $B_{\text{true}} \in \mathbb{R}^{n_{\text{true}}\times m}$, $C_{\text{true}} \in \mathbb{R}^{p\times n_{\text{true}}}$ and $D_{\text{true}} \in \mathbb{R}^{p\times m}$ and $T \geqslant 0$, denote by

$$\begin{aligned} u_{[0,T]} &:= [u(0)\ \dots\ u(T)] \in \mathbb{R}^{m\times(T+1)} \\ y_{[0,T]} &:= [y(0)\ \dots\ y(T)] \in \mathbb{R}^{p\times(T+1)}\ , \end{aligned} \tag{2}$$

a finite input-output (i-o) trajectory generated by (1). The *deterministic system identifiability* problem is usually stated as follows:

> *Determine (necessary and) sufficient conditions on $u_{[0,T]}$ and $y_{[0,T]}$ such that (1) can be uniquely identified, up to a nonsingular transformation of the state variable.*

Standard references on deterministic system identifiability with non-impulsive inputs are Grewal and Glover (1976), Sontag (1980), Kalman (1983), Gevers and Wertz (1984), Willems et al. (2005). More recent publications dealing with finite length data are Heij (1993), Markovsky et al. (2005), Markovsky and Dörfler (2020). The relation of some of these results with ours is deferred to remarks interspersed in the text.

We study identifiability *relative to a model class*. A priori knowledge on (1), or properties required of a model compatible with the data, are integrated in the problem formulation by specifying the *model class* $\mathcal{S}_{pk}$ that the identified systems belong to. $\mathcal{S}_{pk}$ consists e.g. of systems with a given upper bound on the state-space dimension; of controllable systems; of minimal ones; and so on. We use a *data informativity* (see van Waarde et al. (2020)) perspective: an i-o trajectory is informative about a property (e.g. stability, controllability) if it is shared by *all* systems compatible with the data. The problem of *informativity for system identification* is:

> *Given $\mathcal{S}_{pk}$ establish necessary and sufficient conditions on $u_{[0,T]}$ and $y_{[0,T]}$ such that a model in $\mathcal{S}_{pk}$ compatible with the data can be uniquely identified, up to a nonsingular transformation of the state variable.*

The deterministic system identifiability problem is a special case of this one. Due to space limitations, we only state *necessary and sufficient* conditions for identifiability when $\mathcal{S}_{pk}$ consists of *minimal i-s-o systems with a given upper bound on the state dimension*, and we omit the proofs of the necessary results. A complete illustration of our results will be given elsewhere.

Notation and terminology

Intervals. Given $i, j \in \mathbb{N}\cup\{0\}$, $i \leqslant j$, we denote by $[i, j]$ the set $[i, j] := \{k \in \mathbb{N}\cup\{0\} \mid i \leqslant k \leqslant j\}$.

Matrices and vectors. The set of $n \times m$ matrices with real entries is denoted by $\mathbb{R}^{n\times m}$. If one of the dimensions of $M \in \mathbb{R}^{n\times m}$ is zero, then we take $\mathbb{R}^{n\times m}$ to denote the empty set, and M to denote a void matrix, i.e. a matrix with zero rows and zero columns.

Hankel matrices. Given $T \in \mathbb{N}\cup\{0\}$, a set of m-dimensional vectors $\{f_t\}_{t=0,\dots,T}$, and $0 \leqslant i \leqslant T$, we denote by

$$f_{[i,T]} := [f_i\ \dots\ f_T] \in \mathbb{R}^{m\times(T-i+1)},$$

the *matrix associated with* $\{f_t\}_{t=0,\dots,T}$.

Given $f_{[i,j]} = [f_i\ \cdots\ f_j] \in \mathbb{R}^{m\times(j-i+1)}$ and k with $j - k \in [i, j]$, the *Hankel matrix of $f_{[i,j]}$ with depth $k+1$* is the $(k + 1)m \times (j - k - i + 1)$ matrix defined by:

$$H_k(f_{[i,j]}) = \begin{bmatrix} f_i & \cdots & f_{j-k} \\ \vdots & & \vdots \\ f_{i+k} & \cdots & f_j \end{bmatrix}\ . \tag{3}$$

The "depth" is the number of block-rows of (3).

Dynamical systems. Given an i-s-o discrete-time system

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$$x(t+1) = Ax(t) + Bu(t)$$
$$y(t) = Cx(t) + Du(t)\ , \tag{4}$$

where $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$, $C \in \mathbb{R}^{p\times n}$, $D \in \mathbb{R}^{p\times m}$, and $k \in \mathbb{N}$, we define the *k-th observability matrix* by

$$\Omega_k := \begin{bmatrix} C^\top & (CA)^\top & \dots & \left(CA^k\right)^\top \end{bmatrix}^\top \ .$$

We denote by $\ell(C, A)$ the smallest integer $k \in \mathbb{N}$ such that $\operatorname{rank}\Omega_k = \operatorname{rank}\Omega_{k-1}$. Note that $\ell(C, A) \leqslant n$; if (C, A) is observable, then $\ell(C, A)$ is the observability index of (4).

2. PROBLEM FORMULATION

The set of all systems (4) is denoted by

$$\mathcal{S} := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathbb{R}^{(n+p)\times(n+m)} \mid n \geqslant 0 \right\} \ . \tag{5}$$

$\mathcal{S}$ includes memoryless systems ($n = 0$), in which case A, B and C are void.

Definition 1. (Explanatory system). A system $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{S}$ with $A \in \mathbb{R}^{n\times n}$ *explains the data* $(u_{[0,T]}, y_{[0,T]})$ if there exists $x_{[0,T]} \in \mathbb{R}^{n\times(T+1)}$ such that

$$x_{[1,T]} = Ax_{[0,T-1]} + Bu_{[0,T-1]}$$
$$y_{[0,T]} = Cx_{[0,T]} + Du_{[0,T]}\ . \tag{6}$$

The set of all systems explaining $u_{[0,T]}$ and $y_{[0,T]}$ is denoted by $\mathcal{E}$ and called (the class of) *explanatory systems*:

$$\mathcal{E} := \{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{S} \mid \text{ there exists } n \geqslant 0 \text{ and } x_{[0,T]} \in \mathbb{R}^{n\times(T+1)} \text{ such that (6) holds} \} \ . \tag{7}$$

We are also interested in subclasses of explanatory systems such as those with a given state space dimension and those with a given lag, respectively defined by

$$\mathcal{E}(n) := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{E} \mid A \in \mathbb{R}^{n\times n} \right\},$$
$$\mathcal{E}(\ell, n) := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{E}(n) \mid \ell = \ell(C, A) \right\}.$$

The system (1) belongs to $\mathcal{E}$, $\mathcal{E}(n_{\text{true}})$, and $\mathcal{E}(\ell_{\text{true}}, n_{\text{true}})$.

It is straightforward to check that $\mathcal{E}(n)$ and $\mathcal{E}(\ell, n)$ are invariant under nonsingular state space transformations.

Definition 2. (Isomorphism property). $\begin{bmatrix} A_i & B_i \\ C_i & D_i \end{bmatrix} \in \mathcal{E}(n)$, $i = 1, 2$ with $n \geqslant 1$ are called *isomorphic* if $D_1 = D_2$ and there exists a nonsingular matrix $S \in \mathbb{R}^{n\times n}$ such that $A_1 = S^{-1}A_2S$, $B_1 = S^{-1}B_2$, $C_1 = C_2S$.

If $n \geqslant 1$, $\mathcal{E}(n)$ has the *isomorphism property* if *all* systems in it are isomorphic to each other. If $n = 0$, we say that $\mathcal{E}(0)$ has the *isomorphism property* if it is a singleton.

To formalize prior knowledge or assumptions about the 'true' system (1), a subset $\mathcal{S}_{\text{pk}} \subseteq \mathcal{S}$ is defined. For example, bounds on the state dimension or on the observability index are formalized defining $\mathcal{S}_{\text{pk}}$ by

$$\mathcal{S}_N := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{S} \mid A \in \mathbb{R}^{n\times n} \text{ with } n \leqslant N \right\}$$
$$\mathcal{S}_{L,N} := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{S}_N \mid \ell(C, A) \leqslant L \right\} \ . \tag{8}$$

and the class of minimal models defining $\mathcal{S}_{\text{pk}}$ by

$$\mathcal{M} := \left\{ \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \in \mathcal{S} \mid \left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right] \text{ is minimal} \right\} \ . \tag{9}$$

The following definition formalizes the property of a finite i-o sequence that we seek to characterize in this paper.

Definition 3. (Informativity for identification). Define $\mathcal{S}$ by (5), and let $\mathcal{S}_{\text{pk}} \subseteq \mathcal{S}$. The data $(u_{[0,T]}, y_{[0,T]})$

- *uniquely determine the state dimension within* $\mathcal{S}_{\text{pk}}$ if $\mathcal{E} \cap \mathcal{S}_{\text{pk}} \subseteq \mathcal{E}(n_{\text{true}})$.
- are *informative for system identification within* $\mathcal{S}_{\text{pk}}$ if they uniquely determine the state dimension in $\mathcal{S}_{\text{pk}}$, and if $\mathcal{E} \cap \mathcal{S}_{\text{pk}}$ has the isomorphism property.

The following are two standing assumptions.

Assumption A.

$$N \in \mathbb{N} \text{ is given, such that } n_{\text{true}} \leqslant N \leqslant T \ . \tag{A}$$

Assumption B.

$$u_{[0,T]} \text{ has full row rank } . \tag{B}$$

Remark 1. It is straightforward to check that condition (B) is *necessary* for data informativity for system identification, and consequently it is not restrictive. Note also that if (B) holds, then $T \geqslant m - 1$; this provides a lower bound on the number of data points to allow system identification. We give a tighter lower bound on T further in this communication; see Theorem 2 in sect. 3.

3. MAIN RESULT

Our necessary and sufficient conditions for informativity for system identification are formulated in terms of the rank of a Hankel matrix built from the data, and of some structural integers that we now introduce.

For $k \in [0, T]$, we denote by $H_k \in \mathbb{R}^{(k+1)(m+p)\times(T-k+1)}$ the *block-Hankel matrix of depth* $k + 1$ constructed from the data $(u_{[0,T]}, y_{[0,T]})$:

$$H_k := \begin{bmatrix} H_k(u_{[0,T]}) \\ H_k(y_{[0,T]}) \end{bmatrix} = \begin{bmatrix} u_0 & \cdots & u_{T-k} \\ \vdots & & \vdots \\ u_k & \cdots & u_T \\ y_0 & \cdots & y_{T-k} \\ \vdots & & \vdots \\ y_k & \cdots & y_T \end{bmatrix} \ , \tag{10}$$

and by $G_k \in \mathbb{R}^{((k+1)m+kp)\times(T-k+1)}$ the matrix

$$G_k := \begin{bmatrix} u_0 & \cdots & u_{T-k} \\ \vdots & & \vdots \\ u_k & \cdots & u_T \\ y_0 & \cdots & y_{T-k} \\ \vdots & & \vdots \\ y_{k-1} & \cdots & y_{T-1} \end{bmatrix} \ . \tag{11}$$

From H_k and G_k we define

$$\rho_k := \begin{cases} p & \text{if } k = -1 \\ \operatorname{rank} H_k - \operatorname{rank} G_k & \text{if } k \in [0, T] \ . \end{cases} \tag{12}$$

Note that $0 \leqslant \rho_k \leqslant p$ for all k. The Hankel structure of H_k and G_k implies that $\rho_k = 0$ if and only if every annihilator of the i-o sequence with lag $\leqslant k$ is the linear combination of annihilators with lag $\leqslant k-1$ and their shifts. Equivalently, $\rho_k > 0$ if and only if there exists an annihilator of the i-o sequence with lag $\leqslant k$ that is not "implied" by lower lag annihilators and their shifts.

The following result can be proved exploiting the Hankel structure of the matrices H_k and G_k.

Lemma 1. Define s_k by

$$s_k := \rho_{k-1} - \rho_k \quad \text{for} \quad k \in [0, T] \; ; \tag{13}$$

then $s_k \geqslant 0$ for all $k \in [0, T]$. Moreover, $\sum_{i=0}^{T} s_i = p$.

Remark 2. The s_i's are related to the integers ζ_t introduced on p. 569 in Willems (1986) in the context of system identification from infinite length data, associated with the *shortest lag description* of a behavior (p. 569 *ibid.*). Moreover, the maximal lag in the shortest lag description equals the integer $\ell(A, C)$ defined in section 1 (see statement *(vii)* Theorem 6 p. 570 *ibid.*).

We denote by q the smallest integer such that $\sum_{i=0}^{q} s_i = p$:

$$q := \min \left\{ k \in [0, T] \mid \sum_{i=0}^{k} s_i = p \right\} \; . \tag{14}$$

Remark 3. Lemma 1 implies that q is well defined, and can be computed directly from the data, by computing ρ_k from (12), and s_k from (13).

We define *the minimum number of states* $n_{\min}$ and *the shortest lag* $\ell_{\min}$ by:

$$\begin{aligned} n_{\min} &:= \min\{n \geqslant 0 \mid \mathcal{E}(n) \neq \varnothing\} \\ \ell_{\min} &:= \min\{\ell \geqslant 0 \mid \exists\, n \geqslant 0 \text{ such that } \mathcal{E}(\ell, n) \neq \varnothing\} \; . \end{aligned} \tag{15}$$

The following result shows that these two integers can be computed in terms of the integers s_k and q, and consequently, in view of Lemma 1, *directly from the data*, via linear algebraic computations involving the matrices H_k and G_k defined in (10) and (11).

Theorem 1. Define $n_{\min}$ and $\ell_{\min}$ by (15), and q by (14). Then

$$\ell_{\min} = q \;\; \text{and} \;\; n_{\min} = \sum_{i=0}^{\ell_{\min}} i s_i \; .$$

Moreover,

$$\mathcal{E}(n_{\min}) = \mathcal{E}(\ell_{\text{true}}, n_{\min}) = \mathcal{E}(n_{\min}) \cap \mathcal{O} \; .$$

Remark 4. The proof of Theorem 1 is based on a series of intermediate results, some of independent interest. Most prominent among these is an iterative procedure to construct a state sequence with $n_{\min}$ components from a given finite length i-o trajectory. The procedure uses the left-annihilators of the Hankel matrices (10) of the data; it is a modification of the *shift-and-cut procedure* introduced in Rapisarda and Willems (1997). An explanatory model (4) can be straightforwardly computed from the finite length state-trajectory obtained in this way.

This algorithm offers an alternative to subspace identification procedures in the case of finite measurements, *without assumptions on the length of the data set*. On subspace identification for finite length data, see Markovsky et al. (2005), where such procedures are formulated under the assumption that the number of available measurements is at least twice the maximum lag of the system.

Remark 5. It follows from the relation between the s_k's and the shortest lag description of a behavior (see Remark 2) that the equality $n_{\min} = \sum_{i=0}^{\ell_{\min}} i s_i$ in the second claim of Theorem 1 is analogous to statement (v) of Theorem 6 of Willems (1986).

The main result of this paper is the following characterization of informativity for system identification within the class of minimal systems with an upper bound on the state dimension.

Theorem 2. Assume conditions (A) and (B). Define $n_{\min}$ and $\ell_{\min}$ by (15), $\mathcal{S}_N$ by (8), $\mathcal{M}$ by (9). Moreover, define

$$d := N - n_{\min} + \ell_{\min} \; .$$

The data $(u_{[0,T]}, y_{[0,T]})$ are informative for system identification within $\mathcal{S}_N \cap \mathcal{M}$ if and only if the following two conditions hold:

$$\begin{aligned} T + 1 &\geqslant (d+1)m + d + n_{\min} \\ \operatorname{rank} H_d &= (d+1)m + n_{\min} \; . \end{aligned} \tag{16}$$

Remark 6. The constraints (16) represent *truly data-based* necessary and sufficient conditions for system identifiability: to verify them, one only needs to know $\ell_{\min}$ and $n_{\min}$. It follows from Theorem 1 and Remark 3 that both integers are computable directly from the data.

Remark 7. The first constraint in (16) improves on the trivial lower bound $T \geqslant m - 1$ formulated in Remark 1. It implies that identifiability is possible only if a *minimal number of measurements* is available.

Remark 8. (The SISO case). When $m = p = 1$, it can be shown that $\ell_{\min} = n_{\min}$ and consequently $d = N$. The conditions (16) in this case are

$$T \geqslant 2N + n_{\min} \;\; \text{and} \;\; \operatorname{rank} H_N = N + 1 + n_{\min} \; . \tag{17}$$

The relation between T and N appearing in the first condition in (17) has an intuitive interpretation. For example, a larger uncertainty about the complexity of the generating system translates to larger values of N, and implies that more measurements should be available to uniquely identify the dynamics.

In another situation, if prior knowledge about the generating system suggests a high complexity, then a larger N should be chosen; in this case, the complex dynamics require a larger number of measurements to be uniquely identified.

Remark 9. In Sontag (1980) a bound is derived on the minimum number of measurements necessary to identify a linear, discrete-time system from i-o data. However, the underlying assumption in that work is that the system starts from the *zero initial state*, while our bound holds also for the case in which the initial conditions are nonzero. Moreover, the input is assumed to be *generic*, while our result is valid also for the case of *structured* inputs. See also Example 1 below.

Remark 10. The second condition in (16) concerns the *quality* of the data: identifiability requires that the combination of initial conditions and of the input sequence is "sufficiently rich", as reflected in the rank of the Hankel matrix.

The relation between the rank of the data Hankel matrix and the dimension of the state space is known since Kalman's work on realization from impulse response data (see Kalman et al. (1969)). Such relation, together with some "persistency of excitation" conditions on the input

sequence, lies at the foundation of several results and procedures to compute explanatory models (see for example Theorem 2 in Moonen et al. (1989), or Cor. 1 in Willems et al. (2005)). The second condition in (16) is in the same spirit, but with the fundamental difference that *persistency of excitation is not assumed*. The result of Theorem 2 can consequently be applied also to the case of structured inputs.

Example 1. (State construction with structured inputs). For zero initial conditions, $T = 5$ and $u(t) = \frac{1}{2^t}$, $t \in [0, 5]$, the SISO system ($m = p = 1$) described by

$$y(t) + 3y(t-1) + 2y(t-2) = -u(t-1) + u(t-2) \ ,$$

generates the output $y_{[0,5]} = \begin{bmatrix} 0 & -1 & \frac{7}{2} & -\frac{33}{4} & \frac{143}{8} & -\frac{593}{16} \end{bmatrix}$.

It is straightforward to verify that $\operatorname{rank} H_k = k + 2$, $\operatorname{rank} G_k = k+1$, $k = 0, 1$, $\operatorname{rank} H_k = \operatorname{rank} G_k$, $k \in [2, 5]$. It follows that $s_i = 0$ for $i \in \{0, 1, 3, 4, 5\}$, and that $s_2 = 1$. It follows from the definition (14) of q and from Theorem 1 that $q = \ell_{\min} = 2$ and $n_{\min} = 2$.

When $T = 5$, it follows from Remark 8 that the two conditions of Theorem 2 reduce to $5 \geqslant 2N + 3$ and $\operatorname{rank} H_N = N + 3$.

We now show that the data is not informative for *any* bound N on the state space dimension of an explanatory system. The inequality can only be satisfied for $N \leqslant 1$. If $N = 0$, then the second condition cannot be satisfied, since $H_0 \in \mathbb{R}^{2\times 5}$ has rank 2. If $N = 1$, the second condition is satisfied if and only if $\operatorname{rank} H_1 = 4$; however

$$\operatorname{rank} H_1 = \operatorname{rank} \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{4} & \frac{1}{8} & \frac{1}{16} \\ \frac{1}{2} & \frac{1}{4} & \frac{1}{8} & \frac{1}{16} & \frac{1}{32} \\ 0 & -1 & \frac{7}{2} & -\frac{33}{4} & \frac{143}{8} \\ -1 & \frac{7}{2} & -\frac{33}{4} & \frac{143}{8} & -\frac{593}{16} \end{bmatrix} = 3 \ .$$

The data is not informative for system identification.

The vector $[1 \ -1 \ 0 \ -2 \ -3 \ -1]$ is a left annihilator of H_2. Using the "shift-and-cut" procedure mentioned in Remark 4, the following state trajectory is computed:

$$x_{[0,5]} = \begin{bmatrix} 0 & 1 & \frac{5}{2} & -\frac{27}{4} & \frac{133}{8} & -\frac{571}{16} \\ 0 & -1 & \frac{7}{2} & -\frac{33}{4} & \frac{143}{8} & -\frac{593}{16} \end{bmatrix} \ ,$$

corresponding to the matrices A, B, C and D defined by

$$A := \begin{bmatrix} 0 & -2 \\ 1 & -3 \end{bmatrix} \ , \ B := \begin{bmatrix} 1 \\ -1 \end{bmatrix} \ , \ C := [0 \ 1] \ , \ D := 0 \ .$$

These matrices define an i-s-o explanatory model for the given i-o trajectories. It is straightforward to verify that the system described by

$$\widetilde{A} := \begin{bmatrix} 0 & -2 \\ 1 & -3 \end{bmatrix} \ , \ \widetilde{B} := \begin{bmatrix} 3 \\ \frac{2}{-2} \end{bmatrix} \ , \ \widetilde{C} := C \ , \ \widetilde{D} := D \ ,$$

is also a minimal explanatory system, with the state sequence

$$\widetilde{x}_{[0,5]} := \begin{bmatrix} 1 & \frac{3}{2} & \frac{11}{4} & -\frac{53}{8} & \frac{267}{16} & -\frac{1141}{32} \\ 0 & -1 & \frac{7}{2} & -\frac{33}{4} & \frac{143}{8} & -\frac{593}{16} \end{bmatrix} \ .$$

This system is not isomorphic to $\left[\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right]$: the sequences $\widetilde{x}_{[0,5]}$ and $x_{[0,5]}$ cannot be transformed into each other by a nonsingular transformation. Note also that

$$\widetilde{C} \left(zI - \widetilde{A} \right)^{-1} \widetilde{B} + \widetilde{D} = \frac{-4z + 3}{2\left(z^2 + 3z + 2\right)} \ .$$

4. CONCLUSIONS

We introduced the concept of informativity within a model class, and we gave a characterization of such property for the case of minimal models with a given upper bound on the McMillan degree.

Abstract: In this extended abstract we consider input-output systems described by higher order difference equations, also called autoregressive systems. We assume that we have input-output data obtained from an underlying true, but unknown, system. The problems we then consider is to determine on the basis of these data whether this unknown system is stable. We also deal with the problem of determining whether a stabilizing controller exists, and, if so, to determine one using only the data. In order to tackle these problems we heavily rely on methods from the behavioral approach to systems and control, in particular the notion of quadratic difference form.

Keywords: Data-driven control, behavioral approach, input-output data, S-lemma.

1. INTRODUCTION

A research topic that has received a lot of attention in the past few years is data-driven analysis and control. A central problem in this area is to verify certain system properties and to design control laws for an unknown dynamical system using noisy data obtained from that system. The main challenge is to do the analysis and design without the intermediate step of modeling the system using system identification, but work directly with the data instead. This has been the subject of many recent publications in the area, mainly in the context of input-output systems in state space form, see , for example, van Waarde et al. (2020); De Persis and Tesi (2020); Berberich et al. (2021); Trentelman et al. (2020).

In the present note we will leave the realm of input-output systems in state space form, and will instead work with input-output systems described by higher order difference equations, also called auto-regressive (AR) systems. We will assume that noisy input-output data have been obtained from some unknown AR system. These data are available to check stability and to verify whether a dynamic feedback controller exists that stabilizes the unknown system, and, if so, to compute such controller.

We will establish data-based tests to tackle these problems. To do this, we will heavily rely on methods from the behavioral approach to systems and control. In particular we will adopt the notion of quadratic difference form (QDF) as a framework for Lyapunov functions for autonomous systems described by higher order difference equations, see Kojima and Takaba (2005, 2006); Willems and Trentelman (1998).

We will generalize the concepts of informativity of data for quadratic stability and quadratic stabilization in the context of input-state-output systems to input-output AR systems. Our main results will be necessary and sufficient condition for informativity in terms of feasibilty of certain linear matrix inequalities (LMIs) obtained from the data. An important tool in deriving these conditions is a matrix version of Yakubovich's S-lemma, as that was recently established in van Waarde et al. (2022).

We will use the following notation. The space of all symmetric real $q \times q$ matrices is denoted by $\mathbb{S}^q$. For a given partitioned matrix

$$\Pi = \begin{bmatrix} \Pi_{11} & \Pi_{12} \\ \Pi_{21} & \Pi_{22} \end{bmatrix},$$

with $\Pi_{11} \in \mathbb{S}^q$, $\Pi_{12}^\top = \Pi_{21}$ and $\Pi_{22} \in \mathbb{S}^r$, an important role in this note will be played by the quadratic matrix inequality

$$\begin{bmatrix} I \\ Z \end{bmatrix}^\top \Pi \begin{bmatrix} I \\ Z \end{bmatrix} \geqslant 0$$

in the unknown $Z \in \mathbb{R}^{r \times q}$. The set of all solutions Z is denoted $\mathcal{Z}_r(\Pi)$. This set is nonempty and bounded if and only if $\Pi_{22} < 0$ and $\Pi_{11} - \Pi_{12}\Pi_{22}^{-1}\Pi_{21} \geqslant 0$.

2. INPUT-OUTPUT SYSTEMS IN AR-FORM AND NOISY DATA

In this note we consider input-output systems represented by auto-regressive (AR) models of the form

$$P(\sigma)\boldsymbol{y} = Q(\sigma)\boldsymbol{u}, \tag{1}$$

where σ denotes the shift operator $(\sigma \boldsymbol{f})(t) = \boldsymbol{f}(t+1)$ and $P(\xi)$ and $Q(\xi)$ are real $p \times p$ and $p \times m$ polynomial matrices of the form

$$\begin{aligned} P(\xi) &= I\xi^L + P_{L-1}\xi^{L-1} + \ldots P_1\xi + P_0, \\ Q(\xi) &= Q_{L-1}\xi^{L-1} + \ldots + Q_1\xi + Q_0. \end{aligned} \tag{2}$$

Here L is a positive integer, called the *order*. The input $\boldsymbol{u}(t)$ and output $\boldsymbol{y}(t)$ are assumed to take their values in $\mathbb{R}^m$ and $\mathbb{R}^p$, respectively. The parameters of the model are real $p \times p$ matrices $P_0, P_1 \ldots, P_{L-1}$ and $p \times m$ matrices $Q_0, Q_1, \ldots Q_{L-1}$. Note that we assume that the leading coefficient matrix of $P(\xi)$ is the $p \times p$ identity matrix. This immediately implies that $P(\xi)$ is nonsingular and that $P^{-1}(\xi)Q(\xi)$ is strictly proper. Thus, indeed, (1) represents a (strictly) causal input-output system with input $\boldsymbol{u}$ and output $\boldsymbol{y}$.

In this note, we will deal with analysis and control design for systems of the form (1), where the polynomial matrices $P(\xi)$ and $Q(\xi)$ are *unknown*. We do assume that the order L and the dimensions m and p are known. We assume that we have noisy input-output data on a given finite time interval. These data are assumed to be obtained from an underlying true (but unknown) system. In case there are no inputs, i.e. $m = 0$, we want to use these data to check whether the true system is stable. In case that control inputs are present we want to check whether there exists a stabilizing feedback controller and, if so, determine such controller using only the data. In the present section we focus on the situation that $m > 0$, i.e. control inputs are present.

As stated above, we have noisy input-output data

$$u(0), u(1), \ldots, u(T-1),\ y(0), y(1), \ldots, y(T) \tag{3}$$

on a given time interval $\{0, 1, \ldots, T\}$ with $T \geqslant L$. These noisy data are obtained from the true system. Assume that this true system is represented by (unknown) polynomial matrices $P_s(\xi)$ and $Q_s(\xi)$ of the form (2). In other words, the true system is represented by $P_s(\sigma)\boldsymbol{y} = Q_s(\sigma)\boldsymbol{u}$. We assume that the data have been obtained in the presence of unknown noise. More concretely, we assume that $u(0), u(1), \ldots, u(T)$, $y(0), y(1), \ldots, y(T)$ are samples on the interval $\{0, 1, \ldots, T\}$ of $\boldsymbol{u}$ and $\boldsymbol{y}$ that satisfy

$$P_s(\sigma)\boldsymbol{y} = Q_s(\sigma)\boldsymbol{u} + \boldsymbol{v}$$

where $\boldsymbol{v}$ is an unknown noise signal. We do put the following assumption on the noise $\boldsymbol{v}$ during the sampling interval.

Assumption 1. The noise samples $v(0), v(1), \ldots, v(T-L)$, collected in the real $p \times (T-L+1)$ matrix

$$V := [v(0)\ v(1)\ \cdots\ v(T-L)]$$

satisfy the quadratic matrix inequality

$$\begin{bmatrix} I \\ V^\top \end{bmatrix}^\top \Pi \begin{bmatrix} I \\ V^\top \end{bmatrix} \geqslant 0, \tag{4}$$

where $\Pi \in \mathbb{S}^{p+T-L+1}$ is a known partitioned matrix

$$\Pi = \begin{bmatrix} \Pi_{11} & \Pi_{12} \\ \Pi_{21} & \Pi_{22} \end{bmatrix},$$

with $\Pi_{11} \in \mathbb{S}^p$, $\Pi_{12} \in \mathbb{R}^{p \times (T-L+1)}$, $\Pi_{21} = \Pi_{12}^\top$ and $\Pi_{22} \in \mathbb{S}^{T-L+1}$. In addition, $\Pi_{22} < 0$ and the Schur complement $\Pi_{11} - \Pi_{12}\Pi_{22}^{-1}\Pi_{21} \geqslant 0$. In particular this implies that the set $\mathcal{Z}_{T-L+1}(\Pi)$ of matrices $V^\top$ that satisfy (4) is nonempty and bounded.

Now denote $q := p + m$ and denote the unknown $p \times q$ polynomial matrix $[-Q(\xi)\ P(\xi)]$ by $R(\xi)$. Also denote

$$\boldsymbol{w} := \begin{bmatrix} \boldsymbol{u} \\ \boldsymbol{y} \end{bmatrix}.$$

Then (1) can be written as $R(\sigma)\boldsymbol{w} = 0$. Collect the (unknown) coefficient matrices of $R(\xi)$ in the $p \times Lq$ matrix

$$R := [-Q_0\ P_0\ -Q_1\ P_1\ \cdots\ -Q_{L-1}\ P_{L-1}] \tag{5}$$

Also arrange the data $u(0), \ldots, u(T)$, $y(0), \ldots, y(T)$ into the vectors

$$w(t) = \begin{bmatrix} u(t) \\ y(t) \end{bmatrix} \quad (t = 0, 1, \ldots, T)$$

and define an associated depth L Hankel matrix by

$$H_1(w) := \begin{bmatrix} w(0) & w(1) & \cdots & w(T-L) \\ w(1) & w(2) & \cdots & w(T-L+1) \\ \vdots & \vdots & \ddots & \vdots \\ w(L-1) & w(L) & \cdots & w(T-1) \end{bmatrix}. \tag{6}$$

Furthermore, define $H_2(w) := [y(L)\ y(L+1)\ \cdots\ y(T)]$. It is then easily verified that any input-output system (1) for which the coefficient matrix R defined by (5) satisfies

$$[R \quad I] \begin{bmatrix} H_1(w) \\ H_2(w) \end{bmatrix} = V \tag{7}$$

for some V with $V^\top \in \mathcal{Z}_{T-L+1}(\Pi)$ could have generated the noisy input-output data (3). In other words, $w(0), w(1), \ldots, w(T-1), y(T)$ are samples on the interval $\{0, 1, \ldots, T\}$ of $\boldsymbol{w}$ that satisfy

$$R(\sigma)\boldsymbol{w} = \boldsymbol{v}$$

for some $\boldsymbol{v}$ satisfying Assumption 1. Therefore, if R satisfies (7) for some V with $V^\top \in \mathcal{Z}_{T-L+1}(\Pi)$, we call the system with coefficient matrix R *compatible with the data*. Now define

$$N := \begin{bmatrix} I & H_2(w) \\ 0 & H_1(w) \end{bmatrix} \Pi \begin{bmatrix} I & H_2(w) \\ 0 & H_1(w) \end{bmatrix}^\top. \tag{8}$$

Then by combining (4) and (7) we see that the system with coefficient matrix R is compatible with the data if and only if $R^\top$ satisfies the QMI

$$\begin{bmatrix} I \\ R^\top \end{bmatrix}^\top N \begin{bmatrix} I \\ R^\top \end{bmatrix} \geqslant 0, \tag{9}$$

equivalently $R^\top \in \mathcal{Z}_{Lq}(N)$. As the true system is assumed to be compatible with the given data, the set $\mathcal{Z}_{Lq}(N)$ is nonempty.

3. AUTONOMOUS AR SYSTEMS AND DATA

As already touched upon in Section 2, a special case of AR systems of the form (1) occurs if $m = 0$, i.e. the system has no inputs. In that case (1) reduces to

$$P(\sigma)\boldsymbol{y} = 0, \tag{10}$$

which, since $P(\xi)$ is a nonsingular polynomial matrix, represents an autonomous system. In this section we will briefly discuss the notion of noisy data for this special case. In fact, in this case we have only output data

$$y(0), y(1), \ldots, y(T) \tag{11}$$

on a finite time-interval $\{0, 1, \ldots, T\}$ with $T \geqslant L$. We assume that these data come from an unknown true autonomous system. Suppose this true system is represented by the unknown polynomial matrix $P_s(\xi)$, with $P_s(\xi)$ of the form (2). Again we assume that the data samples are noisy, in the sense that they are samples of a signal $\boldsymbol{y}$ that satisfies $P_s(\sigma)\boldsymbol{y} = \boldsymbol{v}$ for some $\boldsymbol{v}$ satisfying Assumption 1.

Any system in the model class of systems of the form (10) with fixed dimension p and order L is parametrized by

its coefficient matrices $P_0, P_1, \ldots, P_{L-1}$. We collect these matrices in the $p \times Lp$ matrix

$$P := [P_0 \ P_1 \ \cdots \ P_{L-1}]. \tag{12}$$

Recalling that there are no inputs present (so $w = y$), let $H(y)$ be the Hankel matrix associated with the data as given by (6), and as before partition this matrix as

$$H(y) = \begin{bmatrix} H_1(y) \\ H_2(y) \end{bmatrix},$$

where $H_1(y)$ contains the first $(L-1)p$ rows and $H_2(y)$ the last p rows. Also define

$$N := \begin{bmatrix} I & H_2(y) \\ 0 & H_1(y) \end{bmatrix} \Pi \begin{bmatrix} I & H_2(y) \\ 0 & H_1(y) \end{bmatrix}^\top. \tag{13}$$

Then as in Section 2, the autonomous system with coefficient matrices collected in the matrix P is compatible with the data if and only if

$$\begin{bmatrix} I \\ P^\top \end{bmatrix}^\top N \begin{bmatrix} I \\ P^\top \end{bmatrix} \geqslant 0, \tag{14}$$

equivalently $P^\top \in \mathcal{Z}_{Lp}(N)$.

4. QUADRATIC DIFFERENCE FORMS AND LYAPUNOV FUNCTIONS

Here we will review the basics of quadratic difference forms. Assume that N and q are positive integers and let $\Phi \in \mathbb{S}^{(N+1)q}$ be a partitioned matrix given by

$$\Phi := \begin{bmatrix} \Phi_{0,0} & \Phi_{0,1} & \cdots & \Phi_{0,N} \\ \Phi_{1,0} & \Phi_{1,1} & \cdots & \Phi_{1,N} \\ \vdots & & \ddots & \vdots \\ \Phi_{N,0} & \Phi_{N,1} & \cdots & \Phi_{N,N} \end{bmatrix}$$

with $\Phi_{i,i} \in \mathbb{S}^q$ and $\Phi_{i,j} = \Phi_{j,i}^\top$. This real symmetric matrix defines a *quadratic difference form* (QDF), to be denoted by Q_Φ. This quadratic difference form is the operator Q_Φ that maps $\mathbb{R}^q$-valued functions $\boldsymbol{w}$ on $\mathbb{Z}_+$ to $\mathbb{R}$-valued functions $Q_\Phi(\boldsymbol{w})$ on $\mathbb{Z}_+$ defined by

$$Q_\Phi(\boldsymbol{w})(t) := \sum_{k,\ell=0}^{N} \boldsymbol{w}(t+k)^\top \Phi_{k,\ell} \, \boldsymbol{w}(t+\ell).$$

For a given QDF Q_Φ, its *rate of change* along a given $\boldsymbol{w} : \mathbb{Z}_+ \to \mathbb{R}^q$ is given by $Q_\Phi(\boldsymbol{w})(t+1) - Q_\Phi(\boldsymbol{w})(t)$. It turns out that the rate of change defines a QDF itself. Indeed, by defining the matrix $\nabla\Phi \in \mathbb{S}^{(N+2)q}$ by

$$\nabla\Phi := \begin{bmatrix} 0_q & 0 \\ 0 & \Phi \end{bmatrix} - \begin{bmatrix} \Phi & 0 \\ 0 & 0_q \end{bmatrix}, \tag{15}$$

it is easily verified that

$$Q_{\nabla\Phi}(\boldsymbol{w})(t) = Q_\Phi(\boldsymbol{w})(t+1) - Q_\Phi(\boldsymbol{w})(t)$$

for all $\boldsymbol{w} : \mathbb{Z}_+ \to \mathbb{R}^q$.

Quadratic difference forms are particularly relevant in combination with AR systems. Let $R(\xi)$ be a real $p \times q$ polynomial matrix and consider the AR system $R(\sigma)\boldsymbol{w} = 0$. Let

$$\mathcal{B}(R) := \{\boldsymbol{w} \mid R(\sigma)\boldsymbol{w} = 0\}$$

be the *behavior* of this system. The QDF Q_Φ is called nonnegative on $\mathcal{B}(R)$ if $Q_\Phi(\boldsymbol{w}) \geqslant 0$ for all $\boldsymbol{w} \in \mathcal{B}(R)$. It is called positive on $\mathcal{B}(R)$ if, in addition, $Q_\Phi(\boldsymbol{w}) = 0$ if and only if $\boldsymbol{w} = 0$. We denote this as $Q_\Phi \geqslant 0$ on $\mathcal{B}(R)$ and $Q_\Phi > 0$ on $\mathcal{B}(R)$. Likewise we define nonpositivity and negativity on $\mathcal{B}(R)$.

Stability of autonomous AR systems can be characterized in terms of QDFs. In fact, the following proposition holds.

Proposition 2. Let $P(\xi)$ be a nonsingular polynomial matrix. The corresponding autonomous system $P(\sigma)\boldsymbol{y} = 0$ is stable if and only if there exists a QDF $Q_\Psi(\boldsymbol{y})$ such that $Q_\Psi \geqslant 0$ on $\mathcal{B}(R)$ and $Q_{\nabla\Psi} < 0$ on $\mathcal{B}(R)$.

For obvious reasons, we refer to Q_Ψ as a *Lyapunov function* for the AR system $P(\sigma)\boldsymbol{y} = 0$.

5. DATA-DRIVEN STABILITY ANALYSIS OF AUTONOMOUS AR SYSTEMS

In this section we study data-based stability *analysis* for autonomous systems of the form (10). Our aim is to develop a test that determines on the basis of the output data $y(0), y(1), \ldots, y(T)$ whether our true system is stable. As we saw, the data do not determine the true system uniquely. Thus we are forced to test stability for all autonomous systems that are compatible with the data, so for all systems in $\mathcal{Z}_{Lp}(N)$, with N given by (13).

In order to proceed, we will first express the existence of a Lyapunov function Q_Ψ for the autonomous system $P(\sigma)\boldsymbol{y} = 0$ in terms of a quadratic matrix inequality. This QMI involves a symmetric matrix Ψ of dimensions $Lp \times Lp$ leading to a Lyapunov function Q_Ψ, and the matrix $P = [P_0 \ P_1 \ \cdots \ P_{L-1}]$. Indeed, we have:

Theorem 3. Let $P(\xi) = I\xi^L + P_{L-1}\xi^{L-1} + \ldots + P_1\xi + P_0$ and let $P(\sigma)\boldsymbol{y} = 0$ be the corresponding autonomous system given by (10). This system is stable if and only if there exists $\Psi \in \mathbb{S}^{Lp}$, $\Psi \geqslant 0$, such that

$$\begin{bmatrix} I \\ -P \end{bmatrix}^\top \left(\begin{bmatrix} 0_p & 0 \\ 0 & \Psi \end{bmatrix} - \begin{bmatrix} \Psi & 0 \\ 0 & 0_p \end{bmatrix} \right) \begin{bmatrix} I \\ -P \end{bmatrix} < 0. \tag{16}$$

Any such Ψ defines a Lyapunov function Q_Ψ.

Based on this, we give the following definition of informativity for quadratic stability.

Definition 4. The noisy output data $y(0), y(1), \ldots, y(T)$ are called *informative for quadratic stability* if there exists a matrix $\Psi \in \mathbb{S}^{Lp}$, $\Psi \geqslant 0$ such that the QMI (16) holds for all $P = [P_0 \ P_1 \ \cdots \ P_{L-1}]$ that satisfy the QMI (14), with N defined by (13).

Informativity for quadratic stability thus means that there exists a matrix $\Psi \in \mathbb{S}^{Lp}$ such that the QDF Q_Ψ is a Lyapunov function for all systems that are compatible with the data, i.e., all systems in $\mathcal{Z}_{Lp}(N)$ are stable with a common Lyapunov function.

Below, we will formulate a necessary and sufficient condition on the data $y(0), y(1), \ldots, y(T)$ to be informative. This condition is in the form of feasibility of a linear matrix inequality. Define a matrix Z by

$$Z := \begin{bmatrix} 0_{(L-1)p \times p} & I_{(L-1)p} \end{bmatrix}. \tag{17}$$

Then we have the following theorem:

Theorem 5. Assume that $H_1(y)$ has full row rank and that

$$\bar{N} = \begin{bmatrix} [0 \ -I_p] & 0 \\ 0 & I_{Lp} \end{bmatrix}^\top \begin{bmatrix} I & H_2(y) \\ 0 & H_1(y) \end{bmatrix} \Pi \begin{bmatrix} I & H_2(y) \\ 0 & H_1(y) \end{bmatrix}^\top \begin{bmatrix} [0 \ -I_p] & 0 \\ 0 & I_{Lp} \end{bmatrix}$$

has at least one positive eigenvalue. Then the output data $y(0), y(1), \ldots, y(T)$ are informative for quadratic stability

if and only if there exists $\Phi \in \mathbb{S}^{Lp}$, $\Phi > 0$ and a scalar $\alpha \geqslant 0$ that satisfy the LMI

$$\begin{bmatrix} \Phi - \begin{bmatrix} Z^\top & 0 \end{bmatrix}^\top \Phi \begin{bmatrix} Z^\top & 0 \end{bmatrix} & \begin{bmatrix} Z^\top & 0 \end{bmatrix}^\top \Phi \\ \Phi \begin{bmatrix} Z^\top & 0 \end{bmatrix} & -\Phi \end{bmatrix} - \alpha \bar{N} \geqslant 0. \quad (18)$$

In that case the QDF Q_Ψ with $\Psi := \Phi^{-1}$ is a Lyapunov function for all systems of the form (10) compatible with the data.

6. DATA-DRIVEN STABILIZATION OF INPUT-OUTPUT AR SYSTEMS

In this section we will discuss data-driven stabilization of input-output systems in AR-form. We will work in the setup of Section 2, with systems of the form (1), with polynomial matrices of the form (2) of given degree L.

A feedback controller for the input-output system (1) with $P(\xi)$ and $Q(\xi)$ of the form (2) will be taken to be of the form

$$G(\sigma)\boldsymbol{u} = F(\sigma)\boldsymbol{y} \quad (19)$$

with

$$G(\xi) = I\xi^L + G_{L-1}\xi^{L-1} + \ldots + G_1\xi + G_0,$$
$$F(\xi) = F_{L-1}\xi^{L-1} + \ldots + F_1\xi + F_0.$$

The leading coefficient matrix of $G(\xi)$ is assumed to be the $m \times m$ identity matrix and $G_i \in \mathbb{R}^{m\times m}$, $F_i \in \mathbb{R}^{m\times p}$ for $i = 0, 1, \ldots, L-1$. The closed loop system obtained by interconnecting the system and the controller is represented by

$$\begin{bmatrix} G(\sigma) & -F(\sigma) \\ -Q(\sigma) & P(\sigma) \end{bmatrix} \begin{bmatrix} \boldsymbol{u} \\ \boldsymbol{y} \end{bmatrix} = 0. \quad (20)$$

Note that the leading coefficient matrix of the polynomial matrix in (20) is the $q \times q$ identity matrix. Hence the controlled system is autonomous. We call the controller (19) a *stabilizing* if the controlled system (20) is stable. Now define

$$C(\xi) := \begin{bmatrix} G(\xi) & -F(\xi) \end{bmatrix}.$$

Then (20) can equivalently be written as

$$\begin{bmatrix} C(\sigma) \\ R(\sigma) \end{bmatrix} \boldsymbol{w} = 0. \quad (21)$$

Collect the coefficient matrices of $F(\xi)$ and $G(\xi)$ in the coefficient matrix C defined by

$$C := \begin{bmatrix} G_0 & -F_0 & G_1 & -F_1 & \cdots & G_{L-1} & -F_{L-1} \end{bmatrix} \quad (22)$$

and recall that the coefficient matrix of $R(\xi)$ is given by (5). Then an immediate application of Theorem 3 yields:

Lemma 6. The controlled system (21) is stable if and only if there exists $\Psi \in \mathbb{S}^{Lq}$, $\Psi \geqslant 0$, such that

$$\begin{bmatrix} I_{Lq} \\ -C \\ -R \end{bmatrix}^\top \left(\begin{bmatrix} 0_q & 0 \\ 0 & \Psi \end{bmatrix} - \begin{bmatrix} \Psi & 0 \\ 0 & 0_q \end{bmatrix} \right) \begin{bmatrix} I_{Lq} \\ -C \\ -R \end{bmatrix} < 0. \quad (23)$$

This leads to the following definition.

Definition 7. We call the input-output data $u(0), u(1), \ldots, u(T), y(0), y(1), \ldots, y(T)$ *informative for quadratic stabilization* if there exist $C \in \mathbb{R}^{m\times Lq}$ and $\Psi \in \mathbb{S}^{Lq}$, $\Psi \geqslant 0$ such that the QMI (23) holds for all R that satisfy the QMI (9), with N defined by (8).

Informativity for quadratic stabilization thus means that there exists a controller $C(\sigma)\boldsymbol{w} = 0$ (equivalently, $G(\sigma)\boldsymbol{u} = F(\sigma)\boldsymbol{y}$) and a matrix $\Psi \in \mathbb{S}^{Lq}$ such that the QDF Q_Ψ is a common Lyapunov function for all closed loop systems obtained by interconnecting the controller with an arbitrary system that is compatible with the data.

We will now state necessary and sufficient conditions for informativity for quadratic stabilization. Define the matrix Z by

$$Z := \begin{bmatrix} 0_{(L-1)q\times q} & I_{(L-1)q} \end{bmatrix}. \quad (24)$$

Let N be given by (8) and define

$$\bar{N} := \begin{bmatrix} [0 & 0 & -I_p] & 0 \\ 0 & & I_{Lq} \end{bmatrix}^\top N \begin{bmatrix} [0 & 0 & -I_p] & 0 \\ 0 & & I_{Lq} \end{bmatrix}$$

Next, consider the LMI in the unknowns D and Φ given by

$$\begin{bmatrix} \Phi & \begin{bmatrix} \Phi Z^\top & D & 0 \end{bmatrix}^\top & \begin{bmatrix} \Phi Z^\top & D & 0 \end{bmatrix}^\top \\ \begin{bmatrix} \Phi Z^\top & D & 0 \end{bmatrix} & -\Phi & 0 \\ \begin{bmatrix} \Phi Z^\top & D & 0 \end{bmatrix} & 0 & \Phi \end{bmatrix} - \alpha \begin{bmatrix} \bar{N} & 0 \\ 0 & 0_{Lq} \end{bmatrix} \geqslant 0. \quad (25)$$

Then the following theorem holds.

Theorem 8. Assume that $H_1(w)$ has full row rank and that $\bar{N}$ has at least one positive eigenvalue. Then the input-output data $u(0), u(1), \ldots, u(T), y(0), y(1), \ldots, y(T)$ are informative for quadratic stabilization if and only if there exist matrices $D \in \mathbb{R}^{Lq\times m}$, $\Phi \in \mathbb{S}^{Lq}$, $\Phi > 0$, and a scalar $\alpha \geqslant 0$ such that the LMI (25) holds. In that case, the feedback controller with coefficient matrix $C := -D^\top \Phi^{-1}$ stabilizes all systems of the form (1) that are compatible with the input-output data. Moreover, the QDF Q_Ψ with $\Psi := \Phi^{-1}$ is a common Lyapunov function for all resulting closed loop systems.

Abstract: We present a nonlinear ODE-based thermo-hydraulic model of a district heating system with multiple heat producers, consumers and storage devices. We analyze the conditions under which the hydraulic and thermal subsystems of the model exhibit shifted passivity properties. For the hydraulic subsystem, our claims on passivity draw on the monotonicity of the vector field associated with the district heating system's flow dynamics, which mainly codifies viscous friction effects on the system's pressures. For the temperature dynamics, we propose a storage function based on the *ectropy function* of a thermodynamic system, recently used in the passivity analysis of heat exchanger networks.

Keywords: Heating networks, modeling, shifted passivity.

1. INTRODUCTION

District heating (DH) has been identified as a key technology to enable the heating sector's potential to reduce greenhouse emissions due to the possibility to seamlessly include environmentally friendly energy sources and storage devices (see, *e.g.*, Lund et al. (2014)). A DH system comprises a network of pipes connecting buildings in a neighborhood, town center or whole city, so that they can be served from varied heat production units (Lund et al., 2014). To further unlock the potential of DH systems, prospective installations will feature multiple, distributed heat sources, *e.g.,* waste-to-energy facilities or solar collectors Lund et al. (2014), promoting as a consequence heat distribution networks of meshed topology, as opposed to the salient tree-like structure of conventional installations with a single heat source (Wang et al., 2017; Vesterlund et al., 2017).

On the one hand, modeling of DH systems with a single heat producer has been addressed, *e.g.,* in De Persis and Kallesoe (2011); Scholten et al. (2015); Hauschild et al. (2020), whereas the multi-producer case has been considered in Wang et al. (2017); Vesterlund et al. (2017); Trip et al. (2019); Alisic et al. (2019). In Wang et al. (2017); Vesterlund et al. (2017), (static) steady-state hydraulic and thermo-hydraulic models are respectively considered for solving operational optimization problems. Dynamic volume storage modeling and control is considered in Trip et al. (2019) for a DH system with multiple storage tanks and neglecting the thermal dynamics. A similar model further considering thermal dynamics is established in Alisic et al. (2019), but it neglects the flow dynamics of the distribution network.

On the other hand, passivity analysis within the context of heating networks has been considered in Mukherjee et al. (2012); Dong et al. (2019). In Mukherjee et al. (2012), a (linear) model to describe the temperature dynamics of a multi-zone building is presented and subsequently shown to be passive via a storage function which is quadratic in the rooms' temperatures. In Dong et al. (2019), a general model of a network of heat exchangers is shown to be *shifted* passive using a novel storage function based on the concept of ectropy (Haddad, 2019). It was mentioned in a previous paragraph that port-Hamiltonian formulations of (single producer) DH system models are presented in Hauschild et al. (2020), thus, passivity follows directly under mild assumptions (van der Schaft and Jeltsema, 2014). [1]

Based on De Persis and Kallesoe (2011); Scholten et al. (2015); Wang et al. (2017); Hauschild et al. (2020) and others (see all the details and proper referencing in Machado

[1] Ectropy is a quadratic function on the total energy of a thermodynamic system and is described in Haddad (2019) as the dual of entropy in the sense that it represents a measure of the tendency of a thermodynamic system to do useful work and grow more organized (see also Willems (2006)). On the other hand, shifted passivity is particularly relevant in these applications by allowing the stability assessment and stabilization of non-trivial equilibria (see Jayawardhana et al. (2007); Monshizadeh et al. (2019b,a)).

et al. (2022)), we present a nonlinear ODE-based model to describe the hydraulic and thermal dynamics of a DH system with multiple heat producers, storage devices and consumers. Moreover, we describe the conditions under which flow and thermal dynamics of the proposed model are shifted passive. Our claims on the passivity of the DH system's flow dynamics are based on the observations made in De Persis and Kallesoe (2011), in the single producer setting, about the monotonicity of the associated vector field. On the other hand, following Dong et al. (2019) (see also Hauschild et al. (2020)), for the thermal dynamics we propose a quadratic storage function based on the total ectropy, extending the results of Dong et al. (2019); Hauschild et al. (2020) to multi-producer systems with storage units.

Notation: The symbol $\mathbb{R}$ denotes the set of real numbers. For a vector $x \in \mathbb{R}^n$, x_i denotes its ith component, *i.e.*, $x = [x_1, \dots, x_n]^\top$; moreover, $\mathbf{sign}(x) = [\mathrm{sign}(x_1), \dots, \mathrm{sign}(x_n)]^\top$, with $\mathrm{sign}(0) = 0$, and $|x| = [|x_1|, \dots, |x_n|]^\top$. An $m \times n$ matrix with all-zero entries is written as $\mathbf{0}_{m\times n}$. An n-vector of ones is written as $\mathbf{1}_n$, whereas the identity matrix of size n is represented by I_n. For any vector $x \in \mathbb{R}^n$, we denote by $\mathrm{diag}(x)$ a diagonal matrix with elements x_i in its main diagonal. For any time-varying signal w, we represent by $\bar{w}$ its steady-state value, if exists. Also, we write time derivatives as $\dot{x}(t)$, and omit the argument t whenever is clear from the context.

2. SYSTEM SETUP

A schematic representation of a DH system with multiple heat producers, consumers and storage tanks is shown in Fig. 1. Producers and consumers are interconnected through a distribution network (DN) with independent supply (hot) and return (cold) layers. The specific composition of producers and consumers is shown in Fig. 2. Note that each producer drains water from the DN's return layer and injects heated water into the supply layer; a converse operation follows for consumers.

A storage tank stores a mixture of hot and cold water perfectly separated by a thermocline, hot layer is on top and the cold one at the bottom. It is assumed that there is no heat or mass exchange between the mixtures. Also, each storage tank has four valves, two at the top and two at the bottom, which are used as inlets and outlets of hot and cold water, respectively. Out of simplicity, we assume that each producer is interfaced to the DN via a storage tank, *i.e.,* each producer drains water from the cold layer of a storage tank and injects it into the storage tank's hot layer. Using the other pair of inlet/outlet valves, each tank drains water from the return layer of the DN and injects it into its cold layer, and at the same time, the storage tank injects the same amount of water from its hot layer into the DN's supply layer.

The overall DH system is viewed as a connected graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$ with no self-loops (see, *e.g.*, De Persis and Kallesoe (2011); Wang et al. (2017); Hauschild et al. (2020)). The set of edges $\mathcal{E}$ contains all two-terminal devices (valves, pumps or pipes), and the set of nodes $\mathcal{N}$ contains all junctions as well as the hot and cold layers of each storage tank. The cardinalities of $\mathcal{N}$ and $\mathcal{E}$ are denoted by n_N and n_E, respectively. Taking as reference the sketch in

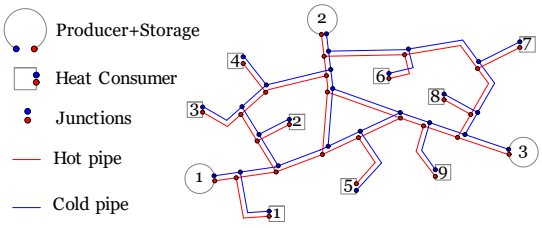

Fig. 1. Sketch based on Wang et al. (2017) of a DH system with 3 heat producers and 9 consumers.

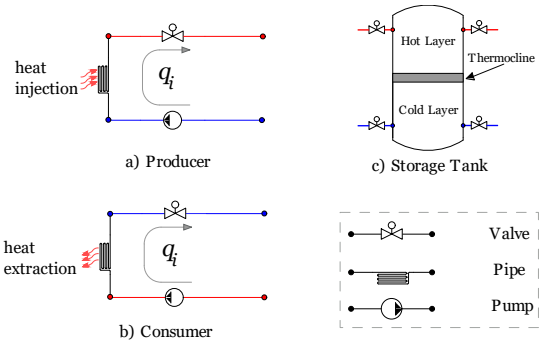

Fig. 2. Topologies of producers, consumers and storage tanks; see Scholten et al. (2015); De Persis and Kallesoe (2011). For producers and consumers, the pipes represent heat exchangers.

Fig. 1, the gray, blue and red lines therein represent edges, whereas colored circles, nodes.

The variables $q_{\mathrm{E},i}$, $V_{\mathrm{E},i}$, $T_{\mathrm{E},i}$ and $p_{\mathrm{E},i}$ denote the flow rate, volume, temperature and pressure of the stream through $i \in \mathcal{E}$. Analogous descriptions follow for the variables $V_{\mathrm{N},k}$, $T_{\mathrm{N},k}$ and $p_{\mathrm{N},k}$, $k \in \mathcal{N}$. Also, we fix an arbitrary orientation to every edge of $\mathcal{G}$. Then, for any $i \in \mathcal{E}$ with end nodes $j, k \in \mathcal{N}$, $j \neq k$, we say that j is the head and k is the tail of i, or viceversa, that j is the tail and k is the head of i. Then, for each node we define the following sets (Hauschild et al., 2020; Krug et al., 2021; Vladimarsson, 2014):

$$\mathfrak{S}_k = \{i \in \mathcal{E} : k \text{ is the tail of } i \in \mathcal{E}\},\ k \in \mathcal{N}, \tag{1a}$$

$$\mathfrak{T}_k = \{i \in \mathcal{E} : k \text{ is the head of } i \in \mathcal{E}\},\ k \in \mathcal{N}. \tag{1b}$$

We define a constant incidence matrix $\mathcal{B}_0$ associated with the arbitrary orientation we have fixed for the DH system's edges, as follows:

$$(\mathcal{B}_0)_{i,j} = \begin{cases} 1, & \text{if node } i \text{ is the head of edge } j, \\ -1, & \text{if node } i \text{ is the tail of edge } j, \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

For simplicity of exposition, we introduce the preliminary assumption that the orientation of any edge $i \in \mathcal{E}$ matches the direction of the stream through it. That is, if $j, k \in \mathcal{N}$, $j \neq k$, are the tail and head of any $i \in \mathcal{E}$, respectively, then the stream through i is assumed to flow from j to k and we consider that $q_{\mathrm{E},i} \geq 0$.

The following are standing assumptions in this work:

Assumption 1. (i) The density $\rho > 0$ and specific heat $c_{\mathrm{s.h.}} > 0$ of water are spatially uniform and constant in time; for ease of notation we take $\rho = c_{\mathrm{s.h.}} = 1$. (ii) All pipes are cylindrical. (iii) The flow through any edge $i \in \mathcal{E}$ is (spatially) one-dimensional. (iv) Gravitational forces are neglected. (v) The pressure of each $k \in \mathcal{N}$ is spatially uniform and for each tank the pressure of its layers is

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

equal. (vi) Each device (pipe, valve, pump, storage tank, junction) is completely filled with water all the time.

3. HYDRAULIC DYNAMICS

In this section we present a model to describe the dynamic behavior of the hydraulic variables of the DH system.

Under Assumption 1, the equations for mass and momentum balance at each edge $i \in \mathcal{E}$ can be written as follows:

$$q_{\mathrm{E},i} = q^{\mathrm{in}}_{\mathrm{E},i} = q^{\mathrm{out}}_{\mathrm{E},i} \tag{3a}$$

$$p^{\mathrm{in}}_{\mathrm{E},i} - p^{\mathrm{out}}_{\mathrm{E,i}} = J_{\mathrm{E},i}\dot{q}_{\mathrm{E},i} + f_{\mathrm{E},i}(q_{\mathrm{E},i}) - w_{\mathrm{E},i}, \tag{3b}$$

$$f_{\mathrm{E},i}(q_{\mathrm{E}}, i) = \theta_{\mathrm{E},i}|q_{\mathrm{E},i}|q_{\mathrm{E},i}, \tag{3c}$$

where $q^{\mathrm{in}}_{\mathrm{E},i}$, $q^{\mathrm{out}}_{\mathrm{E},i}$ and $p^{\mathrm{in}}_{\mathrm{E},i}$, $p^{\mathrm{out}}_{\mathrm{E},i}$ are the pipe's inlet-outlet flow and pressure pairs. Note that $V_{\mathrm{E},i}$ is constant all the time. If $i \in \mathcal{E}$ is a pipe, then $J_{\mathrm{E},i} = (\rho\ell_{\mathrm{E},i})/A_{\mathrm{E},i} > 0$, where $\ell_{\mathrm{E},i}$ and $A_{\mathrm{E},i}$ are the pipe's length and cross-section area; also $\theta_{\mathrm{E},i} > 0$ depends on the pipe's friction factor and diameter. If i is a valve, then $J_{\mathrm{E},i} = V_{\mathrm{E},i} = w_{\mathrm{E},i} = 0$ and $\theta_{\mathrm{E},i} > 0$. The latter parameter is constant and represents the valve's friction coefficient. If i is a pump, then $J_{\mathrm{E},i} = V_{\mathrm{E},i} = 0$ and $w_{\mathrm{E},i}$ is the pressure difference produced between its terminals.

On the other hand, for each node $k \in \mathcal{N}$ the following constraints are considered:

$$\dot{V}_{\mathrm{N},k} = \sum_{i\in\mathfrak{T}_k} q_{\mathrm{E},i} - \sum_{i\in\mathfrak{S}_k} q_{\mathrm{E},i}, \tag{4a}$$

$$p_{\mathrm{N},k} = p^{\mathrm{in}}_{\mathrm{E},i},\ i \in \mathfrak{S}_k, \quad p_{\mathrm{N},k} = p^{\mathrm{out}}_{\mathrm{E},i},\ i \in \mathfrak{T}_k, \tag{4b}$$

where the sets $\mathfrak{S}_k$ and $\mathfrak{T}_k$ are defined in (1). Equation (4a) represents mass balance and (4b) guarantees pressure consistency at each node. Note that under Assumption 1.(vi), the right hand side of (4a) must be zero if $k \in \mathcal{N}$ is a simple junction. Moreover, if $a, b \in \mathcal{N}$ represent the hot and cold layer of a given storage tank, then $p_{\mathrm{N},a} = p_{\mathrm{N},b}$ and $V_{\mathrm{N},a} + V_{\mathrm{N},b} = V^{\max}$, for some $V^{\max} > 0$ denoting the storage tank's capacity. These additional constraints complement (4).

We note that (3) and (4) can be represented in vector form as the following DAE:

$$-B_0^\top p_{\mathrm{n}} = \mathrm{diag}(J_{\mathrm{E}})\dot{q}_{\mathrm{E}} + f_{\mathrm{E}}(q_{\mathrm{E}}) - w_{\mathrm{E}}, \tag{5a}$$

$$\dot{V}_{\mathrm{n}} = 0 = B_0 q_{\mathrm{E}}, \tag{5b}$$

where p_{N}, V_{N} are the pressure and volume vectors of the reduced DH system's graph $G = (N, \mathcal{E})$, resulting from $\mathcal{G}$ when for each storage tank we merge its hot and cold layers. Also, B_0 is an incidence matrix for G.

Following De Persis and Kallesoe (2011), a set of independent flows can be identified from which the entire hydraulic state of the DH system can be determined. These flows are associated with a selected collection of *pipes* that generate fundamental loops of G.

Theorem 1. There exists a collection $\mathcal{C} \subset \mathcal{E}$ of n_{f} pipes whose flows $q_{\mathrm{f},i}$ are independent variables. All system flows can be computed as $q_{\mathrm{E}} = F^\top q_{\mathrm{f}}$, where F is the (full rank) fundamental loop matrix associated with $\mathcal{C}$ (and G). Moreover, the following claims hold true:

(I) If there is an independently controlled pump with pressure $w_{\mathrm{f},i}$ adjacent to each pipe in $\mathcal{C}$, then q_{f} is governed by the dynamics

$$\mathcal{J}_{\mathrm{f}}\dot{q}_{\mathrm{f}} = -f_{\mathrm{f}}(q_{\mathrm{f}}) + w_{\mathrm{f}} + B_{\mathrm{b}}w_{\mathrm{b}}, \tag{6}$$

where $\mathcal{J}_f = F\mathrm{diag}(J_{\mathrm{E}})F^\top > 0$ and $f_{\mathrm{f}}(q_{\mathrm{f}}) = Ff_{\mathrm{E}}(F^\top q_{\mathrm{f}})$ is a monotone function. Also, $B_{\mathrm{b}}w_{\mathrm{b}}$, with $(B_{\mathrm{b}})_{\alpha,\beta} \in \{-1, 0, 1\}$, codifies the effect on q_{f} of any other pump in the system (here we assume they provide a constant pressure difference).

(II) There exists $W \in \mathbb{R}^{n_{\mathrm{ST}}\times n_{\mathrm{f}}}$, with entries in $\{0, 1\}$ and n_{ST} being the number of storage tanks, such that the dynamics of the storage tanks' hot layer volume are given by

$$\dot{V}_{\mathrm{sh}} = Wq_{\mathrm{f}}. \tag{7}$$

Also, $\dot{V}_{\mathrm{sc}} = -Wq_{\mathrm{f}}$ holds for the cold layers' volumes.

(III) If w_{b} is constant, then (6) is shifted passive with passive output q_{f} and storage function $\mathcal{S}_{\mathrm{f}}(q_{\mathrm{f}}) = \frac{1}{2}(q_{\mathrm{f}} - \bar{q}_{\mathrm{f}})^\top\mathcal{J}_{\mathrm{f}}(q_{\mathrm{f}} - \bar{q}_{\mathrm{f}})$. It follows that $\dot{\mathcal{S}}_{\mathrm{f}} \le (w_{\mathrm{f}} - \bar{u}_{\mathrm{f}})^\top(q_{\mathrm{f}} - \bar{q}_{\mathrm{f}})$ holds for all time and for any equilibrium pair $(\bar{w}_{\mathrm{f}}, \bar{q}_{\mathrm{f}})$ of (6).

4. TEMPERATURE DYNAMICS

We present now a model to describe the dynamic behavior of the DH system's temperatures. More details, as well as the standing assumptions behind it are described in Machado et al. (2022). For ease of notation, we assume that the orientation of each $i \in \mathcal{E}$ matches the direction of the stream through it, *i.e.*, $q_{\mathrm{E},i} \ge 0$ all the time.

Let $i \in \mathcal{E}$ either be a pipe, a valve of a pump. Then, the energy balance at i is equivalent to:

$$\begin{aligned} V_{\mathrm{E},i}\dot{T}_{\mathrm{E},i} = q_{\mathrm{E},i}\left(T^{\mathrm{in}}_{\mathrm{E},i} - T^{\mathrm{out}}_{\mathrm{E},i}\right) + \alpha_{\mathrm{pr},i}P_{\mathrm{pr},i} - \beta_{\mathrm{c},i}P_{\mathrm{c},i} \\ + q_{\mathrm{E},i}f_{\mathrm{E},i}(q_{\mathrm{E}}, i), \end{aligned} \tag{8}$$

where $T^{\mathrm{in}}_{\mathrm{E},i}$ ($T^{\mathrm{out}}_{\mathrm{E},i}$) is the temperature at the inlet (outlet) of the pipe. If i is associated with the heat exchanger of a producer (consumer), then $P_{\mathrm{pr},i}$ ($P_{\mathrm{c},i}$) is the heat injection (extraction) into (from) the DH system by the producer (consumer). Also, each $P_{\mathrm{pr},i}$ is a control input, whereas each $P_{\mathrm{c},i}$ is a disturbance. The term $q_{\mathrm{E},i}f_{\mathrm{E},i}(q_{\mathrm{E},i})$ represents heat dissipation due to frictional forces.

Now let $k \in \mathcal{N}$ be an arbitrary node of the DH system. Then, the energy balance at k can be written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(V_{\mathrm{N},k}T_{\mathrm{N},k}\right) = \sum_{j\in\mathfrak{T}_k} q_{\mathrm{E},j}T^{\mathrm{out}}_{\mathrm{E},j} - \sum_{j\in\mathfrak{S}_k} q_{\mathrm{E},j}T^{\mathrm{in}}_{\mathrm{E},j}. \tag{9}$$

The term in the left-hand side represents the rate of change of the thermal energy stored at node k whereas the terms in the right-hand side are the sum of the thermal energies of the streams that target and source from k, respectively.

Based on the (upwind) semi-discretization scheme discussed in Hauschild et al. (2020) and on the nodal constraints described in Krug et al. (2021), we complement (8) and (9) with the following constraints for each $i \in \mathcal{E}$ and $j \in \mathcal{N}$:

$$T^{\mathrm{in}}_{\mathrm{E},i} = T_{\mathrm{N},j},\ \forall i \in \mathfrak{S}_j \subset \mathcal{E}, \text{ and } \quad T^{\mathrm{out}}_{\mathrm{E},i} = T_{\mathrm{E},i}. \tag{10a}$$

It follows that (9) can be written in a the following, equivalent form:

$$V_{\mathrm{N},k}\dot{T}_{\mathrm{N},k} = \sum_{j\in\mathfrak{T}_k} q_{\mathrm{E},j}T_{\mathrm{E},j} - \left(\sum_{j\in\mathfrak{T}_k} q_{\mathrm{E},j}\right)T_{\mathrm{N},k},$$

where we have used (4a). Note that $V_{\mathrm{N},k}$ is constant for most of the nodes, with the exception of the layers of storage tanks.

By defining $\mathcal{T} = \frac{1}{2}(\mathcal{B}_0 + |\mathcal{B}_0|)$ and $\mathcal{S} = \frac{1}{2}(\mathcal{B}_0 - |\mathcal{B}_0|)$, then the system (8), (10) and (11) can be written as follows:

$$\mathrm{diag}(V_{\mathrm{E}}, V_{\mathrm{N}}) \begin{bmatrix} \dot{T}_{\mathrm{E}} \\ \dot{T}_{\mathrm{N}} \end{bmatrix} = \mathcal{A}(q_{\mathrm{E}}) \begin{bmatrix} T_{\mathrm{E}} \\ T_{\mathrm{N}} \end{bmatrix} + B_{\mathrm{pr}} P_{\mathrm{pr}} - B_{\mathrm{c}} P_{\mathrm{c}} + \begin{bmatrix} \mathrm{diag}(q_{\mathrm{E}}) f_{\mathrm{E}}(q_{\mathrm{E}}) \\ 0_{n_{\mathrm{N}} \times n_{\mathrm{E}}} \end{bmatrix}, \tag{11}$$

where

$$\mathcal{A}(q_{\mathrm{E}}) = \begin{bmatrix} -\mathrm{diag}(q_{\mathrm{E}}) & \mathrm{diag}(q_{\mathrm{E}})\mathcal{S}^\top \\ \mathcal{T}\mathrm{diag}(q_{\mathrm{E}}) & -\mathrm{diag}(\mathcal{T} q_{\mathrm{E}}) \end{bmatrix}. \tag{12}$$

Also, P_{pr} (P_{c}) collects the producers (consumers) heat injections (extractions) to (from) the DN, then B_{pr} (B_{c}) is a suitable constant matrix with entries in $\{0, 1\}$.

Consider the following:

Theorem 2. Consider the system (6) and (12) and assume that P_{c} is constant. Then, the following claims hold true:

(I) The system is cyclo-dissipative (van der Schaft, 2021) with the total energy $\mathcal{H} = \frac{1}{2} q_{\mathrm{f}}^\top \mathcal{J}_{\mathrm{f}} q_{\mathrm{f}} + \sum_{i \in \mathcal{E}} V_{\mathrm{E},i} T_{\mathrm{E},i} + \sum_{i \in \mathcal{N}} V_{\mathrm{N},i} T_{\mathrm{N},i}$ as storage function and $w_{\mathrm{f}}^\top q_{\mathrm{f}} + \mathbf{1}^\top P_{\mathrm{pr}} - \mathbf{1}^\top P_{\mathrm{c}}$ as supply rate.

(II) Assume that q_{E} is at equilibrium. Then $\mathcal{A}(q_{\mathrm{E}})$ is a Kirchhoff Convection Matrix, which implies that $\mathcal{A}(q_{\mathrm{E}}) \leq 0$. It follows that (11) is shifted passive with passive output $T_{\mathrm{pr}} := B_{\mathrm{pr}}^\top T_{\mathrm{E}}$ and storage function $\mathcal{S}_{\mathrm{th}}(T_{\mathrm{E}}) = \frac{1}{2}(T_{\mathrm{E}} - \bar{T}_{\mathrm{E}})^\top \mathrm{diag}(V_{\mathrm{E}})(T_{\mathrm{E}} - \bar{T}_{\mathrm{E}}) + \frac{1}{2}(T_{\mathrm{N}} - \bar{T}_{\mathrm{N}})^\top \mathrm{diag}(V_{\mathrm{N}})(T_{\mathrm{N}} - \bar{T}_{\mathrm{N}})$. That is, $\dot{\mathcal{S}}_{\mathrm{th}} \leq (P_{\mathrm{pr}} - \bar{P}_{\mathrm{pr}})^\top (T_{\mathrm{pr}} - \bar{T}_{\mathrm{pr}})$ holds for all time and for any equilibrium pair $(\bar{P}_{\mathrm{pr}}, \bar{T}_{\mathrm{E}}, \bar{T}_{\mathrm{N}})$ of (11).

We note that the storage function $\mathcal{S}_{\mathrm{th}}$ in Theorem 2 is based on the shifted ectropy (Haddad, 2019), which is quadratic in the total energy of the system (Haddad, 2019, Chapter 3). Also, the passive output T_{pr} stacks the temperatures of the heated water streams that each producer injects into the DH system, respectively.

5. CONCLUSION

Invoking conservation laws and graph theoretic tools we have derived a thermo-hydraulic model of a multi-producer DH system and established that it is cyclo-dissipative. Also, its hydraulic and thermal subsystems are shifted passive under certain conditions.

In the talk we will discuss and present numerical simulations about how the established shifted passivity properties can be used in the synthesis of *decentralized* controllers with closed-loop stability guarantees. We will also discuss current modeling extensions aimed at designing optimal control strategies for the real time minimization of meaningful cost functions related with consumers' thermal comfort.

Abstract:
A semilinear infinite-dimensional system with a disturbance input is considered. The observation is modelled by an affine linear map with a different disturbance. An observer, based on the extended Kalman filter (EKF), is constructed and its well-posedness is proven under mild conditions. Moreover, local exponential stability of the error dynamics is shown. Thus, if the error in the initial condition is small enough, the estimation error converges to zero. This is a first generalization of the EKF to infinite-dimensional systems. Since only detectability, not observability, is assumed, this result is new even for finite-dimensional systems. An implementation is provided for a magnetic drug-delivery system and numerical results support the effectiveness of the observer.

Keywords: estimation, extended Kalman filter (EKF), infinite-dimensional system, semilinear partial differential equations

AMS Classification: 93B99 , 93C20

1. INTRODUCTION

In many physical applications, the system's state varies with spatial variables as well as time. The state of such systems is modelled by partial differential equations and evolves on an infinite-dimensional space, and so they are an important class of infinite-dimensional systems, as are systems modelled by delay-differential equations. The full state of these systems cannot be measured. As for finite-dimensional systems, a system, referred to as an observer or estimator, can be designed to estimate the state using the mathematical model and the measurements provided by sensors.

For linear systems, the Kalman filter (KF) minimizes the variance of the error under certain assumptions on the disturbances. The observer can be calculated through solution of a Riccati equation. The Kalman filter is widely used and was extended to infinite-dimensional linear systems in the 1970's; see the review papers Curtain (1975) and **?**. This theory was recently extended to time-varying infinite-dimensional systems, see Wu et al. (2015).

Due to its success in a wide range of applications, an extension of the KF to nonlinear systems, the extended Kalman filter (EKF), was developed for finite-dimensional systems. The EKF design is based on a linear approximation of the system around the estimated state. The linearized system is used to derive a Riccati equation and this is used to calculate the observer gain; e.g. Simon (2006); Grewal and Andrews (2011). This method is widely used; see for example, Reif and Unbehauen (1999); Reif et al. (1999, 2000); Kai et al. (2010, 2011); Einicke and White (1999). However, although this method may work well, it is well known that it may lead to divergent error estimates. Convergence of the estimation error for EKF depends on the size of the nonlinearity and the initial condition, see for instance, Liang (1983); Ribeiro (2004).

Further convergence results include local exponential convergence of the estimation error in Baras et al. (1988) or Reif et al. (1998) under certain conditions, as well as in Ahrens and Khalil (2007) using the normal form of the governing ordinary differential equations.

Observers for nonlinear infinite-dimensional systems are often designed using a finite-dimensional approximation of the system. This enables the use of techniques for nonlinear finite-dimensional systems. For an example thereof, using the EKF, see Rigatos et al. (2017) and Afshar et al. (2018).

There are some studies for nonlinear infinite-dimensional systems where the observer is designed directly using the infinite-dimensional system equations. To name some select examples, see the second-order sliding mode observer in Miranda et al. (2012), an observer with correction by a linear output error injection in Bitzer and Zeitz (2002), or spatially-distributed linear output injection in Efe* et al. (2005) for a one-dimensional nonlinear Burgers' equation.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

The EKF is formally shown here to be well-posed for a class of semilinear infinite-dimensional systems with bounded observation. As for a finite-dimensional EKF, the observer dynamics are a copy of the original system's dynamics with an injection gain defined by the solution of an Riccati equation. Since the Riccati equation is coupled with the observer equation, conventional results in the literature including Curtain and Pritchard (1976) for existence of solutions to the Riccati equation cannot be directly used. This is due to the fact that for linear equations the Riccati equation does not depend on the state of the system. In our, nonlinear, case, such a dependence still remains after linearizing the system, making the analysis more involved.

Also, for sufficiently small initial error, and smooth nonlinearity, the error dynamics are exponentially stable. Similar results for finite-dimensional systems; see Elizabeth and Jothilakshmi (2015); Alonge et al. (2014); Reif et al. (1999, 2000) assumed uniform observability . Here only detectability is assumed so the results are new for finite-dimensional systems. The estimation error is bounded in presence of disturbances.

For implementation, the infinite-dimensional EKF must be approximated using some method. The paper concludes with illustration of implementation using a finite-element method for estimation of concentration in a magnetic drug delivery system.

The proof of well-posedness was done in the thesis Germ (2019) for nonlinearities without time dependence, and briefly sketched in the conference paper Afshar et al. (2020). Complete details of the results described in this talk are in **?**.

2. PROBLEM STATEMENT

Let $\mathcal{H}$ be a Hilbert space and let $\boldsymbol{A} : \mathcal{D}(\boldsymbol{A}) \to \mathcal{H}$ be a linear operator that generates a C_0-semigroup $\boldsymbol{T}(t)$ on $\mathcal{H}$ and $\boldsymbol{F} : \mathcal{H} \times [0, t_f] \to \mathcal{H}$ be strongly continuous in time, satisfying $\boldsymbol{F}(0, t) = 0$ for every t.

We consider the semilinear evolution system

$$\begin{aligned} \frac{\partial \boldsymbol{z}(t)}{\partial t} &= \boldsymbol{A}\boldsymbol{z}(t) + \boldsymbol{F}(\boldsymbol{z}(t), t) + \boldsymbol{B}\boldsymbol{u}(t) + \boldsymbol{G}\boldsymbol{\omega}(t), \\ \boldsymbol{z}(0) &= \boldsymbol{z}_0 \in \mathcal{H}, \end{aligned} \tag{1}$$

where for Hilbert spaces $\mathcal{H}_1$ and $\mathcal{H}_2$, $\boldsymbol{u}(t) \in \mathcal{C}([0, t_f], \mathcal{H}_1)$ is the control input, $\boldsymbol{\omega}(t) \in \mathcal{C}([0, t_f], \mathcal{H}_2)$ is the input disturbance and $\boldsymbol{B} \in \mathcal{L}(\mathcal{H}_1, \mathcal{H})$, $\boldsymbol{G} \in \mathcal{L}(\mathcal{H}_2, \mathcal{H})$, with $\mathcal{L}(\mathcal{A}, \mathcal{B})$ denoting the space of linear and bounded operators from $\mathcal{A}$ to $\mathcal{B}$. We refer to $\boldsymbol{z}(t)$ as the state of the system (1).

Assumption 1. The operator $\boldsymbol{F}$ admits a Fréchet-derivative $\boldsymbol{DF}(\cdot, \cdot)$ such that for a constant $\delta_{DF} > 0$ we have $\|\boldsymbol{DF}(x, t)\| \leq \delta_{DF}$ for all $(x, t) \in \mathcal{H} \times [0, t_f]$, and for every $\delta > 0$ there exists a Lipschitz constant $\iota_{DF} > 0$ such that for all $\|\boldsymbol{x} - \boldsymbol{y}\| < \delta$ and all $t \in [0, t_f]$,

$$\|\boldsymbol{DF}(\boldsymbol{x}, t) - \boldsymbol{DF}(\boldsymbol{y}, t)\| \leq \iota_{DF}\|\boldsymbol{x} - \boldsymbol{y}\|.$$

The disturbance $\boldsymbol{\omega}$ and control $\boldsymbol{u}$ may be lumped as

$$\boldsymbol{B}_d = [\boldsymbol{B}, \boldsymbol{G}], \quad \boldsymbol{u}_d^T(t) = [\boldsymbol{u}^T(t), \boldsymbol{\omega}^T(t)].$$

The state-equation for $\boldsymbol{z}$ in system (1) then becomes

$$\begin{aligned} \frac{\partial \boldsymbol{z}(t)}{\partial t} &= \boldsymbol{A}\boldsymbol{z}(t) + \boldsymbol{F}(\boldsymbol{z}(t), t) + \boldsymbol{B}_d\boldsymbol{u}_d(t), \\ z(0) &= z_0 \in \mathcal{H}. \end{aligned} \tag{2}$$

With disturbance $\boldsymbol{\eta}(t) \in \mathcal{C}([0, t_f], \mathbb{R}^p)$, $p \geq 1$, let

$$\boldsymbol{y}(t) = \boldsymbol{C}\boldsymbol{z}(t) + \boldsymbol{\eta}(t)$$

be the system measurement, where $\boldsymbol{C} \in \mathcal{L}(\mathcal{H}, \mathbb{R}^p)$.

Our objective is to design an observer for the system (2). Most generally, an observer is a dynamical system with state $\hat{\boldsymbol{z}}(t)$ such that, in the absence of disturbances,

$$\lim_{t\to\infty} \|\boldsymbol{z}(t) - \hat{\boldsymbol{z}}(t)\| = 0.$$

In our case, as is common, the observer dynamics contain a copy of the system's dynamics and a feedback term that corrects for the error between the predicted observation, $\boldsymbol{C}\hat{\boldsymbol{z}}$, and the actual observation, $\boldsymbol{y}$. The general form of the observer is

$$\begin{aligned} \frac{\partial \hat{\boldsymbol{z}}(t)}{\partial t} &= \boldsymbol{A}\hat{\boldsymbol{z}}(t) + \boldsymbol{F}(\hat{\boldsymbol{z}}(t), t) + \boldsymbol{B}\boldsymbol{u}(t) + L(t)[\boldsymbol{y}(t) - \boldsymbol{C}\hat{\boldsymbol{z}}(t)] \\ \hat{\boldsymbol{z}}(0) &= \hat{\boldsymbol{z}}_0 \in \mathcal{H}, \end{aligned} \tag{3}$$

where $L(t)$, referred to as observer gain, needs to be selected so that in the absence of disturbances $\boldsymbol{\omega}(t)$ and $\boldsymbol{\eta}(t)$, $\hat{\boldsymbol{z}}(t) \to \boldsymbol{z}(t)$.

3. OBSERVER DESIGN

The problem of observer design for linear systems has been well studied. The most widely known and used approach is the Kalman filter. Consider, instead of (2), the linear system

$$\begin{aligned} \frac{\partial \boldsymbol{z}(t)}{\partial t} &= \tilde{\boldsymbol{A}}(t)\boldsymbol{z}(t) + \boldsymbol{B}\boldsymbol{u}(t) + \boldsymbol{\omega}(t). \\ \boldsymbol{y}(t) &= \boldsymbol{C}\boldsymbol{z}(t) + \boldsymbol{\eta}(t). \end{aligned} \tag{4}$$

where $\tilde{\boldsymbol{A}}(t)$ generates an evolution operator $\boldsymbol{U}(t, s)$,and $\boldsymbol{\omega}(t)$ and $\boldsymbol{\eta}(t)$ are process and output disturbance respectively.

Assumption 2. Let linear operators $\boldsymbol{P}_0 \in \mathcal{L}(\mathcal{H})$, $\boldsymbol{W}(t) \in C([0, t_f], \mathcal{L}(\mathcal{H}))$ and $\boldsymbol{R}(t) \in C([0, t_f], \mathcal{L}(\mathbb{R}^p))$ be self-adjoint. Let $\boldsymbol{P}_0$ be positive definite and $\boldsymbol{W}(t)$ be non-negative definite for all $t \in [0, t_f]$. The operator $\boldsymbol{R}(t)$ is uniformly coercive; meaning that there exists a $\delta_0 > 0$ such that for every $\boldsymbol{w} \in \mathbb{R}^p$ and $t \in [0, t_f]$, $(\boldsymbol{w}, \boldsymbol{R}(t)\boldsymbol{w}) \geq \delta_0\|\boldsymbol{w}\|^2$.

Note that since $\boldsymbol{R}(t)$ is self-adjoint, coercive and bounded for each t, it follows that for all $t \in [0, t_f]$, it has a self-adjoint bounded inverse $\boldsymbol{R}^{-1}(t) \in \mathcal{C}([0, t_f], \mathcal{H})$.

Linear integral Riccati equations are defined in the following theorem. For the proof we refer to (Curtain and Pritchard, 1976, Theorem 3.1 & 3.3) or (Curtain, 1976, Theorem 2.1).

Theorem 3. Let $\boldsymbol{U}(t, s)$ be an evolution operator on $\Delta(t_f) := \{(s, t) \in [0, t_f]^2, 0 \leq s \leq t \leq t_f\}$. Under Assumption 2, the following integral Riccati equation

$$\begin{aligned} \boldsymbol{P}(t)\boldsymbol{w} =& \boldsymbol{U}_P(t, 0)\boldsymbol{P}_0\boldsymbol{U}^*(t, 0)\boldsymbol{w} \\ &+ \int_0^t \boldsymbol{U}_P(t, s)\boldsymbol{W}(s)\boldsymbol{U}^*(t, s)\boldsymbol{w}ds, \quad \boldsymbol{w} \in \mathcal{H}, \end{aligned} \tag{5}$$

where the perturbed evolution operator

$$\boldsymbol{U}_P(t,s)\boldsymbol{w} = \boldsymbol{U}(t,s)\boldsymbol{w} - \int_s^t \boldsymbol{U}(t,r)\boldsymbol{P}(r)\boldsymbol{C}^*\boldsymbol{R}^{-1}(r)\boldsymbol{C}\boldsymbol{U}_P(r,s)\boldsymbol{w}dr, \tag{6}$$

$\boldsymbol{w} \in \mathcal{H}$, admits a unique, positive definite, self-adjoint solution $\boldsymbol{P}(t) \in \mathcal{C}([0,t_f],\mathcal{L}(\mathcal{H}))$.

This solution $\boldsymbol{P}(t)$ defines an observer gain,

$$L_P(t) = \boldsymbol{P}(t)\boldsymbol{C}^*\boldsymbol{R}^{-1}(t).$$

This defines observer dynamics for (4) are

$$\frac{\partial \hat{\boldsymbol{z}}_P(t)}{\partial t} = \tilde{\boldsymbol{A}}(t)\hat{\boldsymbol{z}}_P(t) + \boldsymbol{B}\boldsymbol{u}(t) + L_P(t)(\boldsymbol{y}(t) - C\boldsymbol{z}(t)). \tag{7}$$

In the case that $\boldsymbol{\omega}(t)$ and $\boldsymbol{\eta}(t)$ are process and sensor noises with covariances $\boldsymbol{W}(t)$ and $\boldsymbol{R}(t)$ respectively and the covariance of the initial condition $\hat{\boldsymbol{z}}(0)$ is $\boldsymbol{P}_0$ then the observer gain $L_P(t)$ and corresponding estimate $\hat{\boldsymbol{z}}(t)$ are optimal in a sense that $\hat{\boldsymbol{z}}(t)$ minimizes the error covariance Curtain (1976). This observer is the Kalman filter. For details, see Curtain and Pritchard (1978) and for recent work on time-varying systems, Wu et al. (2015).

The linearization of (2) will be used to define a integral Riccati equation similar to (5). The solution $\boldsymbol{P}$ defines the observer gain. In the case of finite-dimensional systems, this approach is known as an extended Kalman filter (EKF) and this terminology will be used here.

First, the linearization of the system is defined. For this purpose, for $\hat{\boldsymbol{z}}(t) \in C([0,t_f],\mathcal{H})$, at time t the Fréchet-derivative of $\boldsymbol{F}(\cdot,t)$, denoted by $\boldsymbol{DF}(\cdot,t) : \mathcal{H} \to \mathcal{L}(\mathcal{H})$,

$$\boldsymbol{DF}(\hat{\boldsymbol{z}}(t),t) = \frac{\partial \boldsymbol{F}(z,t)}{\partial \boldsymbol{z}} \mid_{\boldsymbol{z}=\hat{\boldsymbol{z}}(t)} . \tag{8}$$

Linearizing the system (2) around $\hat{\boldsymbol{z}}(t)$ yields

$$\frac{\partial \boldsymbol{z}(t)}{\partial t} = \boldsymbol{A}\boldsymbol{z}(t) + \boldsymbol{F}(\hat{\boldsymbol{z}}(t),t) + \boldsymbol{DF}(\hat{\boldsymbol{z}}(t),t)[\boldsymbol{z}(t) - \hat{\boldsymbol{z}}(t)] + \boldsymbol{B}_d\boldsymbol{u}_d(t). \tag{9}$$

To obtain EKF equations, the solution to the integral Riccati equations for the linear system (9) is needed. Since $\boldsymbol{U}$ in (6) is now given by, for $\boldsymbol{w} \in \mathcal{H}$,

$$\boldsymbol{U}(t,s)\boldsymbol{w} = \boldsymbol{T}(t-s)\boldsymbol{w} - \int_s^t \boldsymbol{T}(t-r)\boldsymbol{DF}(\hat{\boldsymbol{z}}_P(r),r)\boldsymbol{U}(r,s)\boldsymbol{w}dr, \tag{10}$$

these will contain the Fréchet-derivative $\boldsymbol{DF}(\hat{\boldsymbol{z}}_P(t),t)$, a possibly nonlinear function of the observer state $\hat{\boldsymbol{z}}_P(t)$. Therefore recent results on the Riccati equation do not provide well-posedness for the coupled system.

For a bounded linear operator $\boldsymbol{P}(t) \in C([0,t_f];\mathcal{L}(\mathcal{H}))$ and $\hat{\boldsymbol{z}}_0 \in \mathcal{H}$, the mild solution $\hat{\boldsymbol{z}}_P(t)$ to (7) is

$$\hat{\boldsymbol{z}}_P(t) = \boldsymbol{T}(t)\hat{\boldsymbol{z}}_0 + \int_0^t \boldsymbol{T}(t-s)\big(\boldsymbol{F}(\hat{\boldsymbol{z}}_P(s),s) + \boldsymbol{B}\boldsymbol{u}(s)\big)ds + \int_0^t \boldsymbol{T}(t-s)\boldsymbol{P}(s)\boldsymbol{C}^*\boldsymbol{R}^{-1}(s)[\boldsymbol{y}(s) - \boldsymbol{C}\hat{\boldsymbol{z}}_P(s)]ds. \tag{11}$$

The following is the first of our main results.

Theorem 4. Let Assumptions 1 and 2 hold. For any $\boldsymbol{u}(t) \in C([0,t_f],\mathcal{H}_1)$, $y(t) \in C([0,t_f],\mathbb{R}^p)$ and $\hat{\boldsymbol{z}}_0 \in \mathcal{H}$ there exist $\hat{\boldsymbol{z}}_P(t) \in C([0,t_f],\mathcal{H})$ and $\boldsymbol{P}(t) \in C([0,t_f],\mathcal{L}(\mathcal{H}))$ such that $\hat{\boldsymbol{z}}_P(t)$ solves (11) and $\boldsymbol{P}(t)$ satisfies the Riccati equation (5), coupled to (6) and (10).

The other main result concerns the error dynamics.

$$\boldsymbol{\phi}(\boldsymbol{e},t) = \boldsymbol{F}(\boldsymbol{z},t) - \boldsymbol{F}(\boldsymbol{z}-\boldsymbol{e},t) - \boldsymbol{D}F(\boldsymbol{z}-\boldsymbol{e},t)(\boldsymbol{e}). \tag{12}$$

The error $\boldsymbol{e}(t) = \boldsymbol{z}(t) - \hat{\boldsymbol{z}}_P(t)$ between the system state $\boldsymbol{z}(t)$ and the observer state $\hat{\boldsymbol{z}}_P(t)$ has the dynamics

$$\frac{\partial \boldsymbol{e}(t)}{\partial t} = \boldsymbol{A}\boldsymbol{e}(t) - L_P(t)\boldsymbol{C}\boldsymbol{e}(t) + \boldsymbol{DF}(\boldsymbol{z}(t)-\boldsymbol{e}(t),t)\boldsymbol{e}(t) + \boldsymbol{\phi}(\boldsymbol{e}(t)) - L_P(t)\boldsymbol{\eta}(t) - \boldsymbol{G}\boldsymbol{w}(t). \tag{13}$$

These dynamics are well-posed, and furthermore, locally exponentially stable.

Theorem 5. Let the system $(\boldsymbol{A}_d(t),\boldsymbol{C})$, where $\boldsymbol{A}_d(t) = \boldsymbol{A} + \alpha\boldsymbol{I} + \boldsymbol{DF}(\hat{\boldsymbol{z}}_P(t),t)$, be uniformly detectable, and $(\boldsymbol{A}_d(t),\boldsymbol{W}^{1/2}(t))$ be uniformly stabilizable. Assume that there exist time $T > 0$ and positive numbers $m > 1$, $\epsilon_\varphi > 0$ and $\delta_\varphi > 0$ such that if $\|\boldsymbol{e}\|_{\mathcal{H}} \le \epsilon_\phi$, then defining $\boldsymbol{\phi}(\cdot)$ as in (12),

$$\|\boldsymbol{\phi}(\boldsymbol{e},t)\|_{\mathcal{H}} \le \delta_\phi \|\boldsymbol{e}\|_{\mathcal{H}}^m, \quad 0 \le t \le T. \tag{14}$$

In the absence of disturbances, $\boldsymbol{\xi} = \boldsymbol{\eta} \equiv 0$, there exists ϵ, $\delta_{e,0} > 0$, $M_e > 0$, such that if $\|e(0)\| = \|\boldsymbol{z}(0) - \hat{\boldsymbol{z}}_P(0)\|_{\mathcal{H}} < \epsilon$ then for $t \ge 0$,

$$\|\boldsymbol{z}(t) - \hat{\boldsymbol{z}}_P(t)\|_{\mathcal{H}} \le M_e \exp(-\alpha_e(t-0))\|\boldsymbol{z}(0) - \hat{\boldsymbol{z}}_P(0)\|_{\mathcal{H}}.$$

If disturbances are present, the estimation error is bounded.

Corollary 6. Consider the same assumptions as in Theorem 5 except that there are disturbances $\boldsymbol{\xi}(t),\boldsymbol{\eta}(t)$ satisfying for some $\delta_d > 0$ $\|\boldsymbol{\xi}(t)\|, \|\boldsymbol{\eta}(t)\| \le \delta_d$. There exists $\delta_e > 0$ such that if $\|\boldsymbol{e}(0)\| \le \delta_e$ and, the estimation error is bounded.

These results will be illustrated by implementation of an EKF observer for a magnetic drug delivery system modelled by a system of semilinear partial differential equations.

Abstract: Dynamic consensus is a property of networked systems that pertains to the case in which all the interconnected systems synchronise their motions and a collective behaviour arises. If the coupling strength is large such behaviour may be modelled by a single system, but if it is weak, the behaviour is best modelled by a reduced-order network. For networks of homogeneous Stuart-Landau oscillators under weak coupling, we characterise the dimension and dynamics of such reduced-order network in function of the coupling strength.

Keywords: Networked Control Systems, Nonlinear Systems and Control, Stability
AMS subject classification: 34D06, 93D20

1. CONTEXT

We analyse the dynamical behaviour of N identical Stuart-Landau oscillators interconnected via a distributed consensus-control law and with interconnection gain $\gamma > 0$,

$$\dot{z}_j = f(z_j) + \mu z_j - \gamma \sum_{k=1}^{N} a_{kj}(z_j - z_k), \qquad j \in \{1, 2, ..., N\}, \tag{1}$$

where $z_j, \mu \in \mathbb{C}$, and $f : \mathbb{C} \to \mathbb{C}$ is defined as

$$f(z_j) = -z_j|z_j|^2. \tag{2}$$

Equations of interconnected Stuart-Landau systems, such as (1)–(2), are often used as a universal dynamical system to model networks exhibiting oscillations, such as lasers, genetic and neuronal networks, among others (Hasty et al., 2001; Soriano et al., 2013).

More precisely, we are interested in the possible synchronised behaviour of these oscillators under the effect of the last term on the right-hand-side of (1). Two factors affect the collective behaviour of the multi-agent system. On one hand, the network's topology, which is defined by the coefficients a_{kj}, and on the other hand, the magnitude of the coupling strength. For instance, for networks of identical oscillators with an underlying undirected connected-graph topology and with $\gamma > 0$ sufficiently large, the networked systems trajectories $z_j(t)$ converge to the solution of an averaged dynamical system,

$$\dot{z}_m = F_m(z_m, e) \tag{3}$$

where $z_m = \frac{1}{\sqrt{N}} \sum_{k=1}^{N} z_k$ and e is a synchronisation error defined as

$$e := z - \frac{1}{N}\mathbf{1}_N\mathbf{1}_N^\top z \quad \Longleftrightarrow \quad \begin{bmatrix} z_1 - z_m \\ \vdots \\ z_N - z_m \end{bmatrix} \tag{4}$$

—see (Pogromsky et al., 1999). For networks of heterogeneous oscillators, *i.e.*, with different μ_js in (1), in (Maghenem et al., 2016) it is shown that for sufficiently large values of γ the synchronisation error defined in (4) is ultimately bounded and the solutions are frequency-synchronised. This is significant because the function $(z_m, e) \mapsto F_m(z_m, e)$ is such that

$$F_m(z_m, 0) = -z_m|z_m|^2 + \mu_m z_m \tag{5}$$

where $\mu_m \in \mathbb{C}$ is defined as $\mu := \mu_R + i\mu_I$ and

$$\mu_R := \frac{1}{\sqrt{N}} \sum_{1}^{N} \mu_{Rk}, \quad \mu_I := \frac{1}{\sqrt{N}} \sum_{1}^{N} \mu_{Ik}. \tag{6}$$

In other words, for sufficiently large values of the coupling strength γ the response of each oscillator in (1) approaches that of a *single* emergent oscillator of the same nature,

$$\dot{z}_m = -z_m|z_m|^2 + \mu_m z_m, \quad z_m \in \mathbb{C}. \tag{7}$$

In general, for heterogeneous systems, such motion is called dynamic consensus (Panteley and Loría, 2017). For Eq. (7), the solutions are either periodic trajectories whose frequency and amplitude are defined by μ or the unstable equilibrium point $\{z_m = 0\}$. Because the right-hand side of (7) corresponds to $F_m(z_m, 0)$, this equation describes the asymptotic collective behaviour of the networked systems, provided they enter in synchrony.

Besides the coupling gain being relatively high, the fact that the collective behaviour of the networked systems (1) may be approximated asymptotically by that of a single oscillator is also a consequence of the graph being connected and undirected. Indeed, in this case, the associated Laplacian matrix

$$L_N := [\ell_{kj}] \in \mathbb{R}^{N\times N}, \qquad \ell_{kj} = \begin{cases} \sum_{l\in\mathcal{N}_k} a_{kl} & k = j \\ -a_{kj} & k \neq j, \end{cases} \tag{8}$$

has exactly one null eigenvalue and $v_1 := \frac{1}{\sqrt{N}}\mathbf{1}_N$ is its associated left eigenvector. That is,

$$z_m := v_1^\top z \quad \text{and} \quad e = [I_N - v_1 v_1^\top]z. \tag{9}$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

It is well-documented in the literature that for relatively small values of γ networks of Stuart-Landau oscillators can exhibit a rich variety of behaviours, such as chaotic motion, emergence of cluster states, and coherence resonance, among others (Golubitsky et al., 2012). Such richer behaviours cannot be captured by that of a single oscillator with dynamics as in (7). In (Tumash et al., 2019) it is shown that, in some cases, rich behaviour can be characterised by a *network* of reduced order. Specifically, the main results in (Tumash et al., 2019) only apply to networks of even dimension and a specific topology, and the reduced-order model's interconnections are nonlinear.

In this extended abstract we consider networks of arbitrary dimension and with circulant-graph topology. We show that the dimension of the reduced model depends on the magnitude of the coupling strength γ relative to the eigenvalues of the Laplacian matrix L_N. Significantly, and in contrast to (Tumash et al., 2019), the reduced-order model has exactly the same structure as the original multiagent system, with linear interconnections.

2. MAIN RESULT

Consider systems modelled by (1), which we rewrite in the compact form

$$\dot{z} = F(z) + \gamma \tilde{L}_N z \tag{10}$$

where $z = [z_1 \ z_2 \ \cdots \ z_N]^\top$,

$$F(z) = [\, f(z_1) \quad f(z_2) \quad \cdots \quad f(z_N) \,]^\top$$

and

$$\tilde{L}_N := \Big[-L_N + \frac{\mu}{\gamma} I_N \Big], \tag{11}$$

under the following hypothesis.

Assumption 1. The network is undirected and connected, has an underlying circulant-graph topology. That is, the adjacency matrix is circulant.

Assumption 1 implies that the Laplacian L_N with coefficients defined in (8) is a circulant matrix. That is, the $(k+1)$st row of L_N corresponds to the kth row in which the last element, ℓ_{kN}, is placed first in the $(k+1)$st row and all other elements are shifted right. An example of a network satisfying Assumption 1 corresponds to one with an underlying ring topology, and in which the nodes may have supplementary cross-links, but with the restriction that each node has the same number of neighbours, $m \geq 2$. See Fig. 1 in Section 3 for an illustration.

Then, we have the following.

Proposition 2. (Main result). Consider a network of N Stuart-Landau oscillators with dynamics (10)–(11), such that the Laplacian L_N satisfies Assumption 1. Then, there exists $\gamma_m > 0$ such that, for each $\gamma > \gamma_m$, there exists $N_R(\gamma) < N$ and a network of reduced order $N_R(\gamma)$, with dynamics given by

$$\dot{z}_R = F(z_R) + \gamma \tilde{L}_R z_R, \tag{12}$$

where $\tilde{L}_R \in \mathbb{C}^{N_R \times N_R}$, $z_R \in \mathbb{C}^{N_R}$, $z = [z_{R_1} \ z_{R_2} \ \cdots \ z_{R_{N_R}}]^\top$,

$$F(z) = [\, f(z_{R_1}) \quad f(z_{R_2}) \quad \cdots \quad f(z_{R_{N_R}}) \,]^\top$$

Moreover, the solutions of (10) satisfy

$$\lim_{t\to\infty} z(t) - \bar{z}_R(t) = 0 \tag{13}$$

for any initial conditions in $\mathbb{C}^N$, where $\bar{z}_R = M z_R$ and $M \in \mathbb{C}^{N \times N_R}$ is a matrix such that its columns generate a subspace of dimension N_R. □

In this extended abstract we do not provide a complete proof of Proposition 2, but the main rationale behind.

First, we observe that because the graph is connected (see Assumption 1), L_N has a unique zero eigenvalue and it admits the Jordan decomposition

$$L_N = U \begin{bmatrix} 0 & 0 \\ 0 & \Lambda_2 \end{bmatrix} U^*, \tag{14}$$

where $U^* \in \mathbb{C}^{N\times N}$ denotes the conjugate transpose of U, which is orthonormal, so $UU^* = U^*U = I_N$. Furthermore, $\Lambda_2 \in \mathbb{C}^{N-1\times N-1}$ is a diagonal matrix whose elements correspond to the nonzero eigenvalues of L_N. Then, in view of its definition—see Eq. (11), $\tilde{L}_N$ satisfies the same decomposition as L_N. That is, denoting by $\lambda_i(L_N)$ the eigenvalues of L_N, after (11), we have

$$\tilde{L}_N = U \begin{bmatrix} \frac{\mu}{\gamma} & 0 & \cdots & & 0 \\ 0 & -\lambda_2(L_N) + \frac{\mu}{\gamma} & & & \vdots \\ \vdots & & & \ddots & 0 \\ 0 & \cdots & & \cdots \ 0 & -\lambda_N(L_N) + \frac{\mu}{\gamma} \end{bmatrix} U^*. \tag{15}$$

Clearly, the number of eigenvalues of the matrix above with positive real part varies from one to N depending on the value of γ. On the other hand, by convention, the eigenvalues λ_i are ordered in a way that $0 < \Re e\{\lambda_2\} \leq \Re e\{\lambda_3\} \leq \ldots \leq \Re e\{\lambda_N\}$.

Furthermore, under Assumption 1, if N is odd, the nonzero eigenvalues λ_k come in conjugate pairs, that is $\Re e\{\lambda_k\} = \Re e\{\lambda_{k+1}\}$ for all $k \in \{2, 4, \ldots, N-1\}$. Hence, for any γ such that for some $k \in \{2, 4, \ldots, N-3\}$

$$\Re e\{\mu/\lambda_{k+2}\} < \gamma < \Re e\{\mu/\lambda_k\}$$

the matrix in (15) has necessarily an odd number $N_R(\gamma) = k+1$ eigenvalues with positive real part, and $N_R(\gamma) = N$ for any $\gamma < \Re e\{\mu/\lambda_{N-1}\}$. Thus, for any $\gamma > \gamma_m := \Re e\{\mu/\lambda_N\} = \Re e\{\mu/\lambda_{N-1}\}$, the matrix in (15) has $N_R(\gamma) < N$ eigenvalues with positive real part. Similar arguments apply to the case in which N is even, considering that $\lambda_N \in \mathbb{R}_{>0}$.

Now, for the sake of argument, let us disregard momentarily the nonlinear terms in (10), $F(z)$. For the system $\dot{z} = \gamma \tilde{L}_N z$, the eigenvalues with positive real part in $\tilde{L}_N$ generate unstable modes while those with negative real part generate stable ones. That is, the solution may be written as

$$z(t) = v_1 v_1^* z(t) + v_2 v_2^* z(t) + \cdots + v_{N_R} v_{N_R}^* z(t) + e(t), \tag{16}$$

where $v_k \in \mathbb{C}^N$, for all $k \in \{1, 2, \ldots, N_R\}$ are eigenvectors associated with eigenvalues with positive real part and $e(t)$ contains the contributions to the solution generated by the stable modes. As $e(t) \to 0$ only the contributions of the unstable modes remain. This motivates the choice for the synchronisation errors,

$$e := z - U_1 U_1^* z, \tag{17}$$

where $U_1 \in \mathbb{C}^{N\times N_R}$ is such that its columns correspond to the N_R eigenvectors associated with the N_R eigenvalues with positive real part, that is, v_k farther above. Since v_k denote the columns of U_1, note that if $N_R = 1$ we recover the expression (4). On the other hand, on the synchronisation manifold $\{e = 0\}$ the dynamics of the

system (10) reduces to that of reduced-order network evoked in Proposition 2. Exponential stability of $\{e = 0\}$ can be established along the lines of (Tumash et al., 2019).

Now, the statement of Proposition 2 asserts that the solution of the networked system converges asymptotically to a trajectory that we denote $\bar{z}_R(t)$. This trajectory, loosely speaking, may be regarded as a linear combination of the elements, $z_{R_k}(t)$, of the vector $z_R(t)$, solution of (12). Indeed, introducing the notation $M = [v'_1\ v'_2\ \cdots\ v'_{N_R}]$, we see that

$$\bar{z}_R = v'_1 z_{R_1} + v'_2 z_{R_2} + \cdots + v'_{N_R} z_{R_{N_R}} \tag{18}$$

and the N_R vectors v'_k are uniquely determined by the properties of the Laplacian L_N and the interconnection strength γ. It is important to remark that $v'_k \neq v_k$. As a matter of fact, it may be shown that

$$M := U_1[\,U_{11}^* - U_{21}^*(U_{22}^*)^{-1}U_{12}^*\,],$$

where the matrices on the right-hand side above come from a suitable partition of U and its conjugate transpose,

$$U =: \begin{bmatrix} U_{11} & U_{21} \\ U_{12} & U_{22} \end{bmatrix}, \quad U^* = \begin{bmatrix} U_{11}^* & U_{21}^* \\ U_{12}^* & U_{22}^* \end{bmatrix}. \tag{19}$$

With these definitions, it may also be shown that $e = z - Mz_R$ or that Eq. (16) is equivalent to $z(t) = e(t) + Mz_R(t)$ so, in the limit, as $e(t) \to 0$, $z(t) = Mz_R(t)$—cf. (13). In that regard, (12) is reminiscent of the zero-dynamics of the networked system (10) with respect to the converging output $e \in \mathbb{C}^N$. This corroborates the initial observation that, for complex networked nonlinear systems, the collective behaviour in the state of synchronisation, that is, on the manifold $\{e = 0\}$ depends on the coupling strength γ.

The importance of the latter observations transcend the rationale behind the proof of Proposition 2, which is omitted due to space constraints. The fact that, asymptotically, $z(t) = Mz_R(t)$, implies that the solutions of the (potentially) high-order network (10) may be reconstructed using the solutions of a reduced-order model, at least asymptotically, as synchronisation is reached. This is possible using a change of coordinates that leads to (12).

3. EXAMPLE

We have that if the coupling gain is large ($\gamma > \gamma_M$) then, $N_R = 1$; that is, (12) becomes, simply, Eq. (7). In this case, the oscillators synchronise globally. If γ is relatively small ($\gamma_M > \gamma > \gamma_m$), which is the case of most interest here, there exists a network of reduced order $N > N_R(\gamma) > 1$.

For illustration, let us consider a network of eleven oscillators modelled as in (1), with $\mu = 1+2i$ and interconnected over a graph satisfying Assumption 1, which is illustrated in Fig. 1. We consider two cases that pertain to different values of the coupling strength. First, we set $\gamma < 1$, which is relatively small given that $\mu_R = 1$. Indeed, for such γ, $\tilde{L}_N$ in (11) has three eigenvalues with positive real part. Hence, according to Proposition 2, there exists a reduced-order network of dimension $N_R = 3$ whose behaviour approaches asymptotically that of the original one. Then, the coupling strength is increased to $\gamma = 2.5$, so only the first element in the diagonal of the matrix in (15) has positive real part. Consequently, it is expected that the collective behaviour of the networked systems approach asymptotically that of a single one with dynamics as in Eq. (7).

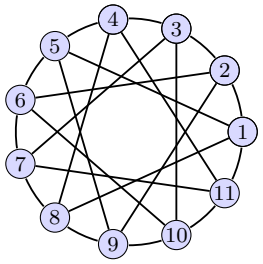

Fig. 1. Example of a ring graph in which each node has the same (even) number of undirected links

In both simulation tests the initial conditions are set to

$$\begin{cases} z_j(0) = 1 + i & \forall\, j \in \{1, 2, \ldots, 5\}, \\ z_6(0) = 0, \\ z_j(0) = -1 - i & \forall\, j \in \{7, 8, \ldots, 11\}. \end{cases} \tag{20}$$

The results are shown in Figs. 2–6, for a coupling strength set to $\gamma = 0.75$, and in Fig. 7 for $\gamma = 2.5$.

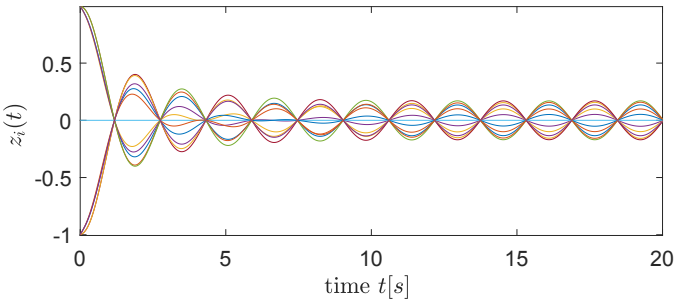

Fig. 2. Response of $N = 11$ oscillators under relatively small coupling strength $\gamma = 0.75$

In Fig. 2 are shown the trajectories of all oscillators. It may be appreciated that they all synchronise in frequency, but the oscillations have different amplitudes and there are two groups of in-phase oscillators. This is also appreciated from Fig. 3, which shows the evolution of the synchronisation errors as defined in (17) and from the plot on the left in Fig. 4 where the trajectories are depicted on the complex plane.

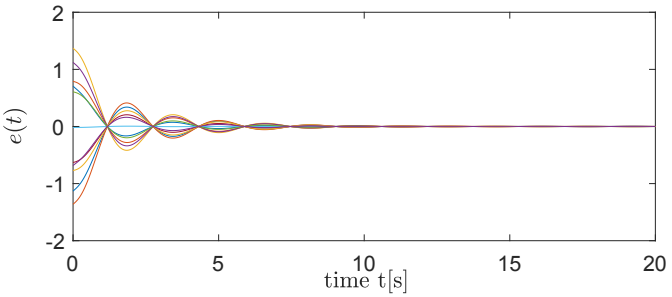

Fig. 3. Synchronisation error $e(t)$ with e as in (17)

The behaviour of the three oscillators composing the reduced-order network (12) is depicted in Fig. 5.

Three different behaviours appear: one, generated by the mode related by the null eigenvalue of L_N, is equivalently equal to 0 since the initial condition is set at the origin, which is an equilibrium. Two other modes, related to the conjugate eigenvectors v_1 and v_2, generate trajectories which are opposite to one another.

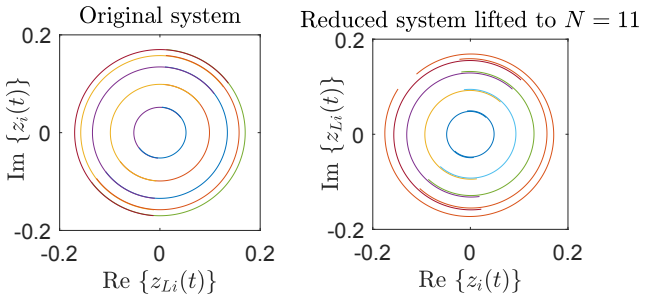

Fig. 4. Oscillators' trajectories on the complex plane for the network of 11 oscillators (left plot) and for their behaviour reconstituted from that of the reduced-order network (right plot)

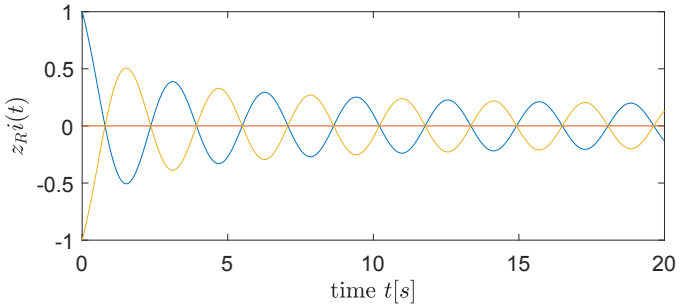

Fig. 5. Simulations results of $N_R = 3$ reduced order system

Note that the oscillators of the original network of dimension 11 do not necessarily synchronise their behaviour with any of the three oscillators described by (12). However, the behaviour of each $z_i(t)$ in (1) may be reconstructed, asymptotically, using the responses of the reduced-order network. The reconstituted behaviour, against time, is shown in Fig. 6 and on the complex plane in the right plot on Figure 4.

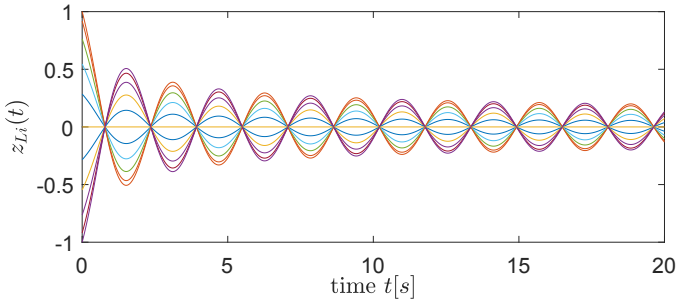

Fig. 6. Simulations results for the reduced system lifted to $N = 11$

In Fig. 7 are shown the oscillators' responses with the initial conditions as in (20) and with high coupling strength, $\gamma = 2.5$. In this case, all the oscillators' trajectories converge exponentially to zero. This is explained by the fact that they approach the dynamics of the average system in (7) with zero initial condition $z_m(0) = 0$, which corresponds to the average of $z_i(0)$ in (20).

Finally, to illustrate the influence of the initial conditions, in Fig. 8 we show the response of the oscillators, with coupling gain $\gamma = 2.5$ and in which case, $z_6(0) = 1 + i$. Asymptotically, all the systems converge to the trajectory of one averaged oscillator, thereby achieving dynamic consensus. In addition, the asymptotic behaviour of the network may also be reconstructed from that of the averaged motion, from $t \approx 1$s.

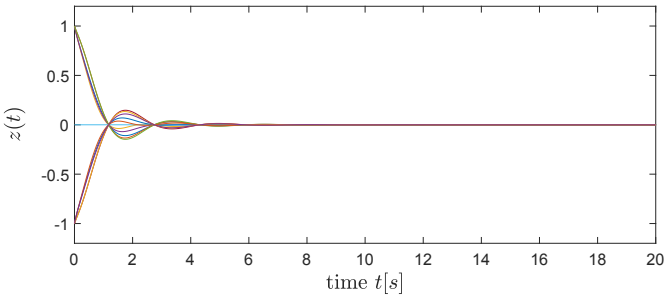

Fig. 7. Oscillators response with $\gamma = 2.5$ with initial conditions as in (20)

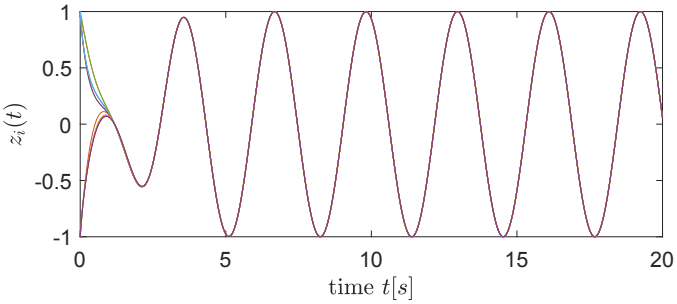

Fig. 8. Oscillators response with $\gamma = 2.5$ with initial conditions as in (20), except for $z_6(0) = -1$

4. CLOSING REMARKS

Our results illustrate how to reconstruct the asymptotic behaviour of complex networked systems, with specific topology, via a model-reduction. Undergoing research is aimed at analysing the reduced-order model and considering other network topologies.

Abstract: Building on the strong connection between dissipativity theory and Integral Quadratic Constraints, we show how feedback loops involving neural networks can be analysed computationally with respect to both stability and robustness. A basic building block is the ReLU (Rectified Linear Unit) nonlinearity and we present both old and new dissipation inequalities that are useful for its analysis.

Keywords: Neural networks, robustness analysis, relaxations, stability of nonlinear systems, convex optimization.

1. INTRODUCTION

The pioneering work on dissipativity in Willems (1972) has been a cornerstone of systems analysis ever since. Many extensions were developed over the years and more recently the concept Integral Quadratic Constraint (IQC) Megretski and Rantzer (1997) emerged in an effort to unify dissipativity analysis with frequency domain methods dating back to Yakubovich (1967). Many IQCs can be expressed as dissipativity inequalities with an explicitly given non-negative storage function. For others, the non-negativity is replaced by a more relaxed constraint and the storage function may not be explicitly given. See Megretski et al. (2010).

In recent years, deep learning with neural networks has achieved impressive successes in many fields. Following in the footsteps of this progress, many groups have worked on robustness for systems involving neural networks. Neural networks are well-suited to the IQC formalism and previous work along this line draws on old results. Static properties like reachability were treated in Hu et al. (2020) and Lipschitz constant estimation was carried out in Fazlyab et al. (2019), which can be used as one part in a larger analysis of robustness of the full system. The closed loop system can also be analysed as a whole as done in Yin et al. (2020), and provides guarantees of global stability in the presence of uncertain dynamics. The IQC formalism has also been used in other contexts to provide other kinds of guarantees, and those kinds of guarantees would transfer to systems with neural networks. The limitation is that the IQC-framework assumes all nonlinear elements, as well as all properties, to be expressed in terms of quadratic forms, limiting the number of questions that the framework can answer. The strength, is that guarantees are global and can be verified even in the face of adversarial attacks on the network.

Here, and in Grönqvist and Rantzer (2022), we present a larger class of constraints that can be used for neural networks, than used in the works cited above. We also provide examples showing that a larger library of constraints can enable stricter bounds on the behaviour of neural networks, and that there is a trade-off in the choice of constraints. After introducing neural networks, we describe three different analysis settings, followed by a listing of the available constraints in each analysis setting. Finally, we present two small examples, highlighting the different levels of expressiveness that can be achieved by choosing an analysis setting and a selection of constraints.

$$\zeta_0 \xrightarrow[b_1]{W_1} \xi_1 \xrightarrow{\varphi} \zeta_1 \xrightarrow[b_2]{W_2} \xi_2 \xrightarrow{\varphi} \zeta_2 \to \cdots \to \zeta_N \xrightarrow[b_{N+1}]{W_{N+1}} \zeta_{N+1}$$

Fig. 1. A neural network, with input ζ_0, output $\zeta_{N+1} = W_{N+1}\zeta_N + b_{N+1}$, and a sequence of N hidden layers with affine mappings $\xi_k = W_k\zeta_{k-1} + b_k$ and nonlinear mappings $\zeta_k = \varphi(\xi_k)$, for $k = 1, \ldots, N$.

2. NEURAL NETWORKS

Figure 1 shows a simple feedforward neural network and lists the defining equations. More generally, the network can be a graph with nodes representing either affine relations or nonlinear activation functions. Activation functions are often scalar and applied componentwise.

The internal variables, ξ_k and ζ_k, are vectors, and we may have several neural networks in our closed loop system. We assemble all components from all variables $\xi_1, \ldots, \xi_N$ into a large vector ξ, and all components from $\zeta_1, \ldots, \zeta_N$ into a large vector ζ, and we write

$$\zeta = \varphi(\xi) \tag{1}$$

where we now have a componentwise application of the nonlinear function φ on a vector with a large number of components.

This structure is described as a repeated nonlinearity, and enables us to find a large set of quadratic constraints to help us obtain guarantees for systems with neural networks.

We note that neural network typically contain affine layers, defined by $\xi_k = W_k\zeta_{k-1} + b_k$ that can be cumbersome in some analyses. We discuss how we handle this issue using the relative setting in section 4.

3. FORMS OF CONSTRAINTS

For the IQC formalism, there are two kinds of blocks in a system. One kind includes linear time invariant systems, and all other blocks are characterized by quadratic inequalities that hold for their inputs and outputs. We describe three kinds of constraints here.

Static constraints, hard IQCs and soft IQCs take the forms

$$\begin{aligned} \begin{pmatrix}\xi(t)\\ \zeta(t)\end{pmatrix}^\top G \begin{pmatrix}\xi(t)\\ \zeta(t)\end{pmatrix} \geq 0 \ \text{ for all } t \\ \int_{t=0}^{T} \begin{pmatrix}\xi(t)\\ \zeta(t)\end{pmatrix}^\top G \begin{pmatrix}\xi(t)\\ \zeta(t)\end{pmatrix} dt \geq 0 \ \text{ for all } T \\ \int_{-\infty}^{\infty} \begin{pmatrix}\hat\xi(i\omega)\\ \hat\zeta(i\omega)\end{pmatrix}^\star \hat G(i\omega) \begin{pmatrix}\hat\xi(i\omega)\\ \hat\zeta(i\omega)\end{pmatrix} d\omega \geq 0. \end{aligned} \tag{2}$$

A static quadratic constraint automatically gives a hard IQC and a hard IQC automatically gives a soft IQC, with the same matrix G used in all cases. We typically have constraints on the structure of G, that reflect the quadratic inequalities they are based on.

We will only list IQCs for the continuous time case, but analogous forms for the discrete time case exist, except for the Popov IQC. The constraints are then combined using the S-procedure to provide guarantees for the neural network or closed loop system, as used in our examples, and as discussed at length in Megretski and Rantzer (1997) and Megretski et al. (2010).

3.1 From Static to Dynamic

There are several ways to construct IQCs from quadratic inequalities, beyond the immediate hard and soft IQCs obtained from static inequalities as described above. Nonnegative expressions in ξ and ζ can be combined using nonnegative matrices or convolution kernels to form IQCs. The two special constructions in our lists, the Popov and Zames-Falb IQCs, are well-established results from the literature, and discussed in more detail in, e.g., Megretski et al. (2010); D'Amato et al. (2001); Safonov and Kulkarni (2000).

4. ANALYSIS SETTINGS

We consider three different analysis settings, and they give us different sets of constraints. We refer to them as the absolute, the relative and the incremental setting, respectively.

The absolute setting uses constraints on the mapping from inputs ξ to outputs ζ.

The relative setting considers a known reference input $\xi^{(\mathrm{ref})}$, that often represents a steady state of the dynamics. It considers constraints on the deviations from the reference signals, in both inputs and output, $\Delta\xi = \xi - \xi^{(\mathrm{ref})}$ and $\Delta\zeta = \zeta - \zeta^{(\mathrm{ref})}$. The nonlinearity from $\Delta\xi$ to $\Delta\zeta$ is now no longer repeated, as we have

$$\Delta\zeta = \varphi\left(\Delta\xi + \xi^{(\mathrm{ref})}\right) - \varphi\left(\xi^{(\mathrm{ref})}\right), \tag{3}$$

which depends on the reference value.

For nonzero reference values, we consider instead the mapping from $\frac{\Delta\xi}{\left|\xi^{(\mathrm{ref})}\right|}$ to $\frac{\Delta\zeta}{\left|\xi^{(\mathrm{ref})}\right|}$ and find that for reference values of the same sign, this is a repeated nonlinearity sharing many of the properties of the relu function. As the reference values are constant and known in advance, this simple rescaling of our signals allows us to use most of our IQCs from the absolute setting.

Referring back to the affine relations in the neural network layers, those relations become linear in the relative setting, which enables us to keep using most of our IQCs for netwoks with nonzero bias terms, b_k, in figure 1.

Lastly, in the incremental setting, we have two arbitrary inputs, $\xi^{(1)}$ and $\xi^{(2)}$, and we study the mapping from $\Delta\xi = \xi^{(1)} - \xi^{(2)}$ to $\Delta\zeta = \zeta^{(1)} - \zeta^{(2)} = \varphi(\xi^{(1)}) - \varphi(\xi^{(2)})$, without any further assumptions on $\xi^{(1)}$ and $\xi^{(2)}$. This has two consequences, compared to the incremental setting. Firstly, we cannot use the rescaling trick to get repeated nonlinearities, and, secondly, we no longer have a function, as knowing $\Delta\xi = 1$ is not sufficient to tell us what $\Delta\zeta$ is.

5. ACTIVATION FUNCTIONS

Several activation functions are used in real networks, but many networks contain almost only relu or leakyrelu activations, with a single softmax nonlinearity in the last layer.

We focus on the relu nonlinearity and note that this enables the corresponding analysis of the very common leakyrelu nonlineary, as the latter satisfies

$$\mathrm{leakyrelu}_a(x) = \max(ax, x) = ax + (1-a)\,\mathrm{relu}(x), \tag{4}$$

where a is a constant that is known in advance.

5.1 Relu

For a single scalar relu, $y = \mathrm{relu}(x) = \max(0, x) \in \mathbb{R}$, we have the basic properties

$$\begin{aligned} y = 0 \ \text{ if } x \leq 0 \\ y \geq 0 \ \text{ and } \ y - x \geq 0 \\ (y-x)y = 0. \end{aligned} \tag{5}$$

For a pair of relus, $y_i = \mathrm{relu}(x_i)$ and $y_j = \mathrm{relu}(x_j)$, we have a sector condition, thanks to a rate-limit and to $\mathrm{relu}(0) = 0$,

$$(y_i - y_j)((x_i - x_j) - (y_i - y_j)) \geq 0. \tag{6}$$

The above relations form the basis for our IQCs.

We now discuss a new form of constraint for the repeated relu-nonlinearity. For our pair of relu operations, we have the linear inequalities of equation (5), and any pairwise product is a quadratic inequality, such as, e.g.,

$$(y_i - x_i)(y_j - x_j) \geq 0 \tag{7}$$

We can convolve with a kernel $h(t)$ such that $h(t) \geq 0$ for all t, to obtain the IQC (where a hat denotes a Laplace transform)

$$\int_{-\infty}^{\infty} (\hat{y}_i(i\omega) - \hat{x}_i(i\omega))^\dagger \hat{h}(i\omega)(\hat{y}_j(i\omega) - \hat{x}_j(i\omega))\, d\omega \geq 0. \quad (8)$$

Including all pairwise producs of linear inequalities, and writing it in terms of our vectors ζ and ξ with a large number of components, we have the IQC

$$\int_{-\infty}^{\infty} \begin{bmatrix} \hat{\zeta}(i\omega) - \hat{\xi}(i\omega) \\ \hat{\zeta}(i\omega) \end{bmatrix}^\dagger \hat{h}(i\omega) \begin{bmatrix} \hat{\zeta}(i\omega) - \hat{\xi}(i\omega) \\ \hat{\zeta}(i\omega) \end{bmatrix} d\omega \geq 0. \quad (9)$$

5.2 Other activation functions

While we focus on leakyrelu and relu as the most common activation functions, other nonlinearities exist, and are primarily of two kinds.

The first kind is a repeated nonlinearity, much like the relu-case, but lacking some of the inequalities from section 5.1. They often satisfy a rate-limit, enabling some of our constraints to hold also for this class of activation functions.

The second kind is the softmax nonlinearity, which is not a repeated nonlinearity. Instead, it is a vector valued function, and it is nonvanishing for vanishing input. These two properties limit the set of constraints available.

6. CONSTRAINTS

We list static constraints and IQCs available to us for the repeated relu-nonlinearity. As discussed above, this enables a corresponding set of constraints on the leakyrelu, thanks to equation (4).

This section assumes a repeated relu-nonlineariy whose input is a vector or vector valued signal. These may be chosen as any subset of the relu-units in the system, i.e., of the vectors ξ and ζ from equation 1.

6.1 Absolute

We look for positive semidefinite quadratic forms in the input and output of the repeated relu-unit.

(1) We can use the quadratic equality of equation (5), multiplied by an arbitrary real number, as a static constraint, and we obtain the corresponding hard and soft IQCs.
(2) As discussed in section 5.1, products of the linear inequalities give us static and dynamic constraints when multiplied with nonnegative coefficients or convolved with nonnegative kernels.
(3) The rate-limit inequalities, equation (6), are also quadratic, and we can use them for any pair of relu-units, giving us static and dynamic constraints.
(4) The Popov IQC is a special construct that we can use for our relu-nonlinearity
(5) There have been several works based on ideas of Zames and Falb, and,we use the results from D'Amato et al. (2001), which are formulated as IQCs, but also give us static constraints as a special case if we set the frequency dependent parts to zero.

6.2 Relative

In the relative setting, we have a set of reference values, as discussed in section 4, and we rescale our inputs and outputs into three sets of repeated nonlinearities, as described in that section.

For rate-limits, we use the full set of inputs and outputs, but for some other constructions, we use the three sets as separate sets of repeated nonlinearities.

(1) The relu units still satisfy linear inequalities in the relative setting, and we again multiply them with nonnegative parameters or convolve with nonnegative kernels to obtain a large family of constraints.
(2) The rate-limit still holds, within each of our three sets of repeated nonlinearties, analogous to the absolute setting.
(3) The rate-limit can be used in an additional way in the relative setting, as every signal is a difference between actual signal and reference signal.
(4) Within each of our three sets of repeated nonlinearities, the results of D'Amato holds, and gives us static and dynamic constraints.

6.3 Incremental

In the incremental case, the rate-limit is our only remaining source of inequalities, and only in a single variant. The linear inequalities no longer hold for the difference between arbitrary signals, and the Zames-Falb construction cannot be used, as our nonlinearity is not a function, as mentioned in section 4.

6.4 Other Activation Functions

Many other activation functions satisfy rate-limits, and the rate-limit related constraints hold for these as well. The corresponding IQCs also hold, similar to the case for the relu-nonlinearity.

As described in section 5.2, the set of constraints for the softmax function is restricted in a different way, due to its special structure.

7. SELECTION OF CONSTRAINTS

The library of constraints is provided here with the aim of completeness, but in practical applications, a selection of which constraints to use is often needed. In particular, for deep neural networks, even the most efficient SDP solvers will struggle as the network grows larger. This can be alleviated by selecting constraints that lead to sparse SDP problems, and we have found it useful to include constraints that couple nonlinearites from adjacent blocks in the block-diagram.

In the neural network, this amounts to constraints that mix signals from adjacent layers, and for a more general setup, it will also mix, e.g., the signals in the first layer of the neural network with the nonlinear block before it, if such constraints are available.

This retains sparsity in the problem, and keeps most of the expressiveness of the IQC formalism.

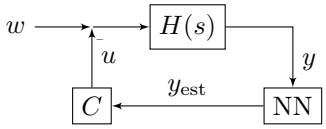

Fig. 2. Block diagram of system used in Closed Loop example.

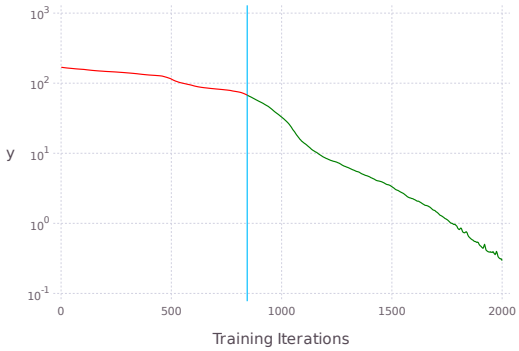

Fig. 3. Training loss vs. number of gradient steps, with guaranteed stability achieved after 884 steps.

8. EXAMPLE

8.1 Static Gain of a Deep Network

We consider a small network defined by

$$\begin{aligned} x_1 &= \begin{pmatrix} 1 \\ -1 \end{pmatrix} y_0; \quad y_1 = \text{relu}(x_1) \\ x_2 &= \begin{pmatrix} 1 & -1 \end{pmatrix} y_1 \end{aligned} \tag{10}$$

where the input y_0 and output x_2 are both scalar.

The network was designed so that $x_2 = y_0$ in all cases, and we will compare analyses of the static gain of this network in the absolute and incremental settings.

In the incremental setting, all we have access to is the rate-limit, and we cannot exclude that $\text{relu}(x) = x$ might hold. In that case, the static gain of the network would be 2, and our analysis is unable to provide a lower bound. In particular, for a deep network that is a repetition of the above structure, the gain bounds of the layers are multiplied together to a gain bound that grows exponentially with the depth of the network.

In the absolute setting, we have a more expressive set of constraints, allowing us to obtain a gain bound of 1, and the gain bound no longer grows exponentially with the depth of the network.

8.2 Closed Loop Stability

We consider a double integrator controlled by a stabilizing PD-controller. The output is filtered through a neural network before passing to the controller. Our network structure is a few-layer variant of the network from the previous example, with the first-layer weights fixed, and with remaining weights trained from random initialization. We use the main theorem of Megretski and Rantzer (1997) together with the KYP lemma discussed in Rantzer (1996) to obtain closed-loop stability guarantees based on the IQC formalism.

Our training progress is shown in figure (3) and sees decreasing loss for a large number of iterations, with our use of the IQC framework giving us guaranteed global stability after 884 gradient steps.

9. CONCLUSION

We provide a list of constraints that can be used for obtaining guarantees for systems involving neural networks. We discuss new constraints, as well as many from previous literature.

We discuss three analysis settings, and provide two small examples showing that we can obtain guarantees using the formalism, and that the absolute setting can provide stronger guarantees than the incremental setting.

Abstract: We introduce a new numerical method to approximate the solutions of a class of static Hamilton-Jacobi-Bellman equations arising from minimum time optimal control problems. We rely on several grid approximations, and look for the optimal trajectories by using the coarse grid approximations to reduce the search space for the optimal trajectories in fine grids. This may be thought of as an infinite dimensional version, for PDE, of the "highway hierarchy" method which has been developed to solve discrete shortest path problems. We obtain, for each level, an approximate value function on a sub-domain of the state space. We show that the sequence obtained in this way does converge to the viscosity solution of the HJB equation. Moreover, the number of arithmetic operations that we need to obtain an error of $O(\varepsilon)$ is bounded by $\tilde{O}(1/\varepsilon^{\frac{2d}{1+\beta}})$, to be compared with $\tilde{O}(1/\varepsilon^{2d})$ for ordinary grid-based methods. Here $\beta \in (0,1]$ depends on the "stiffness" of the value function around optimal trajectories, and the notation $\tilde{O}$ ignores logarithmic factors. Under a regularity condition on the dynamics, we obtain a bound of $\tilde{O}(1/\varepsilon^{(1-\beta)d})$ operations, for $\beta < 1$, and this bound becomes $O(|\log\varepsilon|)$ for $\beta = 1$. This allowed us to solve HJB PDE of eikonal type up to dimension 7.

Keywords: Minimum Time, Eikonal equation, Fast Marching Method, Highway Hierarchies.

1. INTRODUCTION

We consider the minimal time optimal control problem, consisting in finding a trajectory minimizing the travel time between two points. The minimal time, together with optimal trajectories, can be obtained by solving a Hamilton-Jacobi-Bellman (HJB) partial differential equation (PDE) of eikonal type. Such an equation is obtained from the dynamic programming principle, and has to be thought in viscosity sense, see Fleming and Soner (2006).

One of the most famous methods to solve the eikonal PDE is the fast-marching method, see Sethian (1996). Though it is computationally efficient, it is still a grid-based method, and hence suffers from the "curse of dimensionality" of the dynamical programming approach. Our algorithm intends to bypass this difficulty by narrowing the search space around optimal trajectories, hence solving a series of PDE, in which the domain is becoming smaller and smaller with the discretize grid becoming finer and finer. This is inspired by the recent development of the "Highway Hierachies" algorithm, which applies to shortest path problems in discrete time and in discrete space, see Sanders and Schultes (2012).

The idea of our algorithm is as follows: instead of computing the optimal trajectories directly in the whole domain, we first find a subdomain which contains the optimal trajectories, then do the search in such a subdomain. This will be achieved by using coarse and fine grids discretization method. We first use a coarse grid to discretize the whole domain, and do a partial fast marching search in this coarse grid. Then, we find a subdomain which contains the true optimal trajectories, by using the approximate value function on the coarse grid, together with the error bound. Finally we use a finer grid to discretize the subdomain, and perform a fast marching search on this fine grid. We repeat this operation, considering different levels of finer and finer grids.

We show that using our algorithm, the final approximation error is as good as the one obtained by directly discretizing the whole domain with the finest grid. Moreover, the number of elementary operations and the size of the memory needed to get an error of ε are considerably reduced. Indeed, let $\kappa(M) := M \log M$, and recall that the fast marching method implemented in a d-dimensional grid with M points requires a number of arithmetic operations of order $\kappa(M)K_d$, in which the constant $K_d \in [2d, 2^d]$ depends on the stencil of the discretization used for the fast marching method. For our method, the number of arithmetic operations is in the order of $\kappa((\frac{1}{\varepsilon})^{\frac{2d}{1+\beta}})C^d$, where $C > 1$ and $\beta \in (0,1]$ are fixed constants (see Section 5), to be compared with $\kappa((\frac{1}{\varepsilon})^{2d})K_d$ for conventional grid-based methods. Moreover, under a regularity condition on the dynamics, our complexity bound reduces to an order of $\kappa((\frac{1}{\varepsilon})^{(1-\beta)d})C^d$ for $\beta < 1$, and $\kappa(d|\log\varepsilon|)$ for $\beta = 1$.

2. HAMILTON-JACOBI EQUATION FOR MINIMUM TIME PROBLEM

Let Ω be an open, bounded domain in $\mathbb{R}^n$. Let S_1 be the unit sphere in $\mathbb{R}^n$, i.e., $S_1 = \{x \in \mathbb{R}^n, \|x\| = 1\}$, where $\|\cdot\|$ denotes the Euclidean norm. Let $\mathcal{A} = \{\alpha : [0, +\infty] \to S_1 : \alpha(\cdot)$ is measurable$\}$ denote the set of controls. We denote

by f the speed function, and assume the following basic regularity assumption:

Assumption 2.1.

i. $f : \overline{\Omega} \times S_1 \to (0, +\infty)$ is continuous.
ii. There exists positive constants $L_f, \gamma, L_{f,\alpha}$ such that $|f(x,\alpha) - f(x',\alpha)| \leqslant L_f|x - x'|$, and $|f(x,\alpha) - f(x,\alpha')| \leqslant L_{f,\alpha}|\alpha - \alpha'|^\gamma, \forall x, x' \in \Omega, \alpha, \alpha' \in S_1$.

Our goal is to find the minimum time necessary to travel from the source point $x_{\rm src} \in \Omega$ to the destination point $x_{\rm dst} \in \Omega$, and the optimal trajectories, together with the optimal control α. We consider the controlled dynamical system:

$$\dot{x}(t) = f(x(t), \alpha(t))\alpha(t) \ . \tag{1}$$

We denote by $x_{\alpha,x_{\rm src}}$, or simply x_α, the solution of (1) with $\alpha \in \mathcal{A}$, such that $x_\alpha(0) = x_{\rm src}$ and $x_\alpha(s) \in \overline{\Omega}$ for all $0 \leqslant s \leqslant t$. We restrict the set of control trajectories so that the state x_α stays inside the domain $\overline{\Omega}$ forever, i.e., we consider the following set of admissible controls trajectories:

$$\mathcal{A}_{\Omega,x_{\rm src}} := \{\alpha \in \mathcal{A} \mid x_{\alpha,x_{\rm src}}(s) \in \overline{\Omega}, \forall s \geqslant 0\},$$

and we further assume $A_{\Omega,x_{\rm src}} \neq \emptyset$. In other words, the structure of $A_{\Omega,x_{\rm src}}$ is adapted to the state constraint $x_\alpha(s) \in \overline{\Omega}$. By doing so, the minimum time function can be defined as

$$T_{\rm s\to}(x) = \inf_{\alpha \in \mathcal{A}_{\Omega,x_{\rm src}}} \inf\{\tau \mid x_{\alpha,x_{\rm src}}(\tau) = x\} \ .$$

Consider the Kruzkov change of variable:

$$v_{\rm s\to}(x) = 1 - e^{-T_{\rm s\to}(x)} \ .$$

Then, $v_{\rm s\to}(x)$ is the viscosity solution of the following state constrained HJB equation:

$$\begin{cases} F(x, v_{\rm s\to}(x), Dv_{\rm s\to}(x)) = 0, \ x \in \Omega, \\ F(x, v_{\rm s\to}(x), Dv_{\rm s\to}(x)) \geqslant 0, \ x \in \partial\Omega, \\ v_{\rm s\to}(x_{\rm src}) = 0 \ . \end{cases} \tag{2}$$

where $F(x, r, p) = -\min_{\alpha \in S_1}\{-p \cdot f(x,\alpha)\alpha + 1 - r\}$.

3. THE OPTIMAL TRAJECTORIES OF THE CONTINUOUS SPACE PROBLEM

In this section we show how to reduce the state space Ω of the original minimum time problem, while preserving the optimal trajectories.

Definition 3.1. For every $x, y \in \Omega$, we denote by $\Gamma(x,y)$ the set of *geodesic points* from x to y, defined as

$$\Gamma(x,y) = \{x_{\alpha,x}(s) \mid s \in [0,\tau], \alpha \in \mathcal{A}_{\Omega,x}, x_{\alpha,x}(\tau) = y \text{ and } \int_0^\tau e^{-s}ds = \inf_{\tau \geqslant 0, \alpha \in \mathcal{A}_{\Omega,x},\ x_{\alpha,x}(\tau)=y}\{\int_0^\tau e^{-s}ds\}\}.$$

In other words, z is a geodesic point between x and y if an optimal trajectory from x to y passes through z.

Let us consider a new minimal time optimal control problem ending in $x_{\rm dst}$ with the same dynamics as (1), but starting at any $x \in \overline{\Omega}$. The associated minimal time function is

$$T_{\to\rm t}(x) = \inf_{\alpha \in \mathcal{A}_{\Omega,x}} \inf\{\tau \mid x_{\alpha,x}(\tau) = x_{\rm dst}\} \ .$$

By doing so, we have $T_{\rm s\to}(x_{\rm dst}) = T_{\to\rm t}(x_{\rm src})$, and we denote $\tau^* = T_{\rm s\to}(x_{\rm dst}) = T_{\to\rm t}(x_{\rm src})$. We then use the same change of variable technique to get $v_{\to\rm t}(x) = 1 - e^{-T_{\to\rm t}(x)}$.

Let us denote:

$$\mathcal{F}_v(x) := v_{\rm s\to}(x) + v_{\to\rm t}(x) - v_{\rm s\to}(x)v_{\to\rm t}(x) \ .$$

Let $\Gamma^* = \Gamma(x_{\rm src}, x_{\rm dst})$ denote the union of all optimal trajectories from $x_{\rm src}$ to $x_{\rm dst}$. Then, by the dynamic programming principle, the following result holds :

Lemma 3.1. We have

$$v_{\rm s\to}(x_{\rm dst}) = v_{\to\rm t}(x_{\rm src}) = \inf_{y \in \Omega} \mathcal{F}_v(y) \ . \tag{3}$$

Moreover, if Γ^* is not empty, then for every $x \in \Gamma^*$ we have $\mathcal{F}_v(x) = v_{\rm s\to}(x_{\rm dst})$, that is x is optimal in (3). If there exists an optimal trajectory between any two points of Ω, then x is optimal in (3), that is $\mathcal{F}_v(x) = v_{\rm s\to}(x_{\rm dst})$ if and only if $x \in \Gamma^*$.

Let us now consider an open subdomain of Ω, $\mathcal{O}_\eta \subseteq \Omega$, determined by a parameter $\eta > 0$, and defined as follows:

$$\mathcal{O}_\eta = \{x \in \Omega \mid \mathcal{F}_v(x) < \inf_{y \in \Omega}\{\mathcal{F}_v(y) + \eta\}\} \ . \tag{4}$$

We intend to reduce the state space of our original optimal control problem from Ω to $\mathcal{O}_\eta$. More precisely, we consider a new optimal control problem with the same dynamics, but we restrict the controls so that the state x_α stays inside the domain $\mathcal{O}_\eta$, leading to the new set of controls:

$$\mathcal{A}_{\eta,x_{\rm src}} := \{\alpha \in \mathcal{A} \mid x_{\alpha,x_{\rm src}}(s) \in \overline{O_\eta}, \forall s \geqslant 0\}.$$

Let $v^\eta_{\rm s\to}(x)$ denote the value function of the new problem, then $v^\eta_{\rm s\to}(x)$ is a viscosity solution of the following HJB equation:

$$\begin{cases} F(x, v^\eta_{\rm s\to}(x), Dv^\eta_{\rm s\to}(x)) = 0, \ x \in O_\eta, \\ F(x, v^\eta_{\rm s\to}(x), Dv^\eta_{\rm s\to}(x)) \geqslant 0, \ x \in \partial O_\eta, \\ v^\eta_{\rm s\to}(x_{\rm src}) = 0 \ . \end{cases} \tag{5}$$

Then we have the following result:

Proposition 3.1. If Γ^* is not empty, then $\Gamma^* \subseteq \mathcal{O}_\eta$, and for all $x \in \Gamma^*$ we have $v_{\rm s\to}(x) = v^\eta_{\rm s\to}(x), v_{\to\rm t}(x) = v^\eta_{\to\rm t}(x)$.

The above results express properties of exact optimal trajectories. We will also consider approximate, $\delta-$optimal, trajectories:

Definition 3.2. For every $x, y \in \Omega$, for any $\delta > 0$, we denote $\Gamma_\delta(x,y)$ the set of $\delta-$geodesic points from x to y , defined as :

$$\Gamma_\delta(x,y) = \{x_{\alpha,x}(s) \mid s \in [0,\tau], \alpha \in \mathcal{A}_{\Omega,x}, x_{\alpha,x}(\tau) = y, \text{ and } \int_0^\tau e^{-s}ds \leqslant \inf_{\tau \geqslant 0, \alpha \in \mathcal{A}_{\Omega,x},\ x_{\alpha,x}(\tau)=y}\{\int_0^\tau e^{-s}ds\} + \delta\} \ .$$

Let $\Gamma^*_\delta = \Gamma_\delta(x_{\rm src}, x_{\rm dst})$ denote the set of all $\delta-$geodesic points from $x_{\rm src}$ to $x_{\rm dst}$. Then we have the following results:

Lemma 3.2. For every $\eta > \delta > 0$, we have $\Gamma^*_\delta \subseteq \mathcal{O}_\eta$.

Lemma 3.3. For every $\eta > 0$, there exists $\delta' < \eta$ such that $\mathcal{O}_\eta \subseteq \Gamma^*_{\eta+\delta'}$.

The above two lemmas entail that the sets of $\delta-$geodesic points and $\mathcal{O}_\eta$ constitute two equivalent families of neighborhoods. Thanks to these properties, we establish the following result :

Theorem 3.1. For every $x \in \Gamma^*_\delta$, we have

$$v^\eta_{\rm s\to}(x) = v_{\rm s\to}(x), \quad v^\eta_{\to\rm t}(x) = v_{\to\rm t}(x) \ .$$

Thus, if we are only interested to find $v_{s\to}(x_{\text{dst}})$ and the optimal trajectories between x_{src} and x_{dst}, we only need to solve the reduced problem (5) in the subdomain $\mathcal{O}_\eta$. This is equivalent to solving the original problem in Ω as long as $\mathcal{O}_\eta$ contains the optimal trajectories of this problem.

4. THE MULTI-LEVEL FAST-MARCHING ALGORITHM

4.1 Motivation

The main idea of our algorithm is based on the property proposed above. Instead of computing the optimal trajectories directly, we first find an approximate subdomain of O_η by applying the fast marching search in a coarse grid, with relaxed accuracy and error requirements. Then, we further discretize O_η using a finer grid, and perform a search on this fine grid.

4.2 The Update Operator for The Fast-Marching Search

Based on Assumption 2.1, there exist constants $\underline{f}, \overline{f}$ such that: $0 < \underline{f} \leqslant f(x,\alpha) \leqslant \overline{f} < \infty$. We define $\Upsilon := \frac{\overline{f}}{\underline{f}} \geqslant 1$, and observe that this constant can be interpreted as a measure of anisotropy of the minimum time problem.

Let $X = \Omega \cap (h\mathbb{Z})^d$, we define $V_{s\to}$ as the approximation of the value function $v_{s\to}$ in X. Let $x \in X$, for any I adjacent nodes $x_1, x_2, ..., x_I$ in the grid X, we define $x_\rho = \sum_{i=1}^I \rho_i x_i$ for $\rho \in \Delta^I = \{\rho_i \geqslant 0, \sum_{i=1}^I \rho_i = 1\}$. Let us denote $d(\rho) = \|x_\rho - x\|$ and $\alpha_\rho = \frac{x_\rho - x}{\|x_\rho - x\|}$, which are the distance and the direction from x to x_ρ.

Let $\mathcal{I} = \{1, 2, ..., I\}$. Let $V_{s\to}(x; (x_i)_{i\in\mathcal{I}})$ denote the approximate value $V_{s\to}(x)$ of $v_{s\to}(x)$ depending on the nodes $(x_i)_{i\in\mathcal{I}}$. Then, applying a semi-Lagrangian discretization scheme, we have:

$$V_{s\to}(x; (x_i)_{i\in\mathcal{I}}) = \min_{\rho\in\Delta^I}\{(1 - \frac{d(\rho)}{f(x,\alpha_\rho)}) \sum_i (\rho_i V_{s\to}(x_i)) + \frac{d(\rho)}{f(x,\alpha_\rho)}\} .$$

Let us denote $N(x)$ the set of neighborhood nodes of x, defined as follows:

$$N(x) := \{x_j \in X \mid \exists x_k \in X, s.t. \ \exists \tilde{x} \in [x_j, x_k],\ \|\tilde{x} - x\| \leqslant \Upsilon h\},$$

where we use $[a, b]$ to denote the line segment between a and b. Then, the update operator for the value function in the fast-marching method is as follows:

$$\mathcal{U}(V_{s\to}(x)) := \min\{V_{s\to}(x), \min_{(x_i)_{i\in\mathcal{I}}\in N(x)} V_{s\to}(x; (x_i)_{i\in\mathcal{I}})\} .$$

4.3 The Algorithm

Two Level Fast Marching. We start by describing the special case of the algorithm with only two levels of grid. The algorithm consists of three main steps: Step 1. Discretize Ω using the grid X^H, and find a good $O_\eta^{H,I} \subseteq \Omega$. Step 2. Discretize $O_\eta^{H,I}$ using the fine grid O_η^h. Step 3. Doing a fast marching search in grid O_η^h. We give the details of the first two steps:

Step 1, discretization in coarse grid. We start with the full domain Ω. Let $X^H = \Omega \cap (H\mathbb{Z})^d$. Without loss of generality, we assume $x_{\text{src}}, x_{\text{dst}} \in X^H$.

By doing a fast marching search in X^H starting from x_{src} and x_{dst} respectively, we get the numerical approximation $V_{s\to}^H$ for $v_{s\to}$, and $V_{\to t}^H$ for $v_{\to t}$. We use the approximate value functions $V_{s\to}^H$ and $V_{\to t}^H$ to construct a subset of X^H, denoted by O_η^H:

$$O_\eta^H = \{x^H \in X^H \mid \mathcal{F}_{V^H}(x^H) \leqslant \min_{x^H\in X^H} \mathcal{F}_{V^H}(x^H) + \eta^H\}.$$

Then we construct a continuous analogue of the grid O_η^H, denoted by $O_\eta^{H,I}$, by defining the approximate value functions $V_{s\to}$ and $V_{\to t}$ on the whole domain using linear interpolation of the functions $V_{s\to}^H$ and $V_{\to t}^H$.

Step 2, discretization in fine grid-h. Let the finite set X^h denote the approximation of Ω with mesh step h. Without loss of generality we assume $x_{\text{src}}, x_{\text{dst}} \in X^h$. Let the finite set O_η^h be the approximation of $O_\eta^{H,I}$ with the mesh step h, given by:

$$O_\eta^h = \{x^h \in X^h \mid \exists x^H \in O_\eta^H : \|x^h - x^H\| \leqslant \max((H-h), h)\}.$$

Multi-Level Grids. The computation in the 2-level method above can be easily extended to the Multi-Level case. For each level l, we consider the optimal control problem in which the domain Ω is restricted to the fine-grid region $O_{\eta^{l-1}}^{H_{l-1},I}$ of the previous level $l-1$. Then, by applying the first two steps of the 2-level algorithm as above, we get a new domain, $O_{\eta^l}^{H_l,I}$, taken to be the new state space for the optimal control problem to be solved at the next level. At the end, we do a fast-marching search starting from x_{src} in the final fine grid.

4.4 Implementation

Algorithm 1 Two-Level Fast-Marching Method

Input: Mesh step of coarse and fine grids: H, h. The parameter η^H. The update operator for fast-marching method: $\mathcal{U}$. Start and end point: $x_{\text{src}}, x_{\text{dst}}$.
Output: Approximated value function: $V_{s\to}^h(x)$.

```
Do the fast-marching search staring from x_src and x_dst.
for Every node x^H ∈ X^H do
    if F_{V^H}(x) ⩽ min_{x^H∈X^H} F_{V^H}(x^H) + η^H then
        Set x^H as ACTIVE , store it's position.
    end if
end for
Begin with set FINE be empty.
for Every node x^H in the ACTIVE set do
    for Every x^h ∈ X^h : ‖x^h − x^H‖_∞ ⩽ max{H − h, h} do
        if x^h does not exist in set FINE then
            Add x^h in the set FINE, store it's position.
        end if
    end for
end for
Do fast-marching search starting from x_src in FINE.
```

In Algorithm 2, the selection of active nodes corresponds to Step 1 in the two-level algorithm, the selection of fine grid corresponds to Step 2 in the two-level algorithm.

Algorithm 2 Multi-Level Fast-Marching Method

Input: The parameter H_l, η_l, for $l \in \{1, 2, ..., N\}$. The update operator for fast-marching scheme: $\mathcal{U}$. Start and end point: $x_{\rm src}, x_{\rm dst}$.

Output: Approximated value function: $V^h_{\rm s\to}(x)$.

Let X^{H_1} be the COARSE-GRID.
for $l = 1$ to $N - 1$ **do**
    Do the partial fast marching search starting from $x_{\rm src}$ and $x_{\rm dst}$.
    Select the ACTIVE nodes from the COARSE-GRID.
    Select the set FINE nodes based on the ACTIVE nodes, as in Algorithm 1.
    Let the FINE be the new COARSE-GRID.
end for
Do the fast-marching search starting from $x_{\rm src}$ in FINE.

To implement efficiently these algorithms, we need to store the successive constrained grids $O^{H_l}_{\eta_{l-1}}$ in an effective way. In particular, we need to determine if a candidate point $x \in X^{H_l}$ is in the constrained grid $O^{H_l}_{\eta_{l-1}}$, and access to any of its neighbors, in time $O(1)$, while keeping the storage to be in the order of the size of the (constrained) grids. Moreover, we need to store only the points of X^{H_l} that are in the set $O^{H_l}_{\eta_{l-1}}$. These sets are much smaller compared to the sets X^{H_l}, so we maintain them as a collection of nodes (hash table) accessed through a hash function, with a linked list to handle collisions. Each node of the constrained grid $O^{H_l}_{\eta_{l-1}}$ is instrumented with informations providing the value at this node, its position in the grid, and additional variables needed to maintain the set of active nodes in the fast marching propagation. For points of X^{H_l} that are not in the constrained grid $O^{H_l}_{\eta_{l-1}}$, the hash function returns an empty pointer.

5. COMPUTATIONAL COMPLEXITY

In order to choose the parameters of our algorithm, we shall assume that the following error estimation for the approximate value function $V^h_{\rm s\to}$ holds for some $\theta > 0$:

$$|V^h_{\rm s\to}(x) - v_{\rm s\to}(x)| \leqslant Ch^\theta \ . \tag{6}$$

Indeed, by adapting the results of Capuzzo Dolcetta and Ishii (1984), using Assumption 2.1, one can obtain (6) with $\theta = 1/2$. If we further assume that f is of class $\mathcal{C}^2$, then we obtain (6) with $\theta = 1$.

So, our multi-level algorithm need to compute a numerical approximation with an error bound of same order in h, i.e., $\varepsilon \sim Ch^\theta$, for each level. In the two-level case, the two following parameters should be chosen:

1. The mesh step of the coarse grid H.
2. The parameter η^H, which should be big enough for O^H_η to contain the true optimal trajectories.

The estimation (6) give us a theoretical upperbound for η^H. Then, we have the following result:

Proposition 5.1. Assume there exists a finite number of optimal trajectories, and that the distance between $\mathcal{O}_\eta$ and Γ^* is in the order of η^β, with $0 < \beta \leqslant 1$. Then the total computational complexity of the two level fast marching algorithm is

$$\mathcal{C}(H, h) \sim \kappa((\frac{D}{H})^d + (\frac{(\eta^H)^\beta}{h})^{d-1}\frac{D}{h})$$

where D denotes the Euclidean distance from $x_{\rm src}$ to $x_{\rm dst}$.

Note that the "stiffness" parameter β can take any value in $(0, 1]$, as shown in further work. Regarding the error estimation we want to have in fine grid, the parameter H has an optimal value, which we can compute easily.

Similarly, optimizing the parameters of the multi-level fast marching method, and using the error estimation for $V^h_{\rm s\to}$, we get the following result:

Theorem 5.1. With same assumption as Proposition 5.1.

(i) In order to have an error bound ε, we shall take $h = C\varepsilon^2, H_l = C(H_{l+1})^{\frac{2^{l+1}-2}{2^{l+1}-1}}, \forall l \in \{2, 3, ..., N-1\}$. In this case the total computational complexity of our N-level algorithm is in the order of $(\frac{1}{\varepsilon})^{\frac{2}{1+\beta}d}$.

(ii) Suppose now $f \in \mathcal{C}^2$ or $\theta = 1$ in (6), and $\beta < 1$. Then, we shall take $h = C\varepsilon$ and $H_1 = Ch^{\frac{1}{N}}$, $H_l = C(H_{l+1})^{\frac{l}{l+1}}, \forall l \in \{1, 2, ..., N-1\}$. In this case, the total computational complexity of our N-level algorithm in the order of $(\frac{1}{\varepsilon})^{(1-\beta)d}$.

(iii) When $\beta = 1$, set $N = -\lceil d\log(h)\rceil$ and take $\{H_1, H_2, ..., H_{N-1}\}$ as proposed in (ii). Then, the total computational complexity of our algorithm reduces to $\kappa(-C^d d\log(\frac{1}{\varepsilon}))$.

We implememented the algorithm in C++, and ran it on a single core of a Quad-Core IntelCore I7 at 2.3Ghz, with 16Gb of memory. For an eikonal problem on a cubic domain, with obstacles, in dimension 4, with 5 grid levels, the algorithm ran in 59.2s, giving an error of 3.1%, to be compared with a time of 4241.9s for the classical fast marching method, with the same error. Classical fast marching ran out of time from dimension 5. Our algorithm solved a dimension 7 instance in 1300s, with 6 grid levels, leading to an accuracy of 7%.

6. CONCLUSION

We developed a multilevel fast marching algorithm, allowing one to solve an eikonal PDE by reducing the search space to neighborhoods of optimal trajectories. This yields improved complexity bounds, and solves examples of PDE up to dimension 7, for which it leads to a major speedup by comparison with ordinary grid based methods. We believe our method can be extended to HJB PDE of non-eikonal type. To do so, one needs to replace the fast marching sweeps by Bellman-type updates.

Redundant Coordinates and Generalized Momentum Maps in the Optimal Control of Constrained Mechanical Systems

Simeon Schneider, **Peter Betsch**

Institute of Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany (e-mail: simeon.schneider@kit.edu, peter.betsch@kit.edu).

Abstract: The optimal control of mechanical systems satisfies an optimal control version of Noether's theorem. Accordingly, there exist generalized momentum maps on the level of the optimal control problem which are conserved if the system has symmetry. For constrained mechanical systems different approaches to define the necessary optimality conditions are known. These approaches will be compared with respect to their capability to preserve the generalized momentum maps. In addition to that, a discretization approach will be proposed which is capable to preserve the generalized momentum maps.

Keywords: Optimal control, symmetry, constrained mechanical systems, differential-algebraic equations, structure-preservation.

1. INTRODUCTION

In the case of constrained mechanical systems the choice of coordinates plays a crucial role. In particular, the choice of coordinates affects the specific form of the equations of motion. In the case of minimal coordinates the equations of motion take the form of nonlinear ordinary differential equations (ODEs) and numerical methods to solve related optimal control problems are well established. On the other hand, the choice of redundant coordinates facilitates the description of general multibody systems. Due to the presence of holonomic constraints the equations of motion take the form of differential-algebraic equations (DAEs). Numerical methods for optimal control problems with DAEs as state equations have not yet reached the level of maturity when compared to optimal control problems with ODEs as state equations.

Using redundant coordinates in the state equations of the optimal control problem affects the necessary optimality conditions. In addition to that, holonomic constraints in the state equations also place restrictions on the boundary conditions of the optimal control problem. Uncontrolled mechanical systems often have symmetry which leads to the conservation of generalized momentum maps on the level of the optimal control problem (Djukić (1973); van der Schaft (1987); Torres (2002)). An analogous statement can be made in the context of constrained mechanical systems (Betsch and Schneider (2021)).

We show that the generalized momentum maps of the optimal control problem can be preserved under discretization. Moreover, we confirm that the numerical results for the optimal control problem in terms of redundant coordinates converge with the results obtained by using minimal coordinates. In this connection, we investigate the role played by different forms of the optimality conditions commonly used in the optimal control of mechanical systems subject to holonomic constraints.

2. STATE EQUATIONS OF CONSTRAINED MECHANICAL SYSTEMS

The present work deals with the optimal control of mechanical systems subject to holonomic constraints. The motion of such systems is governed by differential-algebraic equations (DAEs). The DAEs are typically in index-3 Hessenberg form. For some applications minimal coordinates can be used along with projection methods to eliminate the holonomic constraints, see e.g. Leyendecker et al. (2010). However, using minimal coordinates may lead to coordinate singularities. To prevent the singularities, coordinate switching can be necessary which, on the other hand, is highly inconvenient in the solution of optimal control boundary value problems. In contrast to that, using redundant coordinates associated with the underlying DAEs may provide a general and singularity-free description of the state equations of constrained mechanical systems.

A simple but representative example of a constrained mechanical system is depicted in Figure 1. The configuration manifold of the mathematical pendulum is just the two-dimensional sphere. Thus, the motion can be either described in minimal coordinates by two angles or in redundant coordinates $\mathbf{q} = (q_1, q_2, q_3)$ along with the constraint

$$g_1(\mathbf{q}) = \frac{1}{2}\left(\mathbf{q}^T\mathbf{q} - l_0^2\right) = 0$$

where l_0 is the length of the pendulum. As already mentioned, by using minimal coordinates there will always be a singular point at the pole of the sphere depending on the choice of the minimal coordinates. These coordinate singularities and the problems arising in the optimal control problem can be circumvented easily by using redundant coordinates instead, which point out the importance of redundant coordinates in optimal control problems.

Using Livens principle, the enhanced action integral reads

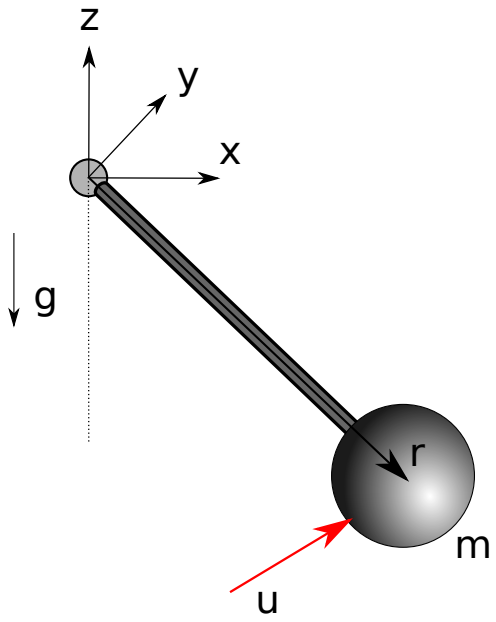

Fig. 1. The controlled mathematical pendulum

$$S = \int_0^T T(\mathbf{q}, \mathbf{v}) - V(\mathbf{q}) - \mathbf{p}^T(\mathbf{v} - \dot{\mathbf{q}}) - \mathbf{y}^T\mathbf{g}(\mathbf{q})\, \mathrm{d}t \quad (1)$$

with $\mathbf{q} \in \mathbb{R}^n$ being the position on the configuration manifold, $\mathbf{v} \in \mathbb{R}^n$ being the velocities at the configuration manifold, $\mathbf{p} \in \mathbb{R}^n$ being the conjugate momenta and $\mathbf{y} \in \mathbb{R}^m$ being the Lagrangian multipliers. Actuating forces can be taken into account by adding their contribution to (1) in the spirit of d'Alembert's principle. Now taking the first variation of (1) yields the equations of motion in the form

$$\left.\begin{aligned} \dot{\mathbf{q}} &= \frac{\partial H(\mathbf{q},\mathbf{p},\mathbf{y})}{\partial \mathbf{p}} \\ \dot{\mathbf{p}} &= -\frac{\partial H(\mathbf{q},\mathbf{p},\mathbf{y})}{\partial \mathbf{q}} + \mathbf{F}(\mathbf{x},\mathbf{u}) \end{aligned}\right\} \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x},\mathbf{y},\mathbf{u}) \quad (2)$$

$$\mathbf{0} = \mathbf{g}(\mathbf{q}) \quad (3)$$

with the Hamiltonian given by

$$H(\mathbf{q},\mathbf{p},\mathbf{y}) = T(\mathbf{q},\dot{\mathbf{q}}) + V(\mathbf{q}) + \mathbf{y}^T\mathbf{g}(\mathbf{q}) \quad (4)$$

In (2) the state variables are summarized in the compact form $\mathbf{x} = (\mathbf{q}, \mathbf{p}) \in P$, where $P = \mathbb{R}^n \times \mathbb{R}^n$ and $F(\mathbf{x}, \mathbf{u}) : \mathbb{R}^n \times \mathbb{R}^{n_u} \to \mathbb{R}^n$ accounts for the actuating forces.

3. OPTIMAL CONTROL PROBLEM

Now let the optimal control problem seek to minimize the cost function

$$\int_0^T \mathbb{L}(\mathbf{x},\mathbf{u})\, \mathrm{d}t \quad (5)$$

subject to the state equations (2) and (3), which need to be satisfied throughout the time interval $[0, T]$. In (5), $\mathbb{L} : P \times \mathbb{R}^{n_u} \mapsto \mathbb{R}$ is the cost density function. The necessary conditions of optimality may be defined within the Hamiltonian formalism in analogy to Livens principle by using the Pontryagin maximum principle. However, there are different approaches to define the Hamiltonian of the optimal control problem. The simple approach incorporates the constraints (3) directly leading to

$$\tilde{\mathbb{H}}(\mathbf{x},\mathbf{y},\mathbf{u},\boldsymbol{\lambda},\boldsymbol{\eta}) = \boldsymbol{\lambda}^T\mathbf{f}(\mathbf{x},\mathbf{y},\mathbf{u}) + \boldsymbol{\eta}^T\mathbf{g}(\mathbf{q}) - \mathbb{L}(\mathbf{x},\mathbf{u}) \quad (6)$$

On the other hand, according to Roubíček and Valášek (2002) the Hamiltonian for the optimal control problem reads

$$\tilde{\mathbb{H}}(\mathbf{x},\mathbf{y},\mathbf{u},\boldsymbol{\lambda},\boldsymbol{\eta}) = \boldsymbol{\lambda}^T\mathbf{f}(\mathbf{x},\mathbf{y},\mathbf{u}) + \boldsymbol{\eta}^T\mathbf{G}(\mathbf{x},\mathbf{y},\mathbf{u}) - \mathbb{L}(\mathbf{x},\mathbf{u}) \quad (7)$$

where $\mathbf{G}(\mathbf{x},\mathbf{y},\mathbf{u}) = \frac{\mathrm{d}^2}{\mathrm{d}t^2}(\mathbf{g}(\mathbf{q}))$. Supposing the Hamiltonian and the cost function have symmetry, then there exists an optimal control version of Noether's theorem. This holds true for state equations both in the form of ordinary differential equations (Betsch and Becker (2017)) and DAEs (Betsch and Schneider (2021)). Accordingly, if the optimal control problem has symmetry, an associated generalized momentum map is conserved along the solution of the optimal control problem.

In the talk the different approaches will be compared with respect to the conservation of the generalized momentum map and a conserving discretization method will be proposed.

Abstract: We present a framework to formulate infinite dimensional port-Hamiltonian systems by means of system nodes, which provide a very general and powerful setting for unbounded input and output operators that appear, e.g., in the context of boundary control or observation. One novelty of our approach is that we allow for unbounded and not necessarily coercive Hamiltonian energies. To this end, we construct finite energy spaces to define the port-Hamiltonian dynamics and give an application in case of multiplication operator Hamiltonians where the Hamiltonian density does not need to be positive or bounded. In order to model systems involving differential operators on these finite energy spaces, we show that if the total mass w.r.t. the Hamiltonian density (and its inverse) is finite, one can define a unique weak derivative.

Keywords: Port-Hamiltonian Systems, Infinite Dimensional Systems Theory, Dissipativity

1. INTRODUCTION

The class of port-Hamiltonian (pH) systems provides a flexible and energy-based modeling framework for a wide range of physical systems. Due to their inherent passivity, pH systems are accessible for various control approaches, such as passivity-based control or control by interconnection (van der Schaft and Jeltsema, 2014; van der Schaft, 2000).

Already in finite dimensions there are manifold formulations of pH systems via, e.g. explicit state-space systems (Beattie et al., 2018) or implicit geometric structures (van der Schaft and Jeltsema, 2014). Some formulations could be shown to be equivalent by means of linear relations (Gernandt et al., 2021). In infinite dimensions, classical definitions of port-Hamiltonian systems range from, e.g., the operator theoretic approach of the textbook (Jacob and Zwart, 2012) for distributed parameter systems on one-dimensional domain and its generalization to multidimensional domains (Skrepek, 2021), to implicit definitions with (Stokes)-Dirac structures (van der Schaft and Maschke, 2021, 2002; Schöberl and Siuka, 2014; Le Gorrec et al., 2005; Reis, 2021).

We present a formulation by means of system nodes. This framework poses a generalization of the class of well-posed systems in the sense of Staffans (2005). One feature of system nodes, that is particularly appealing for modeling, is that the generator A and the input map B are not considered separately but rather as a composite operator $A\&B$, allowing for a natural inclusion of the boundary control directly in $\operatorname{dom}(A\&B)$. For results in view of impedance and scattering passivity of system nodes, we refer to Staffans (2002).

In (Villegas, 2007, Section 2.6, Section 3.2), the concepts and relations of boundary control systems and system nodes for scattering or impendance conserving systems with particular focus on port-Hamiltonian systems on one-dimensional domains was analyzed. More precisely, in (Villegas, 2007, Theorem 2.37) the author showed a one-to-one correspondence between port-Hamiltonian boundary control systems with skew-symmetric main operator and system nodes. Further, a relation between Dirac structure and the graph of the system node was provided in (Villegas, 2007, Theorem 3.12).

Here, we also choose the system node approach to port-Hamiltonian systems. We consider multidimensional domains and possible dissipation by means of a dissipative (not conservative) main operator. To this end, we introduce the notion of dissipative system node. Further, we allow for unbounded Hamiltonians or Hamiltonians with non-trivial kernel, which leads to the definition of finite-energy spaces, being the domain of the Hamiltonian function.

Notation. In the following, $(\mathcal{X},\mathcal{U},\mathcal{Y})$ denotes a triple of Hilbert spaces and by $P_{\mathcal{X}}$, $P_{\mathcal{U}}$ and $P_{\mathcal{Y}}$ we denote the orthogonal projection onto $\mathcal{X}$, $\mathcal{U}$ and $\mathcal{Y}$, respectively. By $\operatorname{dom}(S)$ we mean the domain and by $\rho(S) := \{\lambda \in \mathbb{C} \mid \lambda I - S : \operatorname{dom}(S) \to \mathcal{X} \text{ is bijective}\}$ the resolvent set of a possibly unbounded operator S on $\mathcal{X}$. We denote the closed right-half plane by $\mathbb{C}^+ = \{\lambda \in \mathbb{C} \mid \operatorname{Re}\lambda \geq 0\}$ and nonnegative real numbers by $\mathbb{R}^+$.

2. DISSIPATIVE SYSTEM NODES

Consider an unbounded operator $S : \mathcal{X} \times \mathcal{U} \to \mathcal{X} \times \mathcal{Y}$ describing the (abstract) dynamics

$$\begin{bmatrix} \dot{x}(t) \\ -y(t) \end{bmatrix} = S \begin{bmatrix} x(t) \\ u(t) \end{bmatrix}.$$

The concept of operator nodes poses natural assumptions on the operator S, in order to guarantee favorable properties and a suitable solution concept to the abstract

dynamics above. We provide the standard definition given, e.g., in (Opmeer and Staffans, 2014, Definition 2.1).

Definition 1. (Operator Node). An operator node on the triple $(\mathcal{X},\mathcal{U},\mathcal{Y})$ is defined by a (possibly unbounded) linear operator $S : \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right] \to \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{Y}\end{smallmatrix}\right]$ that is decomposed into $S = \left[\begin{smallmatrix}A\&B\\ C\&D\end{smallmatrix}\right]$ with $A\&B = P_{\mathcal{X}}S : \operatorname{dom}(S) \to \mathcal{X}$ and $C\&D = P_{\mathcal{Y}}S : \operatorname{dom}(S) \to \mathcal{Y}$. Further, we set $Ax = A\&B\left[\begin{smallmatrix}x\\ 0\end{smallmatrix}\right]$ and $\operatorname{dom}(A) = \{x \in \mathcal{X} \mid \left[\begin{smallmatrix}x\\ 0\end{smallmatrix}\right] \in \operatorname{dom}(S)\}$ and demand the following conditions:

(i) $S : \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right] \to \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{Y}\end{smallmatrix}\right]$ with domain $\operatorname{dom}(S)$ is closed.
(ii) $A\&B : \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right] \to \mathcal{X}$ with domain $\operatorname{dom}(S)$ is closed
(iii) For any $u \in \mathcal{U}$ there is $x \in \mathcal{X}$ with $\left[\begin{smallmatrix}x\\ u\end{smallmatrix}\right] \in \operatorname{dom}(S)$.
(iv) $\operatorname{dom}(A)$ is dense in $\mathcal{X}$ and A has nonempty resolvent set. □

The operator A is also called the *main operator* of the operator node, cf. Opmeer and Staffans (2014).

Definition 2. (System Node). An operator node is called a system node, if its main operator A generates a strongly continuous semigroup on $\mathcal{X}$. □

In the following, we will consider the case $\mathcal{Y} = \mathcal{U}$ as usual for passive systems. Recall that a densely defined linear operator $T : X \supset \operatorname{dom} T \to X$ in the Hilbert space X is called *dissipative* if $\operatorname{Re}\langle Tx, x\rangle \leq 0$ for all $x \in \operatorname{dom} T$. It is called *maximally dissipative* if it is dissipative with no proper dissipative extension. By the Lumer-Phillips theorem, the latter is equivalent to $\operatorname{ran}(\lambda - T) = X$ for some $\lambda > 0$. The same theorem shows that T is maximally dissipative if and only if it generates a contraction semigroup. Moreover, a closed and densely defined operator T in X is maximally dissipative if and only if both T and T^* are dissipative.

Proposition 3. For a linear operator $S : \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right] \to \left[\begin{smallmatrix}\mathcal{X}\\ \mathcal{U}\end{smallmatrix}\right]$ the following statements are equivalent:

(i) S is a dissipative system node.
(ii) S is a maximally dissipative system node.
(iii) S is a maximally dissipative operator node.
(iv) S is a dissipative operator node with main operator A satisfying $\operatorname{ran}(\lambda - A) = \mathcal{X}$ for some $\lambda > 0$.

Proof. (i)⇒(ii). This is a consequence of Lemma 5 and (Staffans, 2002, Lemma 4.3).

(ii)⇒(iii). This is trivial.

(iii)⇒(iv). The operator A is dissipative. Indeed,

$$\begin{aligned}\operatorname{Re}\langle Ax, x\rangle_{\mathcal{X}} &= \operatorname{Re}\left\langle A\&B\begin{bmatrix}x\\0\end{bmatrix}, x\right\rangle_{\mathcal{X}}\\ &= \operatorname{Re}\left\langle S\begin{bmatrix}x\\0\end{bmatrix}, \begin{bmatrix}x\\0\end{bmatrix}\right\rangle_{\mathcal{X}\times\mathcal{U}} \leq 0.\end{aligned} \tag{1}$$

Now, by (Malinen et al., 2006, Proposition 2.4), also S^* is an operator node, whose main operator coincides with A^*. As S is maximally dissipative, also S^* is dissipative and so is A^*. Hence, A is maximally dissipative, which implies $\operatorname{ran}(1 - A) = \mathcal{X}$.

(iv)⇒(i). As in (1) it is seen that A is dissipative. The condition in (iv) on A and the Lumer-Phillips theorem hence imply that A is maximally dissipative and thus generates a contraction semigroup. The operator S is thus a system node. □

We briefly recall a suitable solution concept for dynamics governed by system nodes given, e.g., in (Opmeer and Staffans, 2019, Definition 2.3). Let $S = \left[\begin{smallmatrix}A\&B\\ C\&D\end{smallmatrix}\right]$ be an operator node on $(\mathcal{X},\mathcal{U},\mathcal{Y})$. We call the triple

$$\begin{bmatrix}x\\u\\y\end{bmatrix} \in \begin{bmatrix}C^1(\mathbb{R}^+;\mathcal{X})\\ C(\mathbb{R}^+;\mathcal{U})\\ C(\mathbb{R}^+;\mathcal{Y})\end{bmatrix}$$

a classical trajectory if for all $t \geq 0$

$$\begin{bmatrix}x(t)\\u(t)\end{bmatrix} \in \operatorname{dom}(S) \quad \text{and} \quad \begin{bmatrix}\dot{x}(t)\\-y(t)\end{bmatrix} = \begin{bmatrix}A\&B\\C\&D\end{bmatrix}\begin{bmatrix}x(t)\\u(t)\end{bmatrix}.$$

The following result gives existence of unique solutions with suitable control functions and initial values.

Lemma 4. ((Opmeer and Staffans, 2019, Proposition 2.4)). Let S be a system node on $(\mathcal{X},\mathcal{U},\mathcal{Y})$. Then, for all initial values $x_0 \in \mathcal{X}$ and controls $u \in W^{1,2}_{\mathrm{loc}}(\mathbb{R}^+;\mathcal{U})$ with $\left[\begin{smallmatrix}x_0\\ u(0)\end{smallmatrix}\right] \in \operatorname{dom}(S)$, there is a unique classical trajectory with $x(0) = x_0$. □

The following result shows that dynamics governed by dissipative system nodes are impedance passive, cf. also (Staffans, 2002, Theorem 3.3)

Lemma 5. Let $S = \left[\begin{smallmatrix}A\&B\\ C\&D\end{smallmatrix}\right]$ be a dissipative system node. Then, classical trajectories (x, u, y) satisfy

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\tfrac{1}{2}\|x(t)\|^2 \leq \operatorname{Re}\langle u(t), y(t)\rangle_{\mathcal{U}}.$$

Proof. We provide the short proof for the sake of illustration:

$$\begin{aligned}&\tfrac{\mathrm{d}}{\mathrm{d}t}\tfrac{1}{2}\|x(t)\|^2\\ &= \operatorname{Re}\langle x(t), \dot{x}(t)\rangle_{\mathcal{X}}\\ &= \operatorname{Re}\left\langle \begin{bmatrix}x(t)\\u(t)\end{bmatrix}, S\begin{bmatrix}x(t)\\u(t)\end{bmatrix}\right\rangle_{\mathcal{X}\times\mathcal{U}} - \operatorname{Re}\left\langle u(t), C\&D\begin{bmatrix}x(t)\\u(t)\end{bmatrix}\right\rangle_{\mathcal{U}}\\ &\leq \operatorname{Re}\langle u(t), y(t)\rangle_{\mathcal{U}}.\end{aligned}$$

□

3. PORT-HAMILTONIAN SYSTEM NODES

In this part, we will introduce the notion of port-Hamiltonian system nodes by means of dissipative system nodes. To this end, let a closed and densely defined positive sesquilinear form h on $\mathcal{X}$ be given. We will not assume that h is coercive or bounded, but we require $h(x, x) > 0$ for all non-zero $x \in \operatorname{dom} h$. The form h then induces the quadratic energy Hamiltonian $\mathcal{H}$ via

$$\mathcal{H}(x) := \tfrac{1}{2} \cdot h(x, x), \qquad x \in \operatorname{dom}(\mathcal{H}) = \operatorname{dom}(h).$$

By means of Kato's second representation theorem (Kato, 2013, Chapter 6.2), there exists a unique non-negative self-adjoint operator H in $\mathcal{X}$ with $\operatorname{dom}(H^{1/2}) = \operatorname{dom}(h)$ such that for all $x \in \operatorname{dom}(H)$, $y \in \operatorname{dom}(h)$, we have

$$h(x, y) = \langle Hx, y\rangle.$$

Note that our positivity condition on h is equivalent to $\ker H = \{0\}$.

If h is coercive and bounded, one can define infinite-dimensional linear port-Hamiltonian systems as

$$\begin{bmatrix}\dot{x}\\-y\end{bmatrix} = \begin{bmatrix}A\&B\\C\&D\end{bmatrix}\begin{bmatrix}Hx\\u\end{bmatrix} = \left(\begin{bmatrix}A\&B\\C\&D\end{bmatrix}\begin{bmatrix}H & 0\\0 & I\end{bmatrix}\right)\begin{bmatrix}x\\u\end{bmatrix}, \tag{2}$$

where $S = \left[\begin{smallmatrix}A\&B\\ C\&D\end{smallmatrix}\right]$ is a dissipative system node on $(\mathcal{X},\mathcal{U})$. It is not hard to see that then also $\left[\begin{smallmatrix}A\&B\\ C\&D\end{smallmatrix}\right]\left[\begin{smallmatrix}H & 0\\0 & I\end{smallmatrix}\right]$ is a

system node so that solution theory for (2) is available. Here we consider energies that are neither coercive nor bounded. We then define the space $\mathcal{X}_h$ as the completion of $\operatorname{dom}(h) = \operatorname{dom} H^{1/2}$ with respect to the norm induced by the energy, i.e.,

$$\|\cdot\|_h := \sqrt{\mathcal{H}(x)} = \sqrt{\tfrac{1}{2}h(x,x)} = \tfrac{1}{\sqrt{2}} \cdot \left\|H^{1/2}x\right\|.$$

The space $\mathcal{X}_h$ will be refered to as the *space of finite energy*. We note that in case of coercive and bounded energy (i.e., $\|\cdot\| \sim \|\cdot\|_h$ on $\operatorname{dom}(h)$) we have $\mathcal{X}_h = \mathcal{X}$. If the form h is coercive but unbounded, we have $\mathcal{X}_h = (\operatorname{dom}(h), \|H^{1/2}\cdot\|)$, which is already complete. It can be shown that H extends naturally to an isometric isomorphism

$$\widetilde{H} : \mathcal{X}_h \to \mathcal{X}_h^*$$

which actually coincides with the Riesz map for the Hilbert space $\mathcal{X}_h$.

3.1 Definitions and the solution concept

Using the space of finite energies introduced before, we can now state the definition of a port-Hamiltonian system node in case the Hamiltonian is positive. The case of non-negative energies is subject to current research.

Definition 6. Let h be a positive symmetric sesquilinear form on $\mathcal{X}$. Then a linear *port-Hamiltonian system with respect to the energy form* h has the state space $\mathcal{X}_h$ and takes the form

$$\begin{bmatrix} \dot{x} \\ -y \end{bmatrix} = \begin{bmatrix} A\&B \\ C\&D \end{bmatrix} \begin{bmatrix} x \\ u \end{bmatrix},$$

where $\left[\begin{smallmatrix} A\&B \\ C\&D \end{smallmatrix}\right]$ is a dissipative system node on $(\mathcal{X}_h, \mathcal{U})$.

In what follows, let $\mathbb{H} : \mathcal{X}_h \times \mathcal{U} \to \mathcal{X}_h^* \times \mathcal{U}$ denote the isometric isomorphism

$$\mathbb{H} := \begin{bmatrix} \widetilde{H} & 0 \\ 0 & I \end{bmatrix}.$$

We say that an operator $M : \mathcal{X}_h^* \times \mathcal{U} \supset \operatorname{dom}(M) \to \mathcal{X}_h \times \mathcal{U}$ is dissipative, if $M\mathbb{H}$ is dissipative as an operator in $\mathcal{X}_h \times \mathcal{U}$ (or, equivalently, if $\mathbb{H}M$ is dissipative as an operator in $\mathcal{X}_h^* \times \mathcal{U}$).

The next proposition can be proved in a straight-forward manner.

Proposition 7. A linear operator S in $\mathcal{X}_h \times \mathcal{U}$ is a dissipative system node on $(\mathcal{X}_h, \mathcal{U})$ if and only if

$$S = M\mathbb{H},$$

where

$$M : \mathcal{X}_h^* \times U \supset \operatorname{dom}(M) \to \mathcal{X}_h \times U$$

is dissipative and closed and, moreover, satisfies the following properties:

(i) $P_{\mathcal{X}_h} M : \mathcal{X}_h^* \times U \supset \operatorname{dom}(M) \to \mathcal{X}_h$ is closed.
(ii) For any $u \in \mathcal{U}$ there is $x^* \in \mathcal{X}_h^*$ such that $\left[\begin{smallmatrix} x^* \\ u \end{smallmatrix}\right] \in \operatorname{dom}(M)$.
(iii) The operator $F : \mathcal{X}_h^* \supset \operatorname{dom} F \to \mathcal{X}_h$ with $\operatorname{dom} F = \{x^* \in \mathcal{X}_h^* : \left[\begin{smallmatrix} x^* \\ 0 \end{smallmatrix}\right] \in \operatorname{dom} M\}$ and $Fx^* = P_{\mathcal{X}_h} M \left[\begin{smallmatrix} x^* \\ 0 \end{smallmatrix}\right]$ is densely defined.
(iv) There is $\lambda > 0$ such that $\lambda\widetilde{H}^{-1} - F : \operatorname{dom}(F) \to \mathcal{X}_h$ is onto.

In what follows, we shall frequently write M as

$$M = \begin{bmatrix} F\&G \\ K\&L \end{bmatrix},$$

where the operators $F\&G$ and $K\&L$ are defined in the obvious way.

3.2 Multiplication operator Hamiltonians

Let $n \in \mathbb{N}$. Here, we treat the particular case $\mathcal{X} = L^2(0,1)^n \cong L^2((0,1), \mathbb{R}^n)$, where the Hamiltonian is the operator of multiplication with a measurable matrix function $m : (0,1) \to \mathbb{R}^{n\times n}$ such that $m(\xi)$ is symmetric positive definite for a.e. $\xi \in (0,1)$. That is, we have

$$\operatorname{dom} H = \{x \in L^2(0,1)^n : mx \in L^2(0,1)^n\}$$

and $(Hx)(\xi) = m(\xi)x(\xi)$ for $x \in \operatorname{dom} H$ and $\xi \in (0,1)$. It is well known that H is a positive self-adjoint operator in $L^2(0,1)^n$ with

$$\operatorname{dom} H^{1/2} = \{x \in L^2(0,1)^n : m^{1/2}x \in L^2(0,1)^n\}$$

and $(H^{1/2}x)(\xi) = m(\xi)^{1/2}x(\xi)$ for $x \in \operatorname{dom} H^{1/2}$ and $\xi \in (0,1)$.

The Hilbert spaces $\mathcal{X}_h$ and $\mathcal{X}_h^*$ can now be represented as

$$\mathcal{X}_h = \{m^{-1/2}x : x \in L^2(0,1)^n\}$$
$$\text{and} \qquad \mathcal{X}_h^* = \{m^{1/2}x : x \in L^2(0,1)^n\}$$

with inner products

$$\langle m^{-1/2}x, m^{-1/2}y\rangle_{\mathcal{X}_h} = \langle x, y\rangle_2$$
$$\text{and} \qquad \langle m^{1/2}x, m^{1/2}y\rangle_{\mathcal{X}_h^*} = \langle x, y\rangle_2,$$

where $\langle\cdot,\cdot\rangle_2$ denotes the inner product of $L^2(0,1)^n$. Note how the extension $\widetilde{H} : \mathcal{X}_h \to \mathcal{X}_h^*$ of H can be likewise represented as multiplication by m.

Our aim is now to define the domain of differential operators as operators from $\mathcal{X}_h^*$ to $\mathcal{X}_h$. To this end, we need to be able to define a weak derivative on a subset of $\mathcal{X}_h^*$ with values in $\mathcal{X}_h$, that is, for $x \in \mathcal{X}_h^* \cap L^2(0,1)^n$, we want that we recover the integration by parts formula in the pivot space $L^2(0,1)^n$, i.e., for all $\varphi \in C_0^\infty(0,1)^n \cap \mathcal{X}_h^*$ with $\varphi' \in \mathcal{X}_h$:

$$\begin{aligned}\langle x', \varphi\rangle_{\mathcal{X}_h \times \mathcal{X}_h^*} = \langle x', \varphi\rangle_{L^2(0,1)^n} &= -\langle x, \varphi'\rangle_{L^2(0,1)^n} \\ &= -\langle \varphi', x\rangle_{\mathcal{X}_h \times \mathcal{X}_h^*}.\end{aligned}$$

In this regard, we obtain the following result guaranteeing a unique weak derivative.

Proposition 8. If $\|m(\cdot)\|, \|m(\cdot)^{-1}\| \in L^1_{\mathrm{loc}}(0,1)$, then

$$C_0^\infty(0,1)^n \subset \{\varphi \in C_0^\infty(0,1)^n \cap \mathcal{X}_h^* : \varphi' \in \mathcal{X}_h\} \subset \mathcal{X}_h^*$$

and $C_0^\infty(0,1)^n$ is dense in $\mathcal{X}_h^*$. In particular, the weak derivative $x' \in \mathcal{X}_h$ of $x \in \mathcal{X}_h^*$ defined via

$$\langle x', \varphi\rangle_{\mathcal{X}_h \times \mathcal{X}_h^*} = -\langle \varphi', x\rangle_{\mathcal{X}_h \times \mathcal{X}_h^*} \tag{3}$$

for all $\varphi \in C_0^\infty(0,1)^n \cap \mathcal{X}_h^*$ with $\varphi' \in \mathcal{X}_h$, is unique

Proof. The proof follows by straightforward computations and application of the fundamental lemma of calculus of variations.

Example 9. As an example, we consider the wave equation with Dirichlet boundary control on a one-dimensional domain $\Omega = (0, \ell)$.

$$\frac{\partial}{\partial t}\begin{pmatrix}\mathbf{q}(t,\xi)\\ \mathbf{p}(t,\xi)\end{pmatrix} = \left(\begin{bmatrix}0 & \frac{\partial}{\partial\xi}\\ \frac{\partial}{\partial\xi} & 0\end{bmatrix} - \begin{bmatrix}0 & 0\\ 0 & d(\xi)\end{bmatrix}\right)\begin{pmatrix}T(\xi)\mathbf{q}(t,\xi)\\ \frac{1}{\rho(\xi)}\mathbf{p}(t,\xi)\end{pmatrix}$$
$$\begin{pmatrix}\mathbf{q}(0,\xi)\\ \mathbf{p}(0,\xi)\end{pmatrix} = \begin{pmatrix}\mathbf{q}_0(\xi)\\ \mathbf{p}_0(\xi)\end{pmatrix}$$
$$0 = \mathbf{p}(t,0), \quad u(t) = \mathbf{p}(t,\ell),$$
$$y(t) = \mathbf{q}(t,\ell).$$

As state space, we choose $\mathcal{X} = L^2(0,1)^2$, $x = (\mathbf{q},\mathbf{p})$. The Hamiltonian is given by

$$\mathcal{H}(\mathbf{q},\mathbf{p}) = \tfrac{1}{2}\left(\|\sqrt{T(\cdot)}\mathbf{q}\|^2_{L^2(\Omega)} + \|\tfrac{1}{\sqrt{\rho(\cdot)}}\mathbf{p}\|^2_{L^2(\Omega)}\right).$$

Set $Hx = \left[\begin{smallmatrix}T & 0\\ 0 & 1/\rho\end{smallmatrix}\right]x$ for $x \in \mathcal{X}$, $\mathcal{X}_h = (\mathcal{X}, \langle H\cdot,\cdot\rangle)$, and $\widetilde{H} = H$. Further, in order to define spatial derivatives, we asume that the assumptions of Proposition 8 are satisfied, i.e.

$$T, T^{-1}, \rho, \rho^{-1} \in L^1(0,\ell).$$

Note that the condition $\rho \in L^1(0,\ell)$ can be interpreted as a finite total mass assumption.

Further, we set $\mathcal{U} = \mathbb{R}$,

$$F\&G\begin{bmatrix}x\\ u\end{bmatrix} = \left(\begin{bmatrix}0 & \frac{\partial}{\partial\xi}\\ \frac{\partial}{\partial\xi} & 0\end{bmatrix} - \begin{bmatrix}0 & 0\\ 0 & d(\xi)\end{bmatrix}\right)x,$$
$$K\&L\begin{bmatrix}x\\ u\end{bmatrix} = -\mathbf{q}(\ell)$$

and $\operatorname{dom} M = \{((\mathbf{q},\mathbf{p}),u) \in W^{1,2}(\Omega)^2 \times \mathbb{R} : \mathbf{p}(\ell) = u, \mathbf{p}(0) = 0\}$. Dissipativity of $M\mathbb{H}$ can be concluded by straightforward integration by parts arguments. The verification of the remaining assumptions of Proposition 7 are subject to current research, in particular as they have to be checked on the finite energy space.

Abstract: This note discusses an essentially decentralized interior point method, which is well suited for optimization problems arising in energy networks. Advantages of the proposed method are guaranteed and fast local convergence for problems with non-convex constraints. Moreover, our method exhibits a small communication footprint and it achieves a comparably high solution accuracy with a limited number of iterations. Furthermore, the local subproblems are of low computational complexity. We illustrate the performance of the proposed method on an optimal power flow problem with 708 buses.

Keywords: Distributed Optimization, Decentralized Optimization, Interior Point Method

1. INTRODUCTION

Distributed and decentralized optimization algorithms are key for the optimal operation of networked systems. [1] Applications range from power systems (Worthmann et al., 2015; Erseghe, 2015), via optimal operation of gas networks (Arnold et al., 2009), to distributed control of data networks (Low and Lapsley, 1999).

Classical distributed optimization algorithms used in the above works are, however, typically guaranteed to converge only for problems with convex constraints. Sufficiently accurate models are often non-linear leading to problems with non-convex constraints. Thus, researchers either apply classical methods without convergence guarantees in a heuristic fashion (Erseghe, 2015), or they rely on simplified convex models (Worthmann et al., 2015). Both approaches come with the risk of computing infeasible solutions, which leads to severe risks in practice. Moreover, the convergence rate of classical distributed algorithms is at most linear (Hong and Luo, 2017; Yang et al., 2019).

Lu and Zhu (2018), Yan et al. (2011), and Engelmann et al. (2019) propose distributed second-order methods with fast—i.e. superlinear—convergence guarantees for non-convex problems. These approaches rely on the exchange of quadratic models of the subproblems, which in turn implies a substantial amount of communication and/or central coordination. Quadratic model exchange can be avoided by a combination of an active-set strategy and techniques from inexact Newton methods (Engelmann et al., 2020). However, the detection of the correct active set is difficult and often numerically unstable.

Decomposition of interior point methods can be achieved by solving Newton steps in a decentralized fashion leading to an overall essentially decentralized algorithm. Interior point methods have the advantage that they avoid an active set detection and simultaneously guarantee fast—i.e. superlinear—local convergence for non-convex problems. This note considers the application of the essentially decentralized interior point method (d-IP) from (Engelmann et al., 2021) to an optimal power flow problem, which arises frequently in power systems.

2. PROBLEM FORMULATION

A common formulation of optimization problems in the context of networked systems is

$$\min_{x_i,\dots,x_{|\mathcal{S}|}} \sum_{i\in\mathcal{S}} f_i(x_i) \tag{1a}$$

$$\text{subject to} \quad g_i(x_i) = 0, \qquad \forall i \in \mathcal{S}, \tag{1b}$$

$$h_i(x_i) \leq 0, \qquad \forall i \in \mathcal{S}, \tag{1c}$$

$$\sum_{i\in\mathcal{S}} A_i x_i = b, \tag{1d}$$

where, $\mathcal{S} = \{1,\dots,|\mathcal{S}|\}$ denotes a set of subsystems, each of which is equipped with an objective function $f_i : \mathbb{R}^{n_i} \to \mathbb{R}$ and equality and inequality constraints $g_i, h_i : \mathbb{R}^{n_i} \to \mathbb{R}^{n_{gi}}, \mathbb{R}^{n_{hi}}$. The matrices $A_i \in \mathbb{R}^{n_c \times n_i}$ and the vector $b \in \mathbb{R}^{n_c}$ are coupling constraints between the subsystems.

[1] We refer to an optimization algorithm as being *distributed* if one has to solve a (preferably cheap) coordination problem in a central entity/coordinator. We denote an optimization algorithm as being *decentralized* in absence of such a coordinator and when the agents rely purely on neighbor-to-neighbor communication (Bertsekas and Tsitsiklis, 1989; Nedić et al., 2018). We call an algorithm *essentially decentralized* if it requires no central coordination but a small amount of central communication. We remark that the definition of distributed and decentralized control differs (Scattolini, 2009).

3. A DECENTRALIZED INTERIOR POINT METHOD

Interior point methods reformulate problem (1) via a logarithmic barrier function and slack variables $v_i \in \mathbb{R}^{n_{hi}}$,

$$\min_{x_1,\dots,x_{|\mathcal{S}|},v_1,\dots,v_{|\mathcal{S}|}} \sum_{i\in\mathcal{S}} f_i(x_i) - \mathbb{1}^\top \delta \ln(v_i) \tag{2a}$$

$$\text{subject to} \quad g_i(x_i) = 0, \qquad \forall i \in \mathcal{S}, \tag{2b}$$

$$h_i(x_i) + v_i = 0, \quad v_i \geq 0, \qquad \forall i \in \mathcal{S}, \tag{2c}$$

$$\sum_{i\in\mathcal{S}} A_i x_i = b. \tag{2d}$$

The variable $\delta \in \mathbb{R}_+$ is a barrier parameter, $\mathbb{1} = (1,\dots,1)^\top \in \mathbb{R}^{n_{hi}}$ and the function $\ln(\cdot)$ is evaluated component-wise. Note that the inequality constraints are replaced by barrier functions. Moreover, (2) and (1) share the same minimizers for $\delta \to 0$.

The main idea of interior point methods is to solve (2) for a decreasing sequence of δ. It is often too expensive to solve (2) to full accuracy—hence one typically performs a hand full Newton steps only (Nocedal and Wright, 2006). In this note, we use a variant which computes only *one* Newton step per iteration.

Next, we give a brief summary of distributed interior point methods; details are given in (Engelmann et al., 2021).

3.1 Decomposing the Newton Step

An exact Newton step $\nabla F^\delta(p)\Delta p = -F^\delta(p)$ applied to the first-order optimality conditions $F^\delta(p) = 0$ of (2) reads

$$\begin{pmatrix} \nabla F_1^\delta & 0 & \dots & \tilde{A}_1^\top \\ 0 & \nabla F_2^\delta & \dots & \tilde{A}_2^\top \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{A}_1 & \tilde{A}_2 & \dots & 0 \end{pmatrix} \begin{pmatrix} \Delta p_1 \\ \Delta p_2 \\ \vdots \\ \Delta\lambda \end{pmatrix} = \begin{pmatrix} -F_1^\delta \\ -F_2^\delta \\ \vdots \\ b - \sum_{i\in\mathcal{S}} A_i x_i \end{pmatrix}, \tag{3}$$

where

$$\nabla F_i^\delta = \begin{pmatrix} \nabla_{xx} L_i & 0 & \nabla g_i(x_i)^\top & \nabla h_i(x_i)^\top \\ 0 & -V_i^{-1} M_i & 0 & I \\ \nabla g_i(x_i) & 0 & 0 & 0 \\ \nabla h_i(x_i) & I & 0 & 0 \end{pmatrix},$$

$M_i = \operatorname{diag}(\mu_i)$, $V_i = \operatorname{diag}(v_i)$, and $\tilde{A}_i = (A_i \ 0 \ 0 \ 0)$, cf. (Nocedal and Wright, 2006, Thm. 12.1). Here, $p = (p_1,\dots,p_{|\mathcal{S}|},\lambda)$ and $p_i = (x_i, v_i, \gamma_i, \mu_i)$, where γ_i, μ_i, and λ are Lagrange multipliers assigned to (2b), (2c), and (2d) respectively. Observe that the optimality conditions $F^\delta(p) = 0$ are parameterized by the barrier parameter δ.

The coefficient matrix in (3) has an arrowhead structure, which we exploit for decomposition. Note that each ∇F_i^δ can be computed based on local information only. Assume that ∇F_i^δ is invertible. Then, one can reduce the KKT system (3) by solving the first S block-rows for Δp_i. Hence,

$$\Delta p_i = -\left(\nabla F_i^\delta\right)^{-1}\left(F_i^\delta + \tilde{A}_i^\top \Delta\lambda\right) \text{ for all } i \in \mathcal{S}. \tag{4}$$

Inserting (4) into the last row of (3) yields

$$\left(\sum_{i\in\mathcal{S}} \tilde{A}_i \left(\nabla F_i^\delta\right)^{-1} \tilde{A}_i^\top\right)\Delta\lambda = \left(\sum_{i\in\mathcal{S}} A_i x_i - \tilde{A}_i \left(\nabla F_i^\delta\right)^{-1} F_i^\delta\right) - b. \tag{5}$$

Define

$$S_i \doteq \tilde{A}_i \left(\nabla F_i^\delta\right)^{-1} \tilde{A}_i^\top, \quad \text{and} \tag{6a}$$

$$s_i \doteq A_i x_i - \tilde{A}_i \left(\nabla F_i^\delta\right)^{-1} F_i^\delta - \frac{1}{|\mathcal{S}|} b. \tag{6b}$$

Then, equation (5) is equivalent to

$$\left(\sum_{i\in\mathcal{S}} S_i\right)\Delta\lambda - \sum_{i\in\mathcal{S}} s_i = S\Delta\lambda - s = 0. \tag{7}$$

Observe that once (7) is solved, one can compute $\Delta p_1,\dots,\Delta p_{|\mathcal{S}|}$ locally in each subsystem based on $\Delta\lambda$ via back-substitution into (4). This way, we are able to solve (3) in a distributed fashion, i.e., we first compute (S_i, s_i) locally and then collect (S_i, s_i) in a coordinator. Solving (7) and distributing $\Delta\lambda$ back to all subsystems $i \in \mathcal{S}$ yields Δp_i by evaluating (4).

3.2 Decentralization

Solving (5) in a central coordinator is typically undesirable due to the large amount of information exchange for large-scale systems and due to safety reasons. Hence, we solve (7) in a decentralized fashion via decentralized inner algorithms.

One can show that S is symmetric and positive-semidefinite. Hence, a decentralized version of the conjugate gradient method (d-CG) is applicable. As an alternative, the use of decentralized inner optimization algorithms is possible by reformulating (7) as a convex optimization problem (Engelmann and Faulwasser, 2021).

Solving (7) to full accuracy by inner algorithms is typically expensive in terms of communication and computation. Thus, we use techniques from inexact Newton methods to terminate inner algorithms early based on the violation of the optimality conditions $F^\delta(p) = 0$, cf. (Nocedal and Wright, 2006, Chap. 7.1) . Doing so, one can save a severe amount of inner iterations—especially in early outer iterations. When $\|F^\delta(p^k)\|$ gets closer to zero, we also force the residual of (7) to become smaller to guarantee convergence to a minimizer.

Updating Stepsize and the Barrier Parameter The barrier parameter δ and the stepsize α for the Newton step $p^{k+1} = p^k + \alpha\Delta p^k$ require a small amount of central communication but no central computation. Indeed, it is possible to compute local surrogates $\{\alpha_i\}_{i\in\mathcal{S}}$ and $\{\delta_i\}_{i\in\mathcal{S}}$ and take their minimal/maximal values over all subsystems to obtain (α, δ).

The Overall Algorithm The overall distributed interior point algorithm is summarized in Algorithm 1. Algorithm 1 has local superlinear convergence guarantees for non-convex problems in case the barrier parameter and the residual in (5) decrease fast enough, cf. (Engelmann et al., 2021, Thm. 2).

4. APPLICATION TO OPTIMAL POWER FLOW

Optimal Power Flow (OPF) problems compute optimal generator set-points in electrical power systems while meeting grid constraints and technical limits (Frank and Rebennack, 2016).

Algorithm 1 Ess. Decentralized Interior Point Method

Initialization: p_i^0 for all $i \in \mathcal{S}$, $\delta^0, \lambda^0, \epsilon$
while $\|F^0(p^k)\|_\infty > \epsilon$ **do**
  compute (S_i^k, s_i^k) locally via (6)
  while residual of (7) too large **do**
    iterate (7) via a decentralized algorithm
  end while
  compute stepsize α^k and update $p^{k+1} = p^k + \alpha \Delta p^k$
  update $\delta^{k+1} < \delta^k$, $k \to k+1$
end while
return $p^\star$

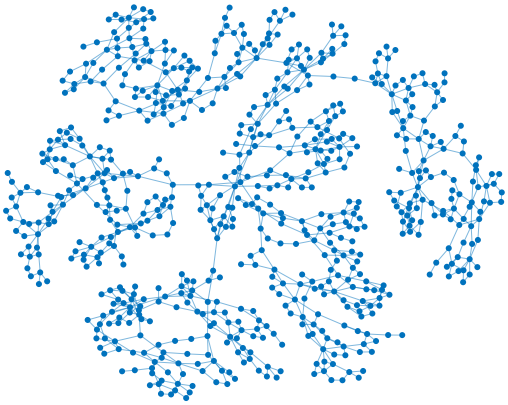

Fig. 1. Six interconnected 118-bus systems.

A basic formulation of the OPF problem reads

$$\min_{s,v \in \mathbb{C}^N} \; f(s) \tag{8a}$$

$$\text{subject to} \quad s - s^d = \operatorname{diag}(v) Y v^*, \tag{8b}$$

$$\underline{p} \le \operatorname{re}(s) \le \bar{p}, \quad \underline{q} \le \operatorname{im}(s) \le \bar{q}, \tag{8c}$$

$$\underline{v} \le \operatorname{abs}(v) \le \bar{v}, \quad v^1 = v^s. \tag{8d}$$

Here, $v \in \mathbb{C}^N$ are complex voltages, and $s \in \mathbb{C}^N$ are complex power injections at all buses N. The operators $\operatorname{re}(\cdot)$ and $\operatorname{im}(\cdot)$ denote the real part and imaginary part of a complex number, and $(\cdot)^*$ denotes the complex conjugate. The objective function $f : \mathbb{C}^N \to \mathbb{R}$ encodes the cost of power generation. The grid physics are described via the power flow equations (8b), where $Y \in \mathbb{C}^{N \times N}$ is the complex bus-admittance matrix describing grid topology and parameters. Moreover, $s^d \in \mathbb{C}^N$ is a fixed power demand. The constraints (8c) describe technical limits on the power injection by generators, and (8d) models voltage limits. The second equation in (8d) is a reference condition on the voltage at the first bus, v^1, where the complex voltage is constrained to a reference value v^s.

Note that one can reformulate the OPF problem (8) in form of (1) by introducing auxiliary variables. Different variants of doing do exist; here we rely on a reformulation from Mühlpfordt et al. (2021).

4.1 A case study

As a case study, we consider 6 interconnected IEEE 118-bus test systems shown in Fig. 1. Each of these systems corresponds to one subsystem $i \in \mathcal{S}$ in problem (1). We use grid parameters from `MATPOWER`, and we interconnect the subsystems in an asymmetric fashion to generate non-zero flows at the interconnection points. In total, we get an optimization problem with about 3.500 decision variables.

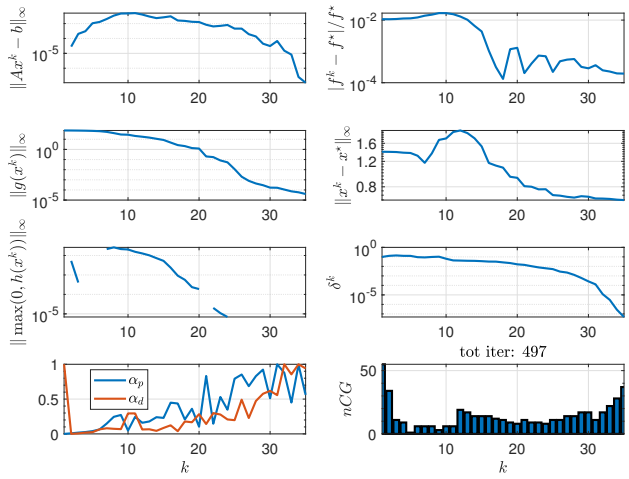

Fig. 2. Convergence of Algorithm 1.

Fig. 2 depicts the convergence of Algorithm 1 over the iteration index k with algorithm parameters from (Engelmann et al., 2021). The figure depicts the consensus violation $\|Ax^k - b\|_\infty$, which can be interpreted as the maximum mismatch of physical values at boundaries between subsystems. Furthermore, the relative error in the objective function $|f^k - f^\star|/f^\star$, the infeasibilities $\|g(x^k)\|_\infty$ and $\|\max(0, h(x^k))\|_\infty$, the distance to the minimizer $\|x^k - x^\star\|_\infty$, the number of inner iterations of d-CG, the barrier parameter sequence $\{\delta^k\}$, and the primal and dual step size (α^p, α^d) are shown. The centralized solution $x^\star$ is computed via the open-source solver `IPOPT` (Wächter and Biegler, 2005).

One can observe that the consensus violation is at the level of 10^{-5} for all iterations. This means that the iterates are feasible with respect to the power transmitted over transmission lines. This results from the fact that the consensus constraint (2d) is implicitly enforced when solving (7) via d-CG. A low consensus violation has the advantage, that one can terminate d-IP early and apply one local NLP iteration to obtain a feasible but possibly suboptimal solution.[2] We note that feasibility is typically of much higher importance than optimality in power systems, since feasibility ensures a safe system operation, cf. Remark 1. From $\|g(x^k)\|_\infty$ and $\|\max(0, h(x^k))\|_\infty$[3] in Fig. 2 one can see that feasibility is ensured to a high degree after 20-30 dIP iterations. At the same time we reach a suboptimality level of almost 0.01%, which is much smaller than in other works on distributed optimization for OPF, cf. (Erseghe, 2015; Guo et al., 2017). Moreover, one can see that the distance to the minimizer $\|x^k - x^\star\|_\infty$ is still quite large due to the small sensitivity of f with respect to the reactive power inputs. This is a well-known phenomenon in the context of OPF problems.

[2] Assuming that the local OPF problem is feasible for the current boundary value iterate.
[3] The blank spots in the plot for $\|\max(0, h(x^k))\|_\infty$ correspond to zero values, since $\log(0) = -\infty$.

Regarding Algorithm 1 itself, one can see that the barrier parameter δ steadily decreases in each iteration. Moreover, during the first 20 iterations, comparably small step-sizes are used. The domain of local convergence is reached after around 30 iterations. Note that we use different stepsizes α_p for the primal variables and α_d for the dual variables. Observe that due to the dynamic termination of inner d-CG iterations based on the inexact Newton theory, Algorithm 1 requires a small amount of inner iterations in the beginning and the number of iterations increases when coming closer to a local minimizer. This effect saves a substantial amount of inner iterations.

The widely used Alternating Direction Method of Multipliers (ADMM) does not converge for the considered case. This seems to occur rarely, but was also reported in other works (Christakou et al., 2017). Algorithm 1 requires 25 seconds for performing 35 iterations with serial execution. The MATPOWER solver `MIPS` needs about 13 seconds when applied to the distributed formulation and 2 seconds when applied to the centralized problem formulation. Executing 497 ADMM iterations—this reflects the number of d-CG iterations in Algorithm 1—requires 210 seconds with serial execution. This illustrates the large computation overhead of ADMM in the local steps, since here one has to solve an NLP in each iteration and for each subsystem. In contrast, d-IP only requires one matrix inversion every outer iteration. All simulations are performed on a standard state-of-the-art notebook.

Remark 1. (Sufficient feasibility in power systems). Note that feasibility in a range of 10^{-3} to 10^{-5} is typically sufficient for a safe power system operation. The parameters in the OPF problem (8), such as power demands and line parameters, induce uncertainty to the problem, which is typically much larger than this level (Kim and Baldick, 2000). Hence, in applications there is typically little-to-no benefit in solving OPF problems to machine precision.

5. SUMMARY & OUTLOOK

We have presented an essentially decentralized interior point method for distributed optimization in energy networks with advantageous properties in terms of convergence guarantees, communication footprint, and practical convergence. We have illustrated the performance of our method on a 708-bus case study. Future work will consider improvements in implementation aspects of d-IP, where we aim faster execution times and at scalability up to several thousand buses.

Abstract: We investigate Singleton-like bounds in the Lee metric and characterize extremal codes. We then focus on Plotkin-like bounds in the Lee metric and present a new bound that extends and refines a previously known bound, which it out-performs in the case of non-free codes. We then compute the density of codes that meet this bound. Finally, we fill a gap in the characterization of Lee-equidistant codes.

Keywords: Ring-linear code, Lee distance, maximum Lee distance, constant weight code

1. INTRODUCTION

We consider codes over $\mathbb{Z}/p^s\mathbb{Z}$ for the Lee metric. One question of interest concerns the behaviour of maximum Lee distance (MLD) codes, which are those codes that are extremal with respect to Singleton-like bounds in the Lee metric. Two proposals of a Lee-metric Singleton bound are known, namely Shiromoto (2000) and Alderson and Huntemann (2013). We show that independently of which bound one considers, MLD codes are sparse, which is done through a characterization of MLD codes. We also provide an answer to the question of whether dual codes preserve this property, by giving examples of MLD codes whose dual is also MLD as well as counterexamples.

We also consider Plotkin-like bounds in the Lee metric. The first such bound was proposed by Wyner and Graham (1968) and was later improved by Chiang and Wolf (1971). However, the Plotkin bound of Chiang and Wolf holds only for free codes. We thus give a generalization of their bound and in addition obtain an improvement. We then characterize codes attaining this new bound and compute their density.

2. PRELIMINARIES

Throughout this paper we will consider codes to be submodules over the integer residue ring $\mathbb{Z}/p^s\mathbb{Z}$, where p is a prime and s is a positive integer. We write $\langle p^i \rangle$ to denote either the ideal $p^i\mathbb{Z}/p^s\mathbb{Z}$ or the submodule $p^i(\mathbb{Z}/p^s\mathbb{Z})^n$, depending on the context. For the remainder, we write $M := \lfloor p^s/2 \rfloor$. See Honold and Landjev (2000) for a detailed treatment of the topic of linear codes over finite chain rings.

Definition 1. A $\mathbb{Z}/p^s\mathbb{Z}$-module of $(\mathbb{Z}/p^s\mathbb{Z})^n$ is called a linear code of length n.

⋆ The second author is supported by the Swiss National Science Foundation grant number 195290.

In the standard case, over finite fields, a code is a linear subspace of $\mathbb{F}_q^n$ and thus has a dimension k. We take as an analogue of the dimension, the parameter given by:

$$k := \log_{p^s}(|\ \mathcal{C}\ |).$$

It is well known that a $\mathbb{Z}/p^s\mathbb{Z}$ module $\mathcal{C}$ is isomorphic to

$$(\mathbb{Z}/p^s\mathbb{Z})^{k_1} \times \left(\mathbb{Z}/p^{s-1}\mathbb{Z}\right)^{k_2} \times \cdots \times (\mathbb{Z}/p\mathbb{Z})^{k_s}.$$

Therefore, as an additional parameter of the code we call $(k_1, \ldots, k_s)$ its subtype. It holds that

$$k = \sum_{i=1}^{s} \frac{s-i+1}{s} k_i.$$

In addition, k_1 is called the free rank of the code and $K = \sum_{i=1}^{s} k_i$ is called its rank.

Definition 2. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of rank K. We call any $K \times n$ matrix G a generator matrix of $\mathcal{C}$, if its row-span is $\mathcal{C}$. For the codes considered here, the socle of $\mathcal{C}$ is $\langle p^{s-1} \rangle \cap \mathcal{C}$.

The dual of the linear code $\mathcal{C}$ is denoted by $\mathcal{C}^\perp$ and defined in the usual way, that is:

$$\mathcal{C}^\perp = \{x \in (\mathbb{Z}/p^s\mathbb{Z})^n \mid x \cdot c = 0 \ \text{ for all } c \in \mathcal{C}\}.$$

Proposition 3. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of order p^{sk}, subtype $(k_1, k_2, \ldots, k_s)$, free rank k_1 and rank K. Then $\mathcal{C}^\perp$ is a linear code of order $p^{s(n-k)}$, subtype $(n - K, k_s, \ldots, k_2)$, free rank $n - K$ and rank $n - k_1$.

In this paper we will focus on the Lee metric. However, this will often be in reference to the Hamming metric. Recall that for $x, y \in (\mathbb{Z}/p^s\mathbb{Z})^n$, the Hamming distance between x and y is defined to be

$$d_H(x, y) = |\{i \in \{1, \ldots, n\} \ \mid \ x_i \neq y_i|\}.$$

Furthermore, the Hamming weight of x is $w_H := d_H(0, x)$. The minimum Hamming distance of $\mathcal{C}$ is $d_H(\mathcal{C}) := \min\{d_H(x, y) \ \mid \ x, y \in \mathcal{C}, x \neq y\}$.

Definition 4. For $x \in \mathbb{Z}/p^s\mathbb{Z}$ we denote by $w_L(x)$ the Lee weight of x, which is defined to be:

$$w_L(x) = \min\{x, p^s - x\},$$

where x is interpreted as an integer in $\{0,\dots,M\}$ in the evalutation $w_L(x)$. For $x \in (\mathbb{Z}/p^s\mathbb{Z})^n$, the Lee weight is defined additively, that is

$$w_L(x) = \sum_{i=1}^{n} w_L(x_i).$$

The Lee weight induces the Lee distance, i.e., for $x, y \in (\mathbb{Z}/p^s\mathbb{Z})^n$ we set

$$d_L(x,y) = w_L(x-y).$$

Note that for $x \in (\mathbb{Z}/p^s\mathbb{Z})^n$, $w_H(x) \leq w_L(x) \leq M w_H(x)$.

Definition 5. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code. Then the minimum Lee distance of $\mathcal{C}$ is defined as

$$d_L(\mathcal{C}) = \min\{w_L(c) \mid c \in \mathcal{C}, c \neq 0\}.$$

One can easily observe that

$$d_H(\mathcal{C}) \leq d_L(\mathcal{C}) \leq M d_H(\mathcal{C}).$$

In order to simplify the proofs used in the following bounds we start by making some initial observations and hence unifying the techniques. For the Hamming metric on $\mathbb{Z}/p^s\mathbb{Z}$ the following Singleton-like bounds are known:

Proposition 6. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a code of order p^{sk}, then

$$d_H(\mathcal{C}) \leq n - k + 1.$$

Of course the above bound holds even if the code is not linear. It is well known (see for example Dougherty (2017); Dougherty and Shiromoto (2000)) that for linear codes one can also formulate a tighter bound:

Proposition 7. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of rank K, then

$$d_H(\mathcal{C}) \leq n - K + 1.$$

Codes that achieve the bound of Proposition 7 are said to have the property of being maximum distance with respect to the rank and are referred to as (MDR) codes. Note that any linear code that is MDS is also MDR and $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ is an MDR code if and only if its socle $\mathcal{C}'$ is an MDS code over $\mathbb{F}_p$.

Let $\mathcal{C}$ be a $\mathbb{Z}/p^s\mathbb{Z}$-module. We define

$$\overline{w}_L(\mathcal{C}) := \frac{1}{|\mathcal{C}|} \sum_{a \in \mathcal{C}} w_L(a),$$

that is, $\overline{w}_L(\mathcal{C})$ is the average Lee weight of the $\mathbb{Z}/p^s\mathbb{Z}$-module $\mathcal{C}$.

A Plotkin-like bound in the Lee metric is:

$$d_L(\mathcal{C}) \leq \frac{|\mathcal{C}|}{|\mathcal{C}|-1} \overline{w}_L(\mathcal{C}). \tag{1}$$

Clearly, this bound is met if and only if every non-zero codeword of $\mathcal{C}$ has the same Lee weight, i.e., if and only if $\mathcal{C}$ is Lee-weight equidistant.

3. OVERVIEW OF EXISTING BOUNDS

3.1 Singleton-like Bounds

For the most well-known case, i.e., $\mathbb{Z}/4\mathbb{Z}$, the Singleton bound is given through the Gray isometry.

Theorem 8. ($\mathbb{Z}/4\mathbb{Z}$-Singleton Bound). Let $\mathcal{C} \subseteq (\mathbb{Z}/4\mathbb{Z})^n$ of order p^{sk}. Then

$$d_L(\mathcal{C}) \leq 2(n-k)+1.$$

Theorem 9. (Shiromoto (2000)). Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ have order p^{sk}. Then

$$\left\lfloor \frac{d_L(\mathcal{C})-1}{M} \right\rfloor \leq n - \lceil k \rceil.$$

Corollary 10. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of rank K. Then

$$d_L(\mathcal{C}) \leq M(n-K+1).$$

Corollary 11. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of rank K. Then

$$\left\lfloor \frac{d_L(\mathcal{C})-1}{M} \right\rfloor \leq n - K.$$

If a linear code $\mathcal{C}$ is such that $d_L(\mathcal{C}) = M(n-k+1)$ which is greater or equal to $M(n-K+1)$, we must have that it attains the bound of Corollary 10 as well and that $\mathcal{C}$ is a free MDS code.

One can also consider the bound provided by Alderson and Huntemann (2013).

Theorem 12. For any code $\mathcal{C}$ in $(\mathbb{Z}/p^s\mathbb{Z})^n$ of order p^{sk}, $k \in \{2,\dots,n\}$ we have that

$$d_L(\mathcal{C}) \leq M(n-k).$$

A first Lee-metric Plotkin-like bound was provided by Wyner and Graham (1968) and then extended in Chiang and Wolf (1971). Equidistant codes attain these bounds.

The following generalizes the result of Chiang and Wolf to any (possibly non-free) code.

Proposition 13. Let $\mathcal{C}$ be a linear code in $(\mathbb{Z}/p^s\mathbb{Z})^n$ of subtype $(k_1,\dots,k_s)$, with $k_1 \geq 1$. Then

$$d_L(\mathcal{C}) \leq \begin{cases} \dfrac{p^s+1}{4}(n-k_1+1) \text{ if } p \text{ is odd,} \\ \dfrac{2^{2s-2}}{2^s-1}(n-k_1+1) \text{ if } p=2. \end{cases}$$

3.2 Characterization

We now characterize codes attaining the Singleton-like bounds in the Lee metric.

Proposition 14. The only linear codes that attain the $\mathbb{Z}/4\mathbb{Z}$-Singleton bound of Theorem 8 are $\mathcal{C} = \langle(2,\dots,2)\rangle$, its dual $\mathcal{C}^\perp$ and the ambient space $(\mathbb{Z}/4\mathbb{Z})^n$ itself.

While the Singleton-like bound from Theorem 9 is sharp, there are very few linear codes that attain this bound. We exclude the trivial case $\mathcal{C} = (\mathbb{Z}/p^s\mathbb{Z})^n$ of minimum Lee distance 1, which always attains the bound.

Theorem 15. The only linear codes $\mathcal{C} \subset (\mathbb{Z}/p^s\mathbb{Z})^n$ of order p^{sk} and rank K that attain the bound of Theorem 9 are

- for p odd: codes equivalent to $\mathcal{C} = \langle(1,2)\rangle \subset (\mathbb{Z}/5\mathbb{Z})^2$ or over any p^s with $k < \lceil k \rceil = K = n < k+1$, i.e., $d_L(\mathcal{C}) = 1$;
- for $p = 2$: $\mathcal{C} = \langle(2^{s-1},\dots,2^{s-1})\rangle$ with $d_L(\mathcal{C}) = 2^{s-1}n$, or such that $k \neq K = \lceil k \rceil \in \{n, n-1\}$ giving $d_L(\mathcal{C}) \leq 2^{s-1}$ and $d_L(\mathcal{C}) = 2^s$ respectively.

In (Alderson and Huntemann, 2013, Lemma 13), it was already observed that for $k > 1 \in \mathbb{N}$, there is no linear code that attains the bound of Theorem 9. We have thus extended their characterization. However, also for the bound of Theorem 12 from Alderson and Huntemann (2013), we have that only very few linear codes are extremal:

Theorem 16. The only linear codes $\mathcal{C} \subset (\mathbb{Z}/p^s\mathbb{Z})^n$ of order p^{sk} and rank K that attain the bound of Theorem 12 are

- for p odd: codes with $p^s = 5, k+1 \leq n \leq k+3$ or free codes with $p^s \in \{7, 9\}, n = k+1$;
- for $p = 2$: free codes with $s = 2, k+1 \leq n \leq k+2$, free codes with $s = 3, n = k+1$ or $k+1 = K \in \{n, n-1\}$.

In particular, this implies that in the case of p odd, we must have $d_L(\mathcal{C}) \in \{2, 3, 4, 6\}$ and if $p = 2$ we must have $d_L(\mathcal{C}) \in \{2, 4, 2^{s-1}, 2^s\}$.

Since an extremal code for the bound of Theorem 9 is such that $\lceil k \rceil = K$ and $d_L(\mathcal{C}) = M(n - \lceil k \rceil) + \alpha$ for some $\alpha \in \{1, \ldots, M\}$, Theorem 15 also includes the bound of Corollary 11.

Corollary 17. The only linear codes $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ that attain the bound of Corollary 11 are:

- for p odd: $K = n$ or a code equivalent to $\mathcal{C} = \langle (1, 2) \rangle \subset (\mathbb{Z}/5\mathbb{Z})^2$;
- for $p = 2$: $\mathcal{C} = \langle (2^{s-1}, \ldots, 2^{s-1}) \rangle$, and $K \in \{n, n-1\}$.

We will call a code maximum Lee distance (MLD) if it is extremal code with respect to any of the considered Singleton-like bounds. One can immediately see that the density of MLD codes is 0 for $p \to \infty$. For any fixed rate $R = k/n$ or for any fixed $p > 7$ we can also see that the density of MLD codes is 0 for $n \to \infty$.

Notice, however, that also with more sophisticated bounds the number of maximum Lee distance codes for $p = 2$ will remain small, due to the fact that the socle $\mathcal{C} \cap \langle 2^{s-1} \rangle$ is a trivial binary MDS code, which cannot be avoided.

The characterizations just shown also answer the question as to whether the dual of MLD codes is also MLD; for the special case of $\mathbb{Z}/4\mathbb{Z}$, we have seen that non-trivial linear codes that achieve the $\mathbb{Z}/4\mathbb{Z}$-Singleton bound, i.e., $d_L(\mathcal{C}) \leq 2(n-k)+1$, are only the codes $\mathcal{C} = \langle (2, \ldots, 2) \rangle$ and its dual. Thus, for this particular bound it is true that the dual of an optimal code attains the bound as well, however, for the other Singleton-like bounds, this is (in general) not true, as the choice of n is very restrictive.

4. NEW BOUNDS

Let $\mathcal{C}$ be a $\mathbb{Z}/p^s\mathbb{Z}$-submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$. For each ideal $i \in \{0, ..., s\}$, we define

$$n_i := |\{j \in \{1, \ldots, n\} \mid \langle \pi_j(\mathcal{C}) \rangle = \langle p^i \rangle\}|,$$

where for each $j \in \{1, \ldots, n\}$, π_j is the projection onto the j-th coordinate. We call $(n_0, \ldots, n_s)$ the support subtype of $\mathcal{C}$.

Lemma 18. Let $\mathcal{C}$ be an $\mathbb{Z}/p^s\mathbb{Z}$-submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$ of support subtype $(n_0, \ldots, n_s)$. Then

$$\overline{w}_L(\mathcal{C}) = \begin{cases} \dfrac{1}{4p^s}\left(p^{2s}(n-n_s) - \displaystyle\sum_{i=0}^{s-1} p^{2i} n_i\right) & \text{if } p \text{ is odd,} \\ 2^{s-2}(n-n_s) & \text{if } p = 2. \end{cases}$$

Theorem 19. Let $\mathcal{C}$ be a $\mathbb{Z}/p^s\mathbb{Z}$-submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$ and let $\mathcal{C}'$ be a non-trivial subcode of $\mathcal{C}$. Then

$$d_L(\mathcal{C}) \leq |\mathcal{C}'|(|\mathcal{C}'|-1)^{-1}\overline{w}_L(\mathcal{C}'). \tag{2}$$

Definition 20. Let p be a prime and let s be a positive integer. Define

$$A(p, s, i) := \begin{cases} \dfrac{p^{s-i}(p^i+1)}{4} & \text{if } p \text{ is odd,} \\ \dfrac{2^{s-2+i}}{2^i-1} & \text{if } p = 2. \end{cases}$$

With respect to this notation, the Chiang-Wolf bound of Proposition 13 is given by:

$$d_L(\mathcal{C}) \leq \lfloor A(p, s, s) \rfloor (n - k_1 + 1).$$

Theorem 21. Let $\mathcal{C}$ be a $\mathbb{Z}/p^s\mathbb{Z}$-submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$. Let $\ell \in \{1, \ldots, s\}$ such that there exists $y \in \mathcal{C}$ satisfying $w_H(y) = d_H(\langle y \rangle)$ and $y \in \langle p^{s-\ell} \rangle$. Then

$$d_L(\mathcal{C}) \leq A(p, s, \ell) d_H(\mathcal{C}).$$

For any linear code $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ there exist words in $\mathcal{C} \cap \langle p^{s-1} \rangle$ of Hamming weight $d_H(\mathcal{C})$, so certainly the hypothesis of Theorem 21 holds with $\ell = 1$.

Combining Proposition 7 and Theorem 19 we get the following bound.

Corollary 22. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a linear code of rank K. Then

$$d_L(\mathcal{C}) \leq \lfloor A(p, s, 1) \rfloor (n - K + 1). \tag{3}$$

Let $\ell \in \{1, \ldots, s\}$ such that there exists $y \in \mathcal{C}$ satisfying $w_H(y) = d_H(\langle y \rangle)$ and $y \in \langle p^{s-\ell} \rangle$. Then

$$d_L(\mathcal{C}) \leq \lfloor A(p, s, \ell) \rfloor (n - K + 1).$$

Corollary 23. Let $\mathcal{C}$ be a $\mathbb{Z}/p^s\mathbb{Z}$-submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$ of rank K. Then

$$\left\lfloor \frac{d_L(\mathcal{C}) - 1}{A(p, s, 1)} \right\rfloor \leq n - K.$$

Example 24. Let $\mathcal{C} = \langle (1, 2, 1, 3) \rangle \subset (\mathbb{Z}/5\mathbb{Z})^4$. Then $d_L(\mathcal{C}) = 6$. $\mathcal{C}$ meets the bound of Proposition 13 and Corollary 23.

Example 25. Let $\mathcal{C} = \langle (0, 1, 1), (2, 0, 0), (0, 0, 2) \rangle \subset (\mathbb{Z}/4\mathbb{Z})^3$. $\mathcal{C}$ attains the bound of Corollary 23 and does not attain the bound of Proposition 13.

4.1 Characterization

Lee-equidistant codes satisfy (1) with equality. The work of Wood (2001) and Dyshko (2019) yields the following.

Corollary 26. Let $\mathcal{C}$ be a constant weight submodule of $(\mathbb{Z}/p^s\mathbb{Z})^n$ of rank K with generator matrix G. Let U be the collection of orbits of $(\mathbb{Z}/p^s\mathbb{Z})^K$ under the action of $\{1, -1\}$. Then one of the following holds:

(1) $s = 1$ and a representative of each member of U appears as a column G with the same multiplicity,

(2) $p = 2$ and every member of $\mathbb{Z}/p^s\mathbb{Z}^K$ appears with the same multiplicity as a column of G,
(3) $K \leq 2$.

Setting $p = 2$ and $\ell = 1$ in Corollary 22 gives the same bound as $p = 2$ in Corollary 11, characterized in Theorem 17. We thus focus on the case p odd.

Proposition 27. Let p be an odd prime. Let $\mathcal{C} \subset (\mathbb{Z}/p^s\mathbb{Z})^n$ have rank K. If $\mathcal{C}$ meets the bound (3) of Corollary 22 then $n \leq p+1$ and either

$$K = n - p + 2 \leq 3 \text{ and } d_L(\mathcal{C}) = \frac{p^{s-1}(p^2-1)}{4}, \text{ or}$$

$$K = n + 1 - \frac{p-1}{2} \leq \frac{p+5}{2} \text{ and } d_L(\mathcal{C}) = \frac{p^{s-1}(p^2-1)}{8}.$$

Theorem 28. The density of optimal linear codes $\mathcal{C} \subset (\mathbb{Z}/p^s\mathbb{Z})^n$ of rank K for the bound of Corollary 22 with $\ell = 1$ is 0 as either $n \longrightarrow \infty$ or $p \longrightarrow \infty$.

5. CHARACTERIZING LEE-EQUIDISTANT CODES

Theorem 29. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a minimal-length linear Lee-equidistant code of rank $K = 1$ and minimum Lee distance w. Let i be the positive integer such that $k_i = 1$, then $\mathcal{C}$ has support subtype $(0, \ldots, 0, n_{i-1}, \ldots, n_{s-1}, 0)$ where, for $1 \leq j \leq s-1$,

$$w = \frac{p+1}{4} p^{s-1} n_{i-1} \text{ and } n_{i-1}(p-1) = p^{j-i+2} n_j.$$

As we have seen in Theorem 29 we have that $p^{s-i+1} \mid n_{i-1}$. Since the socle of $\mathcal{C}$ can be identified with a code over $\mathbb{F}_p$, from Corollary 26 we have that $n_{i-1} = \frac{p-1}{4}a$, for some $a \in \mathbb{N}$. With this we can exactly determine the support subtype of a smallest-length linear Lee-equidistant code.

Corollary 30. Let $\mathcal{C} \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a minimal-length linear Lee-equidistant code of rank $K = 1$ and minimum Lee distance w. Let i be the integer such that $k_i = 1$, then $\mathcal{C}$ has support subtype $(0, \ldots, 0, n_{i-1}, \ldots, n_{s-1}, 0)$ where, for all $j \in \{i, \ldots, s-1\}$,

$$w = p^{2s-i}\frac{p^2-1}{8}, n_{i-1} = p^{s-i+1}\frac{p-1}{2}, n_j = p^{s-j-1}\frac{(p-1)^2}{2}.$$

Corollary 31. Let $\mathcal{C} = \langle g_1, g_2 \rangle \subseteq (\mathbb{Z}/p^s\mathbb{Z})^n$ be a minimal-length linear Lee-equidistant code of rank $K = 2$ and minimum Lee distance w, with $g_1 \in \langle p^{i-1} \rangle$ and $g_2 \in \langle p^{s-1} \rangle$. Then $\mathcal{C}$ has support subtype of the form $(0, \ldots, 0, n_{i-1}, \ldots, n_{s-1}, 0)$ and $\langle g_1 \rangle, \langle g_2 \rangle$ have respective support subtypes

$$(0, \ldots, 0, n_{i-1}, \ldots, n_{s-2}, n_{s-1}^{(1)}, n_s^{(1)}),$$
$$(0, \ldots, 0, n_{s-1}^{(2)}, n_s^{(2)}),$$

where,

$$w = p^{2s-i}\frac{p^2-1}{8}, n_{i-1} = p^{s-i+1}\frac{p-1}{2}, n_s^{(1)} = \frac{p-1}{2},$$
$$n_s^{(2)} = p^{s-i}\frac{p-1}{2}, n_\ell^{(1)} = p^{s-\ell-1}\frac{(p-1)^2}{2},$$

for all $\ell \in \{i, \ldots, s-1\}$.

For each $\ell \in \{i, \ldots, s-1\}$, let U_ℓ be the set of all elements in $\langle p^\ell \rangle \setminus \langle p^{\ell+1} \rangle$ up to ± 1. We denote by u_ℓ the length $(p-1)\alpha_\ell$ tuple consisting of $p-1$ repetitions of each element in U_ℓ. We denote by $\tilde{u}_{i-1}$ the tuple of length $p\alpha_{i-1}$ consisting of p repetitions of all elements in U_{i-1}. Let x be the length $\frac{p-1}{2}$ tuple of all elements in U_{s-1}, let $y = (x, -x)$, and let $z = (0, y)$. Let a be $p^{s-i}\frac{p-1}{2}$ copies of z, b be $\left(p^{s-i}-1\right)\frac{p-1}{2}$ copies of y, and let c be $\frac{p-1}{2}$ copies of x.

Theorem 32. The matrix

$$G = \begin{pmatrix} \tilde{u}_{i-1} & u_i & \cdots & u_{s-1} & \mathbf{0} \\ a & & b & & c \end{pmatrix}$$

generates a Lee-equidistant code over $\mathbb{Z}/p^s\mathbb{Z}$ with $k_i = 1, k_s = 1$.

Example 33. Let us consider the case $\mathbb{Z}/27\mathbb{Z}$ and $k_1 = 1, k_3 = 1$. Let

$$\tilde{u}_0 = (1,1,1,2,2,2,4,4,4,\ldots,13,13,13),$$

i.e., the tuple consisting of 3 repetitions of all elements in

$$\{1,2,4,5,7,8,10,11,13\},$$

let $u_1 = (3,3,6,6,12,12)$ and $u_2 = (9,9)$. Let a be the tuple consisting of 9 repetitions of $(0,9,18)$ and b be the tuple consisting of 4 repetitions of $(9,18)$. Then the matrix

$$G = \begin{pmatrix} \tilde{u}_0 & u_1 & u_2 & 0 \\ a & b & 9 & \end{pmatrix}$$

generates a Lee-equidistant code.

Abstract: In network coding, a *flag code* is a collection of *flags*, that is, sequences of nested subspaces of $\mathbb{F}_q^n$, being $\mathbb{F}_q$ the finite field with q elements. If the sequence of subspace dimensions is $(1, 2, \ldots, n-1)$, we speak about full flag codes. The familiy of flag codes was first introduced in Liebhold et al. (2018). In this work we present some combinatorial tools coming from the classical theory of partitions that can be naturally associated with full flag codes in order to extract relevant information about them. In particular, we state a combinatorial characterization of those full flag codes that attain the maximum possible distance.

Keywords: Flag codes, flag codistance, Ferrers diagrams, integer partitions.

1. INTRODUCTION

In Ahlswede et al. (2000), random network coding was introduced as the most efficient way to send data across a non-coherent network with multiple sources and sinks. However, it is very susceptible to error propagation and erasures. To solve this problem, in Koetter et al. (2008) the authors propose just considering subspaces of $\mathbb{F}_q^n$ as the codewords of *subspace codes*. Since this seminal paper, much research has been made to construct large subspace codes as well as to determine their properties. In case all the subspaces in the code have the same dimension, we have *constant dimension codes*. To have an overview of the most important works in this subject, consult Trautmann et al. (2018) and references therein.

In Liebhold et al. (2018) the authors developed techniques for the use in network coding of constant type *flags*, that is, sequences of nested subspaces of prescribed dimensions. In this context, collections of flags are denominated *flag codes* and they generalize constant dimension codes. The recent works Alonso-González et al. (2020); Alonso-González et al. (2021a); Kurz (2021) are dedicated to this topic.

A way to naturally associate constant dimension codes with a flag code is by considering all the subspaces of a given dimension of all the flags in a flag code. In this way we obtain a *projected code*. In the study of flag codes, one of the principal proplems is the determination of the relationship between the parameters of a flag code and the ones of its projected codes. In Alonso-González et al. (2021b); Alonso-González et al. (2020); Alonso-González et al. (2021a); Navarro-Pérez et al. (2021) this question has been undertaken for the family of flag codes attaining the maximum distance (*optimum distance flag codes*) whereas in Alonso-González and Navarro-Pérez (2020), the authors define *consistent* flag codes as precisely those whose projected codes completely determine their parameters. In this work we contribute to advance in this question from an innovative combinatorial perspective.

One of the main difficulties when investigating the parameters of a flag code relies on the definition of the distance between flags provided that it is obtained as the sum of their subspace distances. This causes that we can attain a flag distance value by many different combinations. To capture such a variability, in Alonso-González et al. (2021), the authors introduce the notion of *distance vector* (associated to a given distance value). Here, we draw distance vectors in the *distance support* to obtain the so-called *distance paths*. This geometrical representation allows us to introduce the *codistance* of the flag code (the complement of the distance) and hence, naturally associate to a flag code different combinatorial objects coming from the classical theory of partitions that result very convenient for our purposes. The results presented in this work summarize the ones appearing in Alonso-González and Navarro-Pérez (2021).

2. SOME PRELIMINAIRES

2.1 Partitions and Ferrers diagrams

Let us first fix some notation on integer partitions and their representation by Ferrers diagrams. Given a positive integer s, a *partition* of s is a sequence of non-increasing positive integers $\lambda = (\lambda_1, \ldots, \lambda_m)$ such that $\lambda_1 + \cdots + \lambda_m = s$. Each value λ_i is called a *part* of λ and we say that m is the *length* of λ.

Ferrers diagrams allow us to give geometrical representations of partitions and to extract relevant properties about them in some cases.

Given a partition $\lambda = (\lambda_1, \ldots, \lambda_m)$, its *associated Ferrers diagram* $\mathfrak{F}_\lambda$ is constructed by stacking right-justified m

⋆ The authors receive financial support from Ministerio de Ciencia e Innovación (PID2019-108668GB-I00).

rows of dots, where the number of dots in the i-th row is λ_i. The dot at the top right position is called the *corner* of the Ferrers diagram.

2.2 Flags and flag distance

Throughout the paper q will denote a fixed prime power and k, n two integers with $1 \leq k < n$. Consider $\mathbb{F}_q$ the finite field with q elements and denote by $\mathcal{G}_q(k,n)$ the *Grassmannian*, that is, the set of k-dimensional subspaces of $\mathbb{F}_q^n$. This set can be equipped with the so-called *injection distance*: given two subspaces $\mathcal{U}, \mathcal{V} \in \mathcal{G}_q(k,n)$, it is defined as

$$d_I(\mathcal{U},\mathcal{V}) = k - \dim(\mathcal{U} \cap \mathcal{V}). \tag{1}$$

Using this distance, we can define a *constant dimension code* $\mathcal{C}$ of length n and dimension k as a nonempty subset of $\mathcal{G}_q(k,n)$. The *minimum distance* of $\mathcal{C}$ is defined as

$$d_I(\mathcal{C}) = \min\{d_I(\mathcal{U},\mathcal{V}) \mid \mathcal{U},\mathcal{V} \in \mathcal{C},\ \mathcal{U} \neq \mathcal{V}\}$$

whenever $|\mathcal{C}| \geq 2$. In case $|\mathcal{C}| = 1$, we put $d_I(\mathcal{C}) = 0$.

See Trautmann et al. (2018) and the references therein for more information on this class of codes.

The concept of constant dimension code can be extended when considering flags of constant type on $\mathbb{F}_q^n$, that is, sequences of nested subspaces of $\mathbb{F}_q^n$ where the list of corresponding dimensions is fixed. The use of flags in network coding as a generalization of constant dimension codes was first proposed in Liebhold et al. (2018). Let us recall some basic background on flag codes.

A *flag* $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_r)$ on $\mathbb{F}_q^n$ is a sequence of nested $\mathbb{F}_q$-vector subspaces $\{0\} \subsetneq \mathcal{F}_1 \subsetneq \cdots \subsetneq \mathcal{F}_r \subsetneq \mathbb{F}_q^n$. The vector $(\dim(\mathcal{F}_1), \ldots, \dim(\mathcal{F}_r))$ is called the *type* of $\mathcal{F}$ and $\mathcal{F}_i$ is the *i-th subspace* of $\mathcal{F}$. In particular, if the type vector is $(1, 2, \ldots, n-1)$, we say that $\mathcal{F}$ is a *full flag*.

The set of all the flags on $\mathbb{F}_q^n$ of a fixed type vector $(t_1, \ldots, t_r)$ is said to be the *flag variety* $\mathcal{F}_q((t_1, \ldots, t_r), n)$ and, for every $i = 1, \ldots, r$, we define the *i-projection* as the map $p_i : \mathcal{F}_q((t_1, \ldots, t_r), n) \to \mathcal{G}_q(t_i, n)$, given by $p_i((\mathcal{F}_1, \ldots, \mathcal{F}_r)) = \mathcal{F}_i$.

The flag variety $\mathcal{F}_q((t_1, \ldots, t_r), n)$ is a metric space: given two flags $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_r)$ and $\mathcal{F}' = (\mathcal{F}'_1, \ldots, \mathcal{F}'_r)$ in $\mathcal{F}_q((t_1, \ldots, t_r), n)$, the *(injection) flag distance* between them is the value

$$d_f(\mathcal{F},\mathcal{F}') = \sum_{i=1}^{r} d_I(\mathcal{F}_i, \mathcal{F}'_i). \tag{2}$$

A *flag code* of type $(t_1, \ldots, t_r)$ on $\mathbb{F}_q^n$ is a nonempty subset $\mathcal{C} \subseteq \mathcal{F}_q((t_1, \ldots, t_r), n)$. Its *minimum distance* is given by

$$d_f(\mathcal{C}) = \min\{d_f(\mathcal{F},\mathcal{F}') \mid \mathcal{F},\mathcal{F}' \in \mathcal{C}, \mathcal{F} \neq \mathcal{F}'\}.$$

when $|\mathcal{C}| \geq 2$. If $|\mathcal{C}| = 1$, we put $d_f(\mathcal{C}) = 0$. The *i-projected code* of $\mathcal{C}$ is the set

$$\mathcal{C}_i = \{p_i(\mathcal{F}) \mid \mathcal{F} \in \mathcal{C}\} \subseteq \mathcal{G}_q(t_i, n).$$

Remark 1. Note that the i-projected code $\mathcal{C}_i$ of $\mathcal{C}$ is a constant dimension code in the Grassmannian $\mathcal{G}_q(t_i, n)$ closely related to the flag code $\mathcal{C}$. Moreover, the cardinality of $|\mathcal{C}_i|$ always satisfies $|\mathcal{C}_i| \leq |\mathcal{C}|$, whereas there is not a clear relationship concerning the distance. In fact, we can have $d_f(\mathcal{C}) > d_I(\mathcal{C}_i)$, $d_f(\mathcal{C}) = d_I(\mathcal{C}_i)$ or even $d_f(\mathcal{C}) < d_I(\mathcal{C}_i)$. So, the problem of obtaining the parameters of a flag code from the ones of its projected codes and conversely is a central one in the study of flag codes.

3. COMBINATORIAL TOOLS

From now on we work just with full flags. For each dimension $0 \leq i \leq n$, we define *the distance support* $\mathrm{S}(i,n)$ of $\mathbb{Z}^2$ by

$$\mathrm{S}(i,n) = \{i\} \times \{0, 1, \ldots, \min\{i, (n-i)\}\}. \tag{3}$$

We extend it to the full flag variety as follows: the *distance support* of the full flag variety on $\mathbb{F}_q^n$ is the set

$$\mathrm{S}(n) = \bigcup_{i=0}^{n} \mathrm{S}(i,n) \subset \mathbb{Z}^2. \tag{4}$$

3.1 Distance paths

If we consider two full flags $\mathcal{F}, \mathcal{F}'$ on $\mathbb{F}_q^n$, their flag distance can be geometrically represented by means of a collection of $n+1$ points in the distance support $\mathrm{S}(n)$, each one of them in a different column $\mathrm{S}(i,n)$, then we can define their *distance path* $\Gamma(\mathcal{F},\mathcal{F}')$ as the directed polygonal path whose vertices are the points $(i, d_I(\mathcal{F}_i, \mathcal{F}'_i))$ for every $0 \leq i \leq n$.

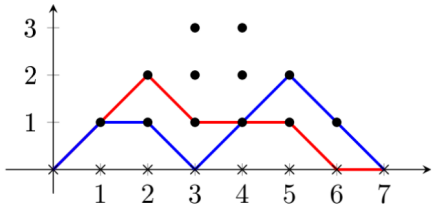

Fig. 1. Two distance paths in S(7).

Similarly, the set of distance paths of a given flag code $\mathcal{C}$ is

$$\Gamma(\mathcal{C}) = \{\Gamma(\mathcal{F},\mathcal{F}') \mid \mathcal{F},\mathcal{F}' \in \mathcal{C},\ \mathcal{F} \neq \mathcal{F}'\}.$$

3.2 Flag codistance

The simple idea of drawing the distance between flags by means of a distance path in a suitable distance support allows us to pay attention to the complementary parameter to the flag distance. If D^n is the maximum possible distance between flags in the full flag variety, given a flag distance value d, i.e., an integer such that $0 \leq d \leq D^n$, we define its *(injection flag) codistance* as the value $\bar{d} = D^n - d$. Similarly, given a full flag code $\mathcal{C}$ on $\mathbb{F}_q^n$, we define its associated *codistance* as the value $\bar{d}_f(\mathcal{C}) = D^n - d_f(\mathcal{C})$.

3.3 Ferrers diagram frame

Now, fixed a positive integer n, we consider the enriched distance support $\hat{\mathrm{S}}(n)$ by adding auxiliary red points and making a rotation around the point $(n, 0)$ as below.

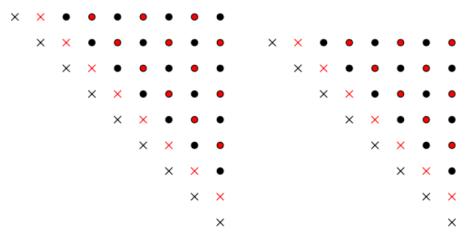

Fig. 2. Rotated enriched supports $\hat{\mathrm{S}}(8)$ and $\hat{\mathrm{S}}(7)$.

If we eliminate the crossed dots, we obtain a Ferrers diagram frame $\mathrm{FF}(n)$. Here we can stablish a one-to-one correspondence between the set of distance paths (associated to a given value of the flag distance) and certain partitions that correspond to the set of circle black points cointained in a suitable *Ferrer subdiagram* of $\mathrm{FF}(n)$.

3.4 Ferrers subdiagrams and embedded partitions

Every Ferrers diagram contained in $\mathrm{FF}(n)$ is said to be a *Ferrers subdiagram*. We also say that the partition $\lambda = (\lambda_1, \ldots, \lambda_m)$ of the integer $\sum_{i=1}^{m} \lambda_i$ is an *embedded partition* on $\mathrm{FF}(n)$ if

(1) $1 \leq m \leq n-1$ and,
(2) for every $1 \leq i \leq m$, it holds $\lambda_i \leq n - i$.

We denote by $\mathfrak{F}_\lambda$ the Ferrers subdiagram associated to an embedded partition λ and also consider the *empty Ferrers subdiagram* $\mathfrak{F}_0$, associated to the *null embedded partition* $\lambda = (0)$.

Two Ferrers subdiagrams of $\mathrm{FF}(n)$ are said to be *distance-equivalent* if they have the same *underlying black diagram*, that is, they contain the same set of black dots. Analogously, two embedded partitions λ and λ' are said to be *distance-equivalent* if their associated Ferrers subdiagrams $\mathfrak{F}_\lambda$ and $\mathfrak{F}_{\lambda'}$ are.

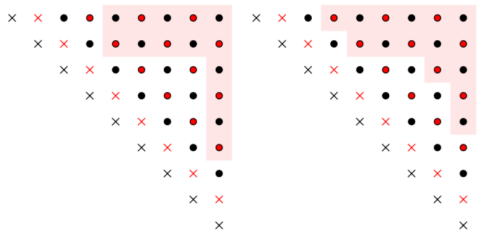

Fig. 3. Distance-equivalent Ferrers subdiagrams in $\mathrm{FF}(8)$.

We can show that a distance path with distance d, determines a set of Ferrers subdiagrams, all of them being distance-equivalent. In fact, each of those Ferrers diagrams is associated to an underlying partition to which we can associate a distinguished value: given $\lambda = (\lambda_1, \ldots, \lambda_m)$ an embedded partition in $\mathrm{FF}(n)$, we define its *underlying distribution* as the vector

$$U_\lambda = \begin{cases} \left(\left\lceil \frac{\lambda_1}{2} \right\rceil, \left\lfloor \frac{\lambda_2}{2} \right\rfloor, \left\lceil \frac{\lambda_3}{2} \right\rceil, \ldots \right) & \text{if } n \text{ is even,} \\ \left(\left\lfloor \frac{\lambda_1}{2} \right\rfloor, \left\lceil \frac{\lambda_2}{2} \right\rceil, \left\lfloor \frac{\lambda_3}{2} \right\rfloor, \ldots \right) & \text{if } n \text{ is odd.} \end{cases}$$

We denote by u_λ the sum of the components of U_λ. With this notation, the next result holds.

Theorem 2. Let Γ_d be a distance path associated to the distance value d. If $\mathfrak{F}_\lambda$ is a Ferrers subdiagram determined by Γ_d, then it holds

$$\bar{d} = D^n - d = u_\lambda.$$

3.5 Codistance splittings

We introduce a new concept that relates embedded partitions and codistance. Given $\lambda = (\lambda_1, \ldots, \lambda_m)$ an embedded partition in $\mathrm{FF}(n)$, we say that its underlying distribution U_λ *splits* the value u_λ defined above, or that it is an *splitting* of u_λ. This value u_λ is common for $\mathfrak{F}_\lambda$ and all its distance-equivalent Ferrers subdiagrams.

Finally, the next result provides the bridge to translate the information given by distance paths to the embedded partitions level and conversely.

Theorem 3. Let $n \geq 2$ be an integer and $0 \leq d \leq D^n$ a flag distance value. Then there is a bijection between the set of distance paths of distance d in $\mathrm{S}(n)$ and the set of splittings of the codistance $\bar{d} = D^n - d$.

4. DERIVED RESULTS FOR FLAG CODES

The previously introduced combinatorial tools can be applied to establish connections between the parameters of a given full flag code and the ones of its projected codes. We summarize here some of the most important consequences. See Alonso-González and Navarro-Pérez (2021) for more details.

Theorem 4. Consider a full flag code $\mathcal{C}$ on $\mathbb{F}_q^n$ with codistance $\bar{d}_f(\mathcal{C})$ and take a dimension $1 \leq i \leq \lfloor \frac{n}{2} \rfloor$. If the codistance satisfies

$$\bar{d}_f(\mathcal{C}) < \left\lceil \frac{i(n-i)}{2} \right\rceil, \tag{5}$$

then $|\mathcal{C}| = |\mathcal{C}_i| = \cdots = |\mathcal{C}_{n-i}|$.

Theorem 5. Let $\mathcal{C}$ be a full flag code on $\mathbb{F}_q^n$ with associated codistance $\bar{d}_f(\mathcal{C})$. Take a dimension $1 \leq i \leq \lfloor \frac{n}{2} \rfloor$ and consider an integer $0 \leq r \leq i$. Hence, whenever

$$\bar{d}_f(\mathcal{C}) < \left\lceil \frac{r(r+n-2i)}{2} \right\rceil, \tag{6}$$

then $|\mathcal{C}_i| = |\mathcal{C}|$ and $d_I(\mathcal{C}_i) > i - r$.

Theorem 6. Let $\mathcal{C}$ be a full flag code on $\mathbb{F}_q^n$ and take $1 \leq i \leq \lfloor \frac{n}{2} \rfloor$.

(1) If $|\mathcal{C}_i| = |\mathcal{C}|$, then

$$d_I(\mathcal{C}_i)^2 \leq d_f(\mathcal{C}) \leq D^n - \left\lceil \frac{(i - d_I(\mathcal{C}_i))(n - i - d_I(\mathcal{C}_i))}{2} \right\rceil$$

(2) If $|\mathcal{C}_i| < |\mathcal{C}|$, then

$$0 \leq d_f(\mathcal{C}) \leq D^n - \left\lceil \frac{i(n-i)}{2} \right\rceil.$$

To finish, we state a combinatorial characterization of full flag codes attaining the maximum possible distance:

Theorem 7. Let $\mathcal{C}$ be a full flag code on $\mathbb{F}_q^n$. They are equivalent:

(1) $d_f(\mathcal{C}) = D^n$ (or $\bar{d}_f(\mathcal{C}) = 0$).

(2) The set $\Gamma(\mathcal{C})$ consists of the only distance path passing either through the point $(\frac{n}{2}, \frac{n}{2})$, if n is even, or through the points $(\lfloor \frac{n}{2} \rfloor, \lfloor \frac{n}{2} \rfloor)$ and $(\lceil \frac{n}{2} \rceil, \lfloor \frac{n}{2} \rfloor)$, if n is odd.

(3) The set of Ferrers subdiagrams associated to $\mathcal{C}$ is

$$\mathfrak{F}(\mathcal{C}) = \begin{cases} \{\mathfrak{F}_0\} & \text{if } n \text{ is even or} \\ \{\mathfrak{F}_0, \mathfrak{F}_{(1)}\} & \text{if } n \text{ is odd.} \end{cases}$$

Abstract: This paper studies the integral turnpike and turnpike in average for a class of random ordinary differential equations. We prove that, under suitable assumptions on the matrices that define the system, the optimal solutions for an optimal distributed control tracking problem remain, in an average sense, sufficiently close to the associated random stationary optimal solution for most of the time horizon.

Keywords: Turnpike property, exponential turnpike property, random ODE, long time behavior, model predictive control.

1. INTRODUCTION

We consider an optimal control distributed tracking-type problem of linear ordinary differential equations with random coefficients. This kind of differential equation is the stochastic counterpart of deterministic differential equations. The term random differential equations, in general, refers to differential equations with random coefficients, having either deterministic or random inhomogeneous parts and initial conditions.

Differential equations with random coefficients have been studied and used for various engineering and science problems. The latter is because the solution of a dynamic system is a function that depends on the parameters which constitute the system. These parameters are experimentally determined and are usually the mean value of a set of experimental observations. However, the observations might be measured with errors due to the conditions' variability, uncertainties, or lack of knowledge. Therefore, a suitable approach to analysis would be to consider systems with random variables as coefficients. We can mention the earlier work on this area Bergmann (1946) where the author studied the propagation of high-frequency sound waves in the atmosphere of randomly varying refraction index. We refer to the books Soong (1973, 1981) for a complete study of this kind of equations and interesting applications in science, engineering, physics, and biomedical systems, among others.

On the other hand, in the context of optimal control, in Porretta and Zuazua (2013) the authors studied the concept of the turnpike for the solutions of an optimal control problem subject to ordinary differential equations without randomness. The turnpike property, roughly speaking, describes that the optimal evolutionary solution is made of three arcs. The first and the last arcs are transient short-time, and the middle piece is a long-time arc remaining exponentially close to the optimal steady-state of the corresponding stationary optimal control problem. This concept was formulated in the earlier work Dorfman et al. (1987), in the context of the econometric field.

Motivated by the previous considerations, we will investigate if any connection exists between the average, with respect to the random variable, of an optimal solution of a certain optimal control problem for an ordinary differential equation with random coefficients, with the corresponding stationary random problem. Specifically, we will analyze the *turnpike phenomenon* for a class of random differential equations, which is important to understand the behavior of solutions to optimal control problems on large time horizons. In the context of stochastic differential equations, this property has been the focus of recent interest Sun et al. (2022). However, to the best of our knowledge, it is the first time that the turnpike property has been studied for ordinary differential equations with random coefficients.

Stating things more mathematically, in this paper we consider a probability space $(\Omega, \mathcal{F}, \mu)$ and three random matrices $A, C \in C^0(\Omega, \mathcal{L}(\mathbb{R}^n))$ and $B \in C^0(\Omega, \mathcal{L}(\mathbb{R}^m, \mathbb{R}^n))$, constant in time, which will represent the random coefficients of the equation, the random observation and the random control, respectively. We assume that the joint probability distribution of matrices A, B and C is specified. We consider the following optimal control problem

$$\min_{u\in L^2(0,T;\mathbb{R}^m)} \left\{ J^T(u) = \frac{1}{2}\left(\int_0^T \|u(t)\|^2_{\mathbb{R}^m} dt + \int_0^T \|C(\cdot)x(t,\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)} dt \right) \right\}, \tag{1}$$

25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

subject to x solving the following evolutionary problem

$$\begin{cases} x_t + A(\omega)x = B(\omega)u & t \in (0,T), \\ x(0,\omega) = x_0(\omega), \end{cases} \tag{2}$$

where $z \in \mathbb{R}^n$ is a fixed target. Here $x = x(t,\omega) \in \mathbb{R}^n$ represents the state and $u(t) \in \mathbb{R}^m$ the control of the system, respectively.

The first aim of this paper it is prove that when the time-horizon goes to infinity, the optimal pair (u^T, x^T) of (1)-(2) converges in an averaged sense to $(\overline{u}, \overline{x})$ in $\mathbb{R}^m \times L^2(\Omega, \mathbb{R}^n)$, where $(\overline{u}, \overline{x})$ solves the associated stationary random optimal control problem

$$\min_{u \in \mathbb{R}^m} \left\{ J^s(u) = \frac{1}{2}\Big(\|u\|^2_{\mathbb{R}^m} + \|C(\cdot)x(\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)} \Big) \right\}, \tag{3}$$

subject to x solving the problem

$$A(\omega)x(\omega) = B(\omega)u, \tag{4}$$

where $z \in \mathbb{R}^n$ is the same target of the problem (1). That is, we will analyze the following limits, which are usually called integral turnpike property

$$\begin{aligned} &\frac{1}{T}\int_0^T x^T(t,\cdot)dt \to \overline{x}(\cdot) \quad \text{in } L^2(\Omega,\mathbb{R}^n), \\ &\frac{1}{T}\int_0^T u^T(t)dt \to \overline{u} \quad \text{in } \mathbb{R}^m. \end{aligned} \tag{5}$$

The second main result is to show an exponential turnpike property. Namely, we will prove the existence of two positive constants K and δ, independent on the time-horizon T, such that the solutions of the extremal equations (u^T, x^T, φ^T) remains exponentially close to the steady state solution, the so-called turnpike, for the majority of the time. That is,

$$\|x^T(t,\cdot) - \overline{x}(\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)} + \|\varphi^T(t,\cdot) - \overline{\varphi}(\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)} \leq K(e^{-\delta(T-t)} + e^{-\delta t}),$$

for every $t \in (0,T)$. Here, $(\varphi^T, \overline{\varphi})$ represents the characterization of minimizers via the first order necessary optimality conditions (the dual variables). In addition, as a consequence of the previous estimate, we prove an average exponential turnpike, that is

$$\|\mathbb{E}(x^T - \overline{x})\|_{\mathbb{R}^n} + \|\mathbb{E}(\varphi^T - \overline{\varphi})\|_{\mathbb{R}^n} + \|u^T - \overline{u}\|_{\mathbb{R}^m} \leq K(e^{-\delta(T-t)} + e^{-\delta t}),$$

for every $t \in (0,T)$ and where $\mathbb{E}(x^T)$ denotes the expected value of x^T and is given by

$$\mathbb{E}(x^T) = \int_\Omega x^T d\mu. \tag{6}$$

Let us mention that both results are based on stability assumptions for A, B, and C, which are the matrices that define the system. These assumptions are related to the existence of feedback operators in such a way that we can ensure an ellipticity-type condition. Besides, these hypotheses allow us to establish relevant observability inequalities, which play an essential role in the proof of our main results. We refer to Section 2 for a complete discussion on the subject. As a final remark, the C matrix must not be square. However, we will continue to assume $C \in C^0(\Omega, \mathcal{L}(\mathbb{R}^n))$ just for simplicity.

2. OPTIMAL CONTROL PROBLEMS

We consider the following random ODE

$$\begin{cases} x_t + A(\omega)x = B(\omega)u & t \in (0,T), \\ x(0,\omega) = x_0(\omega), \end{cases}$$

where $\omega \in \Omega$ corresponds the random parameter, $x = x(t,\omega) \in \mathbb{R}^n$ is the state of the system, the $n \times n$ matrix $A \in C^0(\Omega, \mathcal{L}(\mathbb{R}^n))$ governs its free dynamics, $u(t) \in \mathbb{R}^m$ is the control function which is assumed to be independent of the randomness and acts on the system through the control matrix $B \in C^0(\Omega, \mathcal{L}(\mathbb{R}^m, \mathbb{R}^n))$ which is a $m \times n$ parameter dependent matrix. The initial datum $x_0(\omega)$ belongs to the space $L^2(\Omega, \mathbb{R}^n; \mu)$, which is defined below.

Let us define the space

$$L^2(\Omega,\mathbb{R}^n;\mu) := \Big\{ \omega \in \Omega \mapsto y(\omega) \in \mathbb{R}^n \text{ measurable } : \|y(\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n;\mu)} = \int_\Omega \|y(\omega)\|^2_{\mathbb{R}^n} d\mu(\omega) < \infty \Big\},$$

which is a Hilbert space endowed with the inner product

$$\langle x, y \rangle_{L^2(\Omega,\mathbb{R}^n;\mu)} = \int_\Omega \langle x(\omega), y(\omega) \rangle_{\mathbb{R}^n} d\mu(\omega), \quad \forall x, y \in L^2(\Omega,\mathbb{R}^n;\mu).$$

In what follows, we denote by $L^2(\Omega,\mathbb{R}^n) := L^2(\Omega,\mathbb{R}^n;\mu)$.

Additionally, we also assume that the matrices A and B are uniformly bounded with respect to ω.

Concerning the integrability of the solutions for (2), we have the next result, which can be consulted in Lohéac and Zuazua (2016).

Theorem 1. ((Lohéac and Zuazua, 2016, Corollary 2.2)).

Assume the map $\omega \mapsto (A(\omega), B(\omega))$ is continuous on Ω. Then, for every $x_0 \in L^2(\Omega,\mathbb{R}^n)$, every $u \in L^2_{loc}(\mathbb{R}^+,\mathbb{R}^m)$, and every $t \geq 0$, the solution x of (2) satisfies $x(t,\cdot) \in L^2(\Omega,\mathbb{R}^n)$. In addition, the solution x can be represented by

$$x(t,\omega) = e^{tA(\omega)}x_0(\omega) + \int_0^T e^{(t-s)A(\omega)}B(\omega)u(s)ds, \quad \forall \omega \in \Omega,\ t \in [0,T].$$

2.1 Evolutionary problem

Let us consider first the optimal control for the evolutionary problem (2) with initial datum independent of ω. That is,

$$\min_{u \in L^2(0,T;\mathbb{R}^m)} J^T(u), \tag{7}$$

where

$$J^T(u) = \frac{1}{2}\Big(\int_0^T \|u(t)\|^2_{\mathbb{R}^m} dt + \int_0^T \|C(\cdot)x(t,\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)} dt \Big),$$

subject to x solving the following evolutionary problem

$$\begin{cases} x_t + A(\omega)x = B(\omega)u & t \in (0,T), \\ x(0,\omega) = x_0, \end{cases} \tag{8}$$

where $z \in \mathbb{R}^n$ is a fixed target. The case of initial condition $x_0 \in L^2(\Omega,\mathbb{R}^n)$ does not lead to any essential new difficulty throughout the following. Thus, for sake of simplicity of the presentation, we only deal with the case where x_0 is independent of ω.

By using the direct method of the calculus of variations and noting that the solution x of (8) depends linearly and continuously on u, we obtain the existence and uniqueness result of the optimal control. Besides, the characterization of the control can be done using the Gateaux derivative of J^T. These results are included in the following theorem.

Theorem 2. There exists a unique solution $(u^T, x^T) \in L^2(0,T;\mathbb{R}^m) \times C^0([0,T];L^2(\Omega,\mathbb{R}^n))$ to the minimization problem (7)-(8), where x^T is the optimal state associated to the control u^T. In addition,

$$u^T(t) = -\int_\Omega B^*(\omega)\varphi^T(t,\omega)d\mu, \tag{9}$$

where $\varphi^T \in C^0([0,T];L^2(\Omega,\mathbb{R}^n))$ is the solution of the backward problem

$$\begin{cases} -\varphi_t^T + A^*(\omega)\varphi^T = C^*(\omega)(C(\omega)x^T - z) \quad t \in (0,T), \\ \varphi^T(T,\omega) = 0. \end{cases} \tag{10}$$

In what follows, we assume the following two conditions concerning the dynamics and the cost functional.

Hypothesis 1: For the pair (A, C) we assume the following condition. There exists a feedback operator $K_C \in C^0(\Omega, \mathcal{L}(\mathbb{R}^n))$ uniformly bounded with respect to ω such that, and there exist $\alpha > 0$ such that

$$\langle (A + K_C C)v, v\rangle_{L^2(\Omega,\mathbb{R}^n)} \geq \alpha \|v(\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)}, \tag{11}$$

for all $v \in L^2(\Omega,\mathbb{R}^n)$.

Hypothesis 2: For the pair (A^*, B^*) we consider the next assumption. There exists $\kappa_1 \in \mathbb{R}$ and $\kappa_2 > 0$ such that

$$\langle A^*v, v\rangle_{L^2(\Omega,\mathbb{R}^n)} + \kappa_1 \left\| \int_\Omega B^*(\omega)v(\omega)d\mu \right\|^2_{\mathbb{R}^m} \geq \kappa_2 \|v(\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)}, \tag{12}$$

for all $v \in L^2(\Omega,\mathbb{R}^n)$.

These assumptions are closely related to exponential stabilizability and exponential detectability, as mentioned in Grüne et al. (2019) for abstract differential equations. Under the previous assumptions we have the following "observability" estimates for $x^T(T)$ and $\varphi^T(0)$.

Lemma 3. Let us assume that **Hypothesis 1** holds. Then, there exists a constant $K > 0$ independent of $T > 0$ such that, for every $t \in [0,T]$

$$\|x^T(t,\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)} \leq K\bigg(\int_0^T \Big[\|B(\cdot)u^T(t)\|^2_{L^2(\Omega,\mathbb{R}^n)} + \|C(\cdot)x^T(t,\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)} \Big] dt + \|x_0\|^2_{\mathbb{R}^n} \bigg), \tag{13}$$

where (u^T, x^T) is the optimal pair given by Theorem 2.

Lemma 4. Let us assume that **Hypothesis 2** holds. Then, there exists a constant $K > 0$ such that for every $t \in [0,T]$

$$\|\varphi^T(t,\cdot)\|^2_{L^2(\Omega,\mathbb{R}^n)} \leq K \int_0^T \Big[\|C(\cdot)x^T(t,\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)} + \left\| \int_\Omega B^*(\omega)\varphi^T(t,\omega)d\mu \right\|^2_{\mathbb{R}^m} \Big] dt, \tag{14}$$

where φ^T is the solution of (10).

2.2 Stationary problem

We continue analyzing the stationary optimal control problem (3)–(4).

Under the **Hypothesis 2** we have the following existence and uniqueness for the optimal pair for problem (3)–(4).

Theorem 5. Assume that **Hypothesis 2** holds true. Then the problem (3)–(4) admits a unique optimal pair $(\overline{u}, \overline{x}) \in \mathbb{R}^m \times L^2(\Omega,\mathbb{R}^n)$, with $\overline{x}$ the optimal state associated to $\overline{u}$.

Now, we define the following set

$$D := \{u \in \mathbb{R}^m \ : \ B(\omega)u \in \mathrm{Ran}(A(\omega)), \text{ for each } \omega \in \Omega\}. \tag{15}$$

Theorem 6. Assume that **Hypothesis 2** holds true and let $(\overline{u}, \overline{x})$ be the unique solution of the optimal control (3)–(4). Then, there exists $\overline{\varphi} \in L^2(\Omega,\mathbb{R}^n)$ such that for a.e. $\omega \in \Omega$ we have

$$A^*(\omega)\overline{\varphi} = C^*(\omega)(C(\omega)\overline{x} - z), \tag{16}$$

and

$$\langle \overline{u}, v\rangle_{\mathbb{R}^m} + \langle \overline{\varphi}, Bv\rangle_{L^2(\Omega,\mathbb{R}^n)} = 0, \quad \forall v \in D. \tag{17}$$

3. MAIN RESULTS

In this section we state and prove the main results of this work. For this, let us recall the evolutionary and stationary optimality systems. Let (u^T, x^T) be the optimal pair of (7)–(8), and $(\overline{x}, \overline{u})$ the optimal pair of (3)–(4) (see Theorems 2 and 6). In addition, we have that there exist φ^T solution of (10), such that the optimal control u^T of (7) is given by

$$u^T(t) = -\int_\Omega B^*(\omega)\varphi^T(t,\omega)d\mu, \tag{18}$$

and $\overline{u}$ the optimal control associate to (3) satisfies

$$\langle \overline{u}, v\rangle_{\mathbb{R}^m} + \langle \overline{\varphi}, B(\omega)v\rangle_{L^2(\Omega,X)} = 0, \quad \forall v \in D, \tag{19}$$

where $\overline{\varphi}$ is the solution of (16). Besides, the following optimality systems hold:

$$\begin{cases} x_t^T + A(\omega)x^T = B(\omega)u^T \quad t \in (0,T), \\ -\varphi_t^T + A^*(\omega)\varphi^T = C^*(\omega)(C(\omega)x^T - z) \quad t \in (0,T), \\ x^T(0,\omega) = x_0, \quad \varphi^T(T,\omega) = 0, \end{cases} \tag{20}$$

and

$$\begin{cases} A(\omega)\overline{x} = B(\omega)\overline{u}, \\ A^*(\omega)\overline{\varphi} = C^*(\omega)(C(\omega)\overline{x} - z). \end{cases} \tag{21}$$

The first main result concerns the average convergence of the optimal pair (u^T, x^T) to the corresponding stationary ones $(\overline{u}, \overline{x})$, stated in the following theorem. The proof is based on the results contained in Porretta and Zuazua (2013).

Theorem 7. Let us assume that **Hypothesis 1 and 2** hold. Then,

$$\frac{1}{T}\int_0^T x^T(t,\cdot)dt \longrightarrow \overline{x}(\cdot) \quad \text{in } L^2(\Omega,\mathbb{R}^n),$$
$$\frac{1}{T}\int_0^T u^T(t)dt \longrightarrow \overline{u} \quad \text{in } \mathbb{R}^m,$$

as $T \to \infty$, where (u^T, x^T) is the optimal pair of (7)–(8), and $(\overline{x}, \overline{u})$ is the optimal pair of (3)–(4).

Corollary 8. Let us assume that **Hypothesis 1 and 2** hold. Then, there exists a unique $\overline{\varphi}$ solution of (16). In addition, the stationary optimal control $\overline{u}$ is given by

$$\overline{u} = -\int_\Omega B^* \overline{\varphi} d\mu.$$

Our second main result, which is the following theorem, shows the average exponential turnpike property. The proof is inspired by the results obtained in Grüne et al. (2019).

Theorem 9. Let us assume that **Hypothesis 1 and 2** hold. Let $\delta \geq 0$ be a real number. Let (u^T, x^T, φ^T) be the solution of (20) and $(\overline{u}, \overline{x}, \overline{\varphi})$ the corresponding stationary solution of (21). Then, there exists a positive constant $K = K(\delta) > 0$ (independent of T) such that

$$\left\|x^T(t,\cdot) - \overline{x}(\cdot)\right\|^2_{L^2(\Omega,\mathbb{R}^n)} + \left\|\varphi^T(t,\cdot) - \overline{\varphi}(\cdot)\right\|^2_{L^2(\Omega,\mathbb{R}^n)} \leq K(e^{-\delta(T-t)} + e^{-\delta t}), \quad (22)$$

for every $t \in (0,T)$. In particular, we obtain an averaged exponential turnpike as follows

$$\left\|\mathbb{E}(x^T - \overline{x})\right\|_{\mathbb{R}^n} + \left\|\mathbb{E}(\varphi^T - \overline{\varphi})\right\|_{\mathbb{R}^n} + \left\|u^T - \overline{u}\right\|_{\mathbb{R}^m} \leq K(e^{-\delta(T-t)} + e^{-\delta t}),$$

for every $t \in (0,T)$.

Remark 10. (1) It is immediately noted that in Theorems 7 and 9 one can also consider the case where $x_0, z \in L^2(\Omega,\mathbb{R}^n)$. The proof of both Theorems applies replacing the terms $\|x_0\|_{\mathbb{R}^n}, \|z\|_{\mathbb{R}^n}$ by $\|x_0(\cdot)\|_{L^2(\Omega,\mathbb{R}^n)}, \|z\|_{L^2(\Omega,\mathbb{R}^n)}$, respectively.

(2) Finally, it is interesting to note that our second main result, namely estimates (22) in Theorem 9, means that the turnpike holds for each parameter separately. This result is a strong consequence of our main assumptions Hypothesis 1 and 2. Also is interesting that this holds with optimal control, which is independent of random parameters. However, it captures, at the same time, all the information of the adjoint system (in an average sense).

4. NUMERICAL EXPERIMENTS

This section will perform numerical experiments to validate the average turnpike property. We focus our attention on the particular case $A(\omega) = \alpha(\omega)A$ and $B(\omega) = \beta(\omega)B$, with A and B constant matrices and α, β scalar random variables. Besides, the observability matrix will be independent of ω. In addition, we consider a discrete sample space Ω.

Let $\Omega = \mathbb{R}^+$ and β be a random variable with exponential distribution with parameter $\lambda = 7$ i.e. $\beta \sim exp(7)$ and $\alpha \sim Unif([1/2, 2])$. We consider the following optimal control problem

$$\min\left\{J^T(u) = \frac{1}{2}\left(\int_0^T \|u(t)\|^2_{\mathbb{R}^m} + \|Cx(t,\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)}\, dt\right)\right\},$$

subject to x solves the system

$$\begin{cases} x_t + \alpha(\omega)Ax = \beta(\omega)Bu & t \in (0,T), \\ x(0) = x_0. \end{cases}$$

where A, B and C satisfy the **Hypothesis 1 and 2**. The corresponding stationary optimal control problem is

$$\min\left\{J^s(u) = \frac{1}{2}\left(\|u\|^2_{\mathbb{R}^m} + \|Cx(\cdot) - z\|^2_{L^2(\Omega,\mathbb{R}^n)}\right)\right\},$$

subject to x solves the problem $\alpha(\omega)Ax = \beta(\omega)Bu$. We compute the optimal solutions (x^T, u^T) in time $T = 10$, and $(\overline{x}, \overline{u})$, by using the Gekko library on Python and considering seven realizations of the random variables β and α, which were generated using the numpy.random library on Python.

(e-mail: steven.m.snyder@nasa.gov).

Abstract: Learn-to-Fly is a framework for incorporating learning methods into the development cycle of new aircraft. This paper provides an overview of the concept and summarizes some results from previous test campaigns. It will also discuss some perceived benefits of Learn-to-Fly and improvements to the procedure for more practical and widespread use. Ongoing efforts are needed to continue to develop the necessary underlying technologies for integration into this framework.

Keywords: Learning methods, Autonomous control, Aircraft system identification, Real time.

1. INTRODUCTION

NASA's Learn-to-Fly (L2F) concept seeks to apply learning methods to the modeling and control of aircraft. The current paradigm for aerodynamic modeling and control law design of a new vehicle relies on significant input from ground-based methods, such as computational fluid dynamics (CFD) simulations and wind tunnel testing, to develop a simulation model that is then used for the development of the control law. With the control law designed based on the simulation model, flight tests are performed, and it is often determined from the flight data that there are areas requiring additional data for aerodynamic model improvement. Additional flight test sorties are planned until sufficient data has been captured and the control laws are improved to desired levels of performance and robustness. This iterative, sequential process requires many different subject matter experts to be engaged throughout the development of the aerodynamic model and control law. Conversely, the L2F concept is built upon real-time modeling, real-time guidance, and learning control that work together to identify the aerodynamic model and design the control law for the vehicle with minimal human input. By developing the aerodynamic model based on flight data, the control system is designed with actual flight dynamics responses rather than analogous results, removing the need for corrections due to Reynolds number (if flights are full-scale), wind tunnel blockage, boundary-layer turbulence, etc.

Recent advances in aerodynamic modeling allow such learning processes to operate onboard an aircraft in real time with commercially available computing hardware, e.g., see Morelli (2018, 2020). This allows the flight data content to be assessed in near real time while performing system identification maneuvers, providing a means of determining when a valid aerodynamic model has been generated. If an aerodynamic model of a vehicle can be determined in flight, then there is the potential for automatically modifying control laws, allowing the aircraft to autonomously "learn to fly" and improve its performance with additional flight time (experience). See Snyder et al. (2018), Snyder (2020), Weinstein et al. (2018), and Grauer (2018) for examples.

One would be remiss not to acknowledge the advances in ground testing capabilities. Over time, CFD simulations have become more accurate and cost efficient to perform, and CFD methods are expected to continue improving (see Cary et al. (2021)). Murphy and Brandon (2017) have applied modern design of experiment methods to improve wind tunnel test designs. Additional research has been performed on automating some of these test procedures to reduce the amount of engineering judgment and human input required, as described by Murphy et al. (2020, 2021). Given this, it seems likely that the future may hold a combination of automated ground testing and automated inflight modeling and control updates, like those in L2F.

The remainder of this paper includes a brief overview of the technologies within the current L2F framework in Section 2 along with some highlights of early L2F flight test results in Section 3. Finally, Section 4 contains a discussion of some open areas of research that should be filled to improve implementations of the L2F concept.

2. COMPONENTS OF THE LEARN-TO-FLY FRAMEWORK

As mentioned above, L2F contains three primary components: 1) real-time modeling, 2) real-time guidance, and 3) learning control. A block diagram showing the connections between these components and some of the data flow is depicted in Figure 1. Each of these pieces is described briefly below with references for more details on the implementation used in flight testing. Note that different algorithms that perform these functions could be swapped in and out of this framework.

Real-time Modeling
The goal of the real-time modeling module is to iden-

⋆ Current funding for Learn-to-Fly technologies is provided by NASA under the Transformational Tools and Technologies (TTT) project.

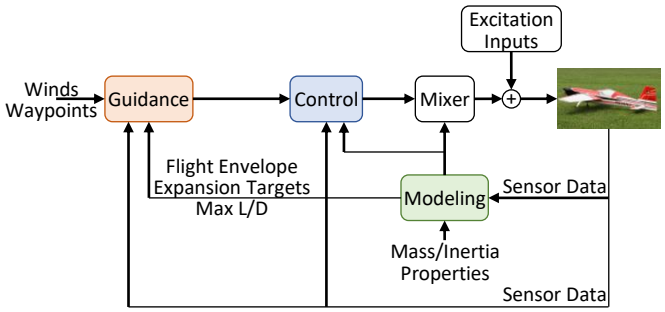

Fig. 1. Block diagram of the Learn-to-Fly architecture.

tify a six-degree-of-freedom mathematical model of the aerodynamic forces and moments acting on the vehicle. It is assumed that the rigid-body kinematic relations are known. The measured states and control surface positions are used as the explanatory variables for the aerodynamic forces and moments. Non-dimensional forces and moments depend not only on the measured aircraft states, but also on the vehicle geometry and mass properties. Since these cannot be measured directly during flight, the geometry and mass properties must be known a priori. Two factors play a role in the creation of an accurate global aerodynamics model during flight: safe and efficient flight maneuvers to sufficiently excite the targeted aircraft dynamics, and a recursive system identification algorithm that can be implemented in real time.

The maneuvers used for excitation were created by injecting orthogonal phase-optimized multi-sine inputs into the control surface commands during portions of the flight tests, as discussed by Morelli (2018, 2020). These inputs are referred to as programmed test inputs (PTIs). The phase optimization indirectly minimizes the peak amplitude, and they only result in a small net perturbation to the aircraft dynamics because the inputs have zero mean. Because these signals are orthogonal, the effect of the inputs can be determined despite simultaneous actuation. This provides a rich amount of excitation over a small window of time.

The recursive system identification algorithm that was implemented is described in detail by Morelli (2018). The approach is based on a candidate pool of multivariate orthogonal functions, referred to as regressors. These functions can be of arbitrary complexity and are selected a priori by the designer. Theoretically, the pool of candidates could be arbitrarily large, yet in practice, the size is limited by onboard computing capabilities. A recursive QR decomposition is used to recursively orthogonalize the regressors in order to isolate and quantify their explanatory capabilities of the dynamics. A least-squares estimator then calculates coefficients for each orthogonalized regressor by minimizing the sum of squared differences between the computed non-dimensional forces and moments, and those predicted by the model. Measures of model fit quality and a penalty for model complexity are then balanced to determine the model structure, i.e., the orthogonalized regressors that will be included within the model. Finally, the model is transformed back into physical quantities by reversing the orthogonalization procedure. Applying this multivariate orthogonal function modeling to each of the rigid-body degrees of freedom will result in the desired six-degree-of-freedom mathematical model. Uncertainty bounds corresponding to each model parameter estimate can also be computed from the generated statistics. A more thorough discussion of the time-domain modeling procedure is given by Morelli (2018). Morelli (2020) provides updates to the modeling procedure in the frequency domain.

Real-time Guidance

Several functions were overseen by the real-time guidance algorithm, including waypoint navigation, energy management for autonomous landing, and limited flight envelope protection. Some degree of autonomous envelope expansion was also provided by the guidance, which systematically adjusted the nominal angle of attack and sideslip commands so that the PTIs could excite the vehicle dynamics in different parts of the flight envelope. By monitoring the real-time global model for instabilities, the guidance algorithm could limit the envelope expansion in order to preserve system safety and keep the vehicle within the stable portion of the flight envelope. Navigation was performed by computing the ground track to the desired waypoint. After flying through a given acceptance radius of the waypoint, the guidance would advance to the next waypoint and compute the ground track relative to it.

When flown on a glider-type aircraft, an altitude trigger would switch the guidance commands over to a landing mode. In this mode, the longitudinal guidance command would switch from angle of attack to flight path angle. The optimal angle, in terms of maximizing the ratio of lift to drag, would be calculated from the real-time aerodynamic model and sent to the control law.

For a powered vehicle flyable by a radio control (R/C) pilot, takeoffs and landings can be performed by the pilot. An altitude and speed profile can be provided along with the waypoint tracking, and the guidance algorithm can then compute a desired flight path angle and speed to demand from the control law. Additionally, with the capability of piloted flight, the real-time modeling can be performed either under manual control or autonomous control. More details on the guidance algorithm and capabilities are given by Foster (2018).

Learning Control

The main objective of the vehicle's control law is to robustly stabilize the vehicle and track the provided guidance commands. The controller must handle disturbances and uncertainties within the system. It uses a traditional adaptive control architecture, complete with a reference model, to react to any immediate disturbances or unknowns. However, as patterns emerge within these unknowns, the real-time modeling results capture these patterns, making those unknowns known. The baseline controller and reference model are modified based on the real-time modeling results, and the system no longer needs to react to those specific disturbances since it can now predict them. The distinction here is between modifying behavior based on a reaction to something that has already happened (adaptation) and modifying behavior based on a prediction of what will happen (learning). Past experiences are required to generate an appropriate prediction.

Some amount of perturbation from the flight condition is required for the real-time modeling to learn the aerodynamics. This is provided by the multi-sine inputs described

above, yet the excitation provided by these inputs goes contrary to the controller's goal of stabilization and are seen by the controller as a disturbance. Simulation studies during the L2F development have shown that rejecting too much disturbance reduced the real-time aerodynamic modeling's ability to identify a model. These conflicting goals of identification and stabilization need to be balanced throughout the L2F process.

The structure of the controller used contains two elements, a baseline controller and an adaptive augmentation. For the baseline controller, a nonlinear dynamic inversion (NDI) control law was designed based on the model learned in real time. NDI essentially seeks to cancel any undesirable dynamics within the determined mathematical model. The desired dynamics after inversion were chosen such that the natural frequency of the vehicle is preserved and sufficient damping is provided for tracking the guidance commands. To augment the baseline controller, a model-based adaptive law compares the measured response to the predicted response of the desired dynamics, adjusting the control signal to reduce any discrepancies. Additional details and results on the control laws are given by Snyder et al. (2018).

Due to the periodic updates of the learned model, the reference model (desired dynamics) exhibits a switching behavior. Switching makes the theoretical analysis of the model-based adaptive controller more challenging than for simple linear time-invariant systems, but an initial analysis framework for an $\mathcal{L}_1$ adaptive controller for this class of systems was developed by Snyder et al. (2022).

3. FLIGHT TESTS

The flight tests discussed here were performed on a 40%-scale, conventional, powered aircraft. The vehicle, known as E1, was modified to split the flaperons into conventional flaps and ailerons and to split the elevator into independent left and right surfaces. These extra control surfaces enabled the use of a hidden feedback loop to modify the apparent dynamics of the vehicle. This feedback loop could, for example, command the left elevator to destabilize the pitch channel based on the angle of attack, unbeknownst to the modeling, guidance, or control modules. The destabilization could be used to create a static instability in pitch or, by feeding back the roll rate to the flaps, create unstable roll damping. Thus, the L2F method could be tested on an effectively unstable vehicle. Figure 2 shows how the surfaces were allocated between stability degradation and control.

Of course, for piloted takeoffs and landings, it is undesirable to have an unstable vehicle. Therefore, the R/C pilot was provided the ability to engage or disengage this destabilizing feedback. Three modes were available to the pilot. The first mode bypassed the L2F computer and allowed the pilot to fly with conventional R/C avionics. The second mode passed the pilot commands through the L2F computer, allowing the pilot commands to be augmented, such as with the destabilizing feedback. The final mode was for fully autonomous flight.

Select Test Results

In the tests described here, the pilot took off in the bypass

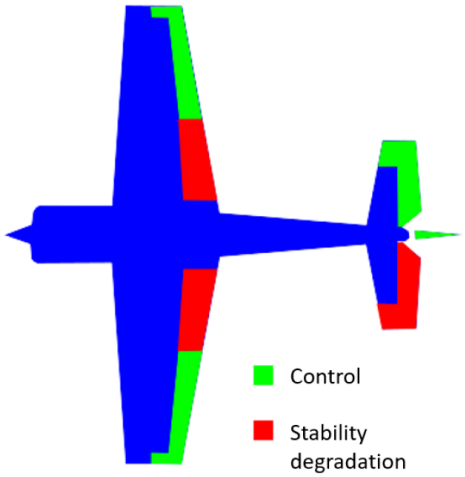

Fig. 2. Schematic of how control surfaces were allocated between control and stability degradation.

mode. Upon reaching the specified test altitude, he then either engaged the autonomous mode, which enabled both the modeling PTIs and the destabilization feedback loop along with the L2F software, or he engaged the pilot pass through mode, which injected the PTIs on top of the pilot inputs and also enabled the destabilizing feedback. The vehicle was flown twice with the pitch destabilization, once piloted and once autonomously.

Figure 3 overlays the responses of the autonomous L2F system and the pilot. A post-flight analysis of the data determined that the static margin of the vehicle was approximately -16.4%, which is a significant instability. This can explain why the R/C pilot had difficulty getting the pitch angle under control, even with large inputs. The pilot traces within the figure are short because the pilot felt uncomfortable attempting to fly the destabilized vehicle through a turn that was required for range safety purposes. As such, he reverted to the safety mode to regain control of the vehicle. With the autonomous L2F system running, some initial pitch oscillations occur. The pitch angle θ of the vehicle can be seen in the first plot, along with the elevator deflection (input signal) δ_e in the second plot as the controller tries to stabilize the aircraft. While the real-time modeling procedure does not rely on any sort of initial guess of the vehicle dynamics, the control laws do. In each case, the initial guess provided to the controller was of a stable aircraft, which can be seen by the initial negative value of the model's pitch coefficient due to angle of attack, C_{m_α}, in the third plot. Thus, the initial pitch oscillations are not surprising.

After about 1 s, the autonomous system begins learning the vehicle dynamics and updating the model parameters (highlighted area). Remember that learning requires experience. This is why one cannot expect the model to update instantaneously. It must first see the pattern in order to learn it. The principal frequency of the pitch dynamics of this vehicle is roughly 1 Hz. Notice that it takes about two cycles (approximately 2 seconds) for the real-time modeling to learn what it is seeing and converge appropriately. Based on the updated model, the gains of the control law, as represented by K_α in the fourth plot, are also updated.

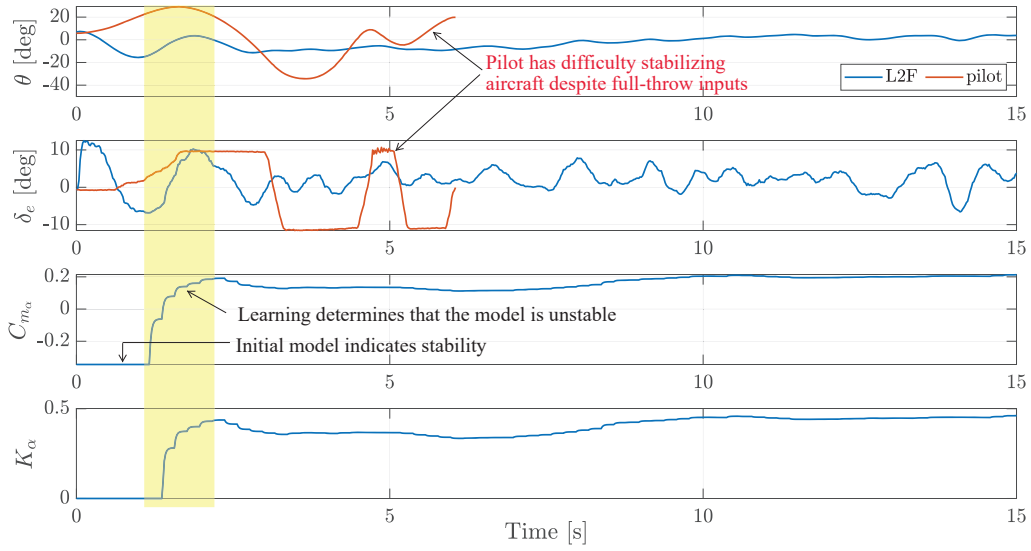

Fig. 3. Overlay of two flights with pitch destabilization, one with the pilot and one with the autonomous L2F system.

4. DISCUSSION

Learn-to-Fly is an interesting application area for learning-based methods in control and one that could benefit the aviation industry. However, many of the improvements needed to push L2F forward are the same developments generally needed for higher level autonomous agents.

Imagine cooperative agents whose objectives compete, at least temporarily. How can those conflicts be resolved so that the team can thrive, especially in cases when the agents are not just cooperative but also codependent? In the L2F scenario, the modeling and control modules are exactly that—codependent. Without model information, control of the vehicle could easily be lost, and if the vehicle is out of control—whether tumbling or possibly crashing—meaningful models cannot be produced.

Many systems that contain some sort of learning element will always have its learning engaged or have it be controlled by a human user. If the system response is consistent with the autonomous agent's expectation, then the learning process need not be active, freeing up resources. However, some level of monitoring would likely be prudent in case the expectation and measured response should, at some future point, diverge. How can resources be balanced between learning and doing? For a system like L2F, it is worth noting that different levels of learning could be applied, such as self learning—which has been the focus thus far—and external learning, which is learning about the environment or other agents within it. Balance would need to be struck between these tasks as well.

ACKNOWLEDGEMENTS

The hard work and dedication of the Learn-to-Fly team are gratefully acknowledged.

Abstract: In the recent history of the theory of network coding the multi-shot network coding has been prove as a good alternative for the classical one-shot network theory which is managed by using block codes. To perform communications in this multi-shot context we have, among others, rank-metric convolutional codes and concatenated codes (using a convolutional code as an outer code and a rank-metric code as inner code). In this work we analyse their performance over the rank deficiency channel (described by Gilbert-Elliot channel model) in terms of the correction capabilities and the complexity of the two decoding schemes.

Keywords: concatenated codes, rank-metric codes, convolutional codes, rank-deficiency channel, complexity

1. INTRODUCTION

Since its raising at the beginning of 2000's, network coding has been a research topic that has attracted significant interest in many areas, including electrical engineering, computer science and applied mathematics. Network coding theory provides a pragmatic instrument to disseminate information (packets) over networks where there may be many information sources and possibly many receivers. From a mathematical point of view, these packets can be modelled by columns of matrices over a finite field $\mathbb{F}_q$ and during the transmission, these columns are linearly combined at each node of the network. To achieve reliable communication over this channel, *rank-metric codes* are typically employed.

Most of the literature deals with the situation in which the network is used only once to propagate the information. Such scenario is referred to as *one-shot* network coding, as the encoding and transmission is performed over one use (shot) of the network. If one needs to transmit more data (packets), then these packets are again encoded and transmitted in the following instant, independently on the previous transmissions. However, one can improve the error-correction capability of the code in the scenario where we need to use the network several times (*multi-shot*) by creating correlation among the transmitted data in different shots. This new approach has recently attracted much attention due to possible interesting applications, e.g., in streaming communications Mahmood et al. (2015). Nevertheless, network coding techniques for streaming are fundamentally different from the classical ones. To be optimised they must operate under low-latency, sequential encoding and decoding constraints, and as such they must inherently have a convolutional structure. That is the reason why most of the proposed schemes for this scenario employ convolutional codes in different ways Wachter-Zeh et al. (2015); Napp et al. (2017a); Mahmood et al. (2015); Almeida et al. (2020).

In this work we present a comparison of two different and important schemes for multi-shot network coding: rank metric convolutional codes and concatenated codes (concatenation of a convolutional code and a rank metric code) Napp et al. (2018). In particular, we compare their performance over a rank-deficiency channel focusing on the correction capabilities and the complexity of the encoding and decoding procedures of each proposal. For practical reasons, in our comparison we limit the field size. Since the construction of optimal rank-metric codes for this channel exists Mahmood et al. (2015) only for large finite fields, such codes cannot be used in this context. The concatenated codes, however, can be constructed optimally. In Section 2 we present the necessary background about convolutional codes, rank-metric convolutional codes and concatenated codes and the nature of the used channel. In Section 3 we make a comparison of the performance of both codes over this kind of channel. Later, in Section 4 we compare the complexity in the decoding process under the circumstances established in the previous section. Finally, in Section 5 we make some review of this work and present future possible works.

2. PRELIMINARIES

2.1 Convolutional codes

Let $\mathbb{F}_q$ be a finite field and $\mathbb{F}_q[D]$ the ring of polynomials with coefficients in $\mathbb{F}_q$. A *convolutional code* $\mathcal{C}$

⋆ This work has been partially supported by the Portuguese Foundation for Science and Technology (FCT-Fundação para a Ciência e a Tecnologia), through CIDMA - Center for Research and Development in Mathematics and Applications, within project UIDB/04106/2020. The second author was also supported by the Ministerio de Ciencia e Innovación under the grant with ref. PID2019-108668GB-I00.

of rate k/n is a rank k $\mathbb{F}_q[D]$-submodule of $\mathbb{F}_q[D]^n$. If $G(D) \in \mathbb{F}_q[D]^{k\times n}$ is a full row rank matrix such that

$$\mathcal{C} = \mathrm{Im}_{\mathbb{F}_q[D]} G(D) = \left\{ u(D)G(D) : u(D) \in \mathbb{F}_q[D]^k \right\},$$

then $G(D)$ is called an encoder of $\mathcal{C}$.

Any other encoder $\tilde{G}$ of $\mathcal{C}$ differs from $G(D)$ by a unimodular matrix $U(D) \in \mathbb{F}_q[D]^{k\times k}$. *i.e.*, $\tilde{G}(D) = U(D)G(D)$. Therefore, we can consider $G(D)$ to be minimal, *i.e.*, in row reduced form Johannesson and Zigangirov (1999). In this case, the sum of the row degrees of $G(D)$ attains its minimum among all the encoders. This value is usually denoted by δ and called the degree of $\mathcal{C}$. A convolutional code with rate k/n and degree δ is called an (n, k, δ) convolutional codes, McEliece (1998). The largest row degree over one, and therefore all, reduced encoders of $\mathcal{C}$ is called the memory of $\mathcal{C}$ and denoted by μ. If the memory is considered instead of the degree, a convolutional code with rate k/n and memory μ is referred to as an (n, k, μ) convolutional code Mahmood et al. (2015).

An important distance measure for convolutional codes $\mathcal{C}$ is its free distance which is defined as

$$d_{free}(\mathcal{C}) = \min_{v(D)\in\mathcal{C}, v(D)\neq 0} wt(v(D)),$$

where $wt(v(D))$ is the Hamming weight of a polynomial vector $v(D) = \sum_{i\in\mathbb{N}} v_i D^i \in \mathbb{F}_q[D]^n$, defined as

$$wt(v(D)) = \sum_{i\in\mathbb{N}} wt(v_i),$$

being $wt(v_i)$ the number of the nonzero components of v_i. Another important distance measure is the *j-th column distance*,

$$d_H^j(\mathcal{C}) = \min\left\{ wt(v(D)|_{[0,j]}) \,|\, v(D) \in \mathcal{C}, v_0 \neq 0 \right\}$$

where $v(D) = \sum_{i\in\mathbb{N}} v_i D^i$ and $v(D)|_{[0,j]} = \sum_{i=0}^{j} v_i D^i$. This measure is also upper-bounded in Johannesson and Zigangirov (1999):

$$d_H^j(\mathcal{C}) \leq (n-k)(j+1)+1$$

for $j \leq L$ where $L = \lfloor \delta/k \rfloor + \lfloor \delta/(n-k) \rfloor$. The convolutional code achieving the bound for all $j \in \{0, \ldots, L\}$ is called *maximum distance profile* (MDP) convolutional code Gluesing-Luerssen et al. (2006).

2.2 Rank-metric codes

Let $A, B \in \mathbb{F}_q^{n\times m}$. The rank distance between two matrices is

$$d_{rank}(A, B) = rank(A - B).$$

This defines a distance, called *rank distance*, and rank-metric codes are subsets of $\mathcal{C} \subseteq \mathbb{F}_q^{n\times m}$ equipped with the rank distance. Rank metric codes in $\mathbb{F}_q^{n\times m}$ are usually constructed as block codes of length n over the extension field $\mathbb{F}_{q^m}$ as in Kötter and Kschischang (2008). For a given basis of $\mathbb{F}_{q^m}$ viewed as an m vector space over $\mathbb{F}_q$, any element of $\mathbb{F}_{q^m}$ can be seen as a vector in $\mathbb{F}_q^m$. In this paper we will follow this approach and consider rank-metric codes as linear codes $[n, k]$ over $\mathbb{F}_{q^m}$. For the sake of simplicity we assume that $m \leq n$. In this case, linear rank metric codes of length n and dimension k over $\mathbb{F}_{q^m}$ must satisfy the following Singleton-type bound:

$$d_{rank}(\mathcal{C}) \leq n - k + 1.$$

A code that achieves this bound is called *Maximum Rank Distance* (MRD). Gabidulin codes are a well-known class of MRD codes as showed in Gabidulin (1985).

2.3 Rank-metric convolutional codes

Rank metric convolutional codes over $\mathbb{F}_{q^m}$ were first introduce in Wachter-Zeh et al. (2015) for unitmemory codes and for unrestricted memory in Mahmood et al. (2015); Almeida et al. (2020). These are convolutional codes defined over an extension field $\mathbb{F}_{q^m}$ and equipped with a rank-type metric, and as such, are referred to as (n, k, δ)-rank metric convolutional codes (over $\mathbb{F}_{q^m}$) if have length n, dimension k and degree δ. Later, a wider definition of convolutional codes over $\mathbb{F}_q$ (instead of over $\mathbb{F}_{q^m}$) was proposed in Napp et al. (2017b).

In Mahmood et al. (2015) a new column rank-base distance is considered. Let $\mathcal{C}$ be a (n, k, μ) be a convolutional code over $\mathbb{F}_{q^M}$. The *j-th column rank distance* of $\mathcal{C}$ is:

$$d_{SR}^j(\mathcal{C}) = \min_{x_{[0,j]}\in\mathcal{C}} \sum_{t=0}^{j} rank(\phi_n(x_{[0,j]}))$$

where $\phi_n : \mathbb{F}_{q^M}^n \to \mathbb{F}_q^{n\times M}$ is the bijective mapping which allows to use the rank based metric instead of the Hamming metric. This column distance is upper-bounded by:

$$d_{SR}^j(\mathcal{C}) \leq (n-k)(j+1)+1.$$

The codes which achieves this bound are named *Maximum Sum Rank codes* (MSR). These codes are showed to exists and a construction is given Mahmood et al. (2015). The larger the column distance is, the better is the correction capability within an interval of time. Hence, rank metric convolutional codes with optimal column distance profile are ideal for fast decoding, *i.e.,* for streaming application with low delay constrains. For these reasons we shall consider in this work MSR convolutional codes for our analysis.

2.4 Concatenated codes

In this section we introduce a completely different class of codes in the context of multi-shot network coding. Such a scheme comprises the concatenation of a Hamming metric convolutional code as an "outer code" and a rank metric block code as an "inner code". These codes are described by the concatenation scheme proposed in Napp et al. (2018) as follows: Let $\mathcal{C}_I$ be a linear (n_I, k_I) rank metric code over $\mathbb{F}_{q^m}$ with (rank) distance $d_{rank}(\mathcal{C}_I)$ and generator matrix $G_I \in \mathbb{F}_{q^m}^{k_I\times n_I}$. Let $\mathcal{C}_O$ be an (n_O, k_O, δ) convolutional code over the field $\mathbb{F}_{q^{mk_I}}$ with Free distance $d_H(\mathcal{C}_O)$, column distance $d_H^j(\mathcal{C}_O)$ and a generator matrix $G_O(D) \in \mathbb{F}_{q^{mk_I}}[D]^{k_O\times n_O}$.

The information (row) vector $u(D) = u_0 + u_1 D + u_2 D^2 + \cdots \in \mathbb{F}_{q^{mk_I}}[D]^{k_O}$ is encoded through $G_O(D)$ to generate

$$v(D) = v_0 + v_1 D + v_2 D^2 + \cdots = u(D)G_O(D) \in \mathcal{C}_O.$$

We write $v_i = (v_i^0, v_i^1, \ldots, v_i^{n_O-1}), v_i^j \in \mathbb{F}_{q^{mk_I}}$. Now, we identify $v_i^j \in \mathbb{F}_{q^{mk_I}}$ with a vector $\nu_i^j \in \mathbb{F}_{q^m}^{k_I}$ (for a given

basis of $\mathbb{F}_{q^{mk_I}}$) and write $\nu_i = (\nu_i^0, \nu_i^1, \ldots, \nu_i^{n_O-1}) \in (\mathbb{F}_{q^m}^{k_I})^{n_O}$ and therefore

$$\nu(D) = \nu_0 + \nu_1 D + \nu_2 D^2 + \cdots \in \mathbb{F}_{q^m}^{k_I}[D]^{n_O}.$$

Finally, the codewords $x(D)$ of the concatenated code $\mathcal{C}$ are obtained through the matrix $G_I \in \mathbb{F}_{q^m}^{k_I \times n_I}$ in the following way:

$$x_i^j = \nu_i^j G_I \in \mathbb{F}_{q^m}^{n_I},$$
$$x_i = (x_i^0, x_i^1, \ldots, x_i^{n_O-1}) \in (\mathbb{F}_{q^m}^{k_I})^{n_O},$$
$$x(D) = x_0 + x_1 D + x_2 D^2 + \cdots \in \mathcal{C} \subset \mathbb{F}_{q^m}^{k_I}[D]^{n_O}.$$

The sum rank metric and the j-th column sum rank distances are bounded by (see Napp et al. (2018)):

$$d_{SR}(\mathcal{C}) \leq (n_O n_I - k_O k_I)(\left\lfloor \frac{\delta}{k_O} \right\rfloor + 1) + \delta k_I + 1,$$

$$d_{SR}^j(\mathcal{C}) \leq (n_O n_I - k_O k_I)(j+1) + 1,$$

respectively.

2.5 Network model

In multi-shot network coding the information (packets) sent in the different uses of the network (shots) are correlated to improve the correction capability of the codes. The natural tool to use in this network are the convolutional codes which take into account this delay in the transference of the information. The network channel considered here is the *deficiency channel* which is a simplification of more general network channel and can be seem as the analogue of the erasure channel in the context of networks, see Mahmood et al. (2015) for more details. In this channel, at each shot the destination node observes $y_t = x_t A_t$, where $A_t \in \mathbb{F}_q^{n \times n}$ is the channel matrix at time t, and is known to the receiver, as explained in Ho et al. (2006). Communication over a window $[t, t+W-1]$ of W shots is described using $y_{[t,t+W-1]} = x_{[t,t+W-1]} A_{[t,t+W-1]}$, where $A_{[t,t+W-1]} = diag(A_t, \ldots, A_{t+W-1})$ is a block diagonal channel matrix as described in Mahmood et al. (2015). Let $\rho_t \triangleq rank(A_t)$ denote the rank of A_t, for all $t \geq 0$, we have that $\sum_{i=t}^{t+W-1} \rho_i = rank(A_{[t,t+W-1]})$. If during the circulation of the information, some of the intermediate nodes fails, the transmission will continue to work without including it in the linear combinations of the packets If all links are functional in the shot at any time t, then $\rho_t = n$, but failing links may result in a rank-deficient channel matrix at that time.

In the context of rank deficiency channels, we shall consider channels that satisfy certain conditions within an interval of time (window), see Mahmood et al. (2015). These are called *Rank-Deficient Sliding Window Networks*, denoted by $\mathcal{CH}(S, W)$ and have the property that in any sliding window of length W, the rank of the block diagonal channel decreases by no more than S, i.e., $\sum_{i=t}^{t+W-1} \rho_i \geq nW - S$ for each $t \geq 0$. We will say that a linear code $\mathcal{C}$ over $\mathbb{F}_{q^M}$ is defined as *feasible* for the channel $\mathcal{CH}(S, W)$ if the encoding and decoding functions for the code are capable of perfectly recovering every source packet transmitted over it with delay T, *i.e.*, to achieve the information of the packet x_t received at moment t by performing the necessary operations with at most the next T received packets, that is $x_t, \ldots, x_{t+T-1}$.

3. PERFORMANCE OF THE CODES

3.1 Discussion

In this subsection we will compare the correction capabilities of the two proposed codes over a rank-deficient sliding window channels. First, we will see under which constrains the cited codes are feasible for the channel $\mathcal{CH}(S, W)$. Secondly, we will compare their bounds on the j-th column distances and discuss the capabilities of them.

In Mahmood et al. (2015), a construction for the MSR convolutional codes is proposed. It is said that these codes are feasible for a rank-deficiency sliding window channel $\mathcal{CH}(S, W)$ with delay $T \geq W$ under the assumption $S < d_{SR}^{W-1}(\mathcal{C})$, where $\mathcal{C}$ is the MSR convolutional code. In the case in which $T < W$ it is enough to consider $S < d_{SR}^{T}(\mathcal{C})$. These codes guarantee the recover of the information under the worst channel conditions for a fixed delay and rate, i.e., they identify the largest rank deficiency S for which a code with a given rate is feasible.

On the other hand, we consider the concatenated codes constructed in Napp et al. (2018). Let $\mathcal{C}$, $\mathcal{C}_O$ and $\mathcal{C}_I$ be the concatenated code, the convolutional code and the rank-metric code, respectively as described above. The concatenated codes are also feasible for the rank-deficiency sliding window channel $\mathcal{CH}(S, W)$ with delay $T' \geq W$ if $S < d_H^{T'}(\mathcal{C}_O) d_{rank}(\mathcal{C}_I)$ where $T' = \left\lfloor \frac{W-1}{n_I} \right\rfloor$ due to the construction of the code. When $T < W$ it is enough to consider $S < d_H^{T'}(\mathcal{C}_O) d_{rank}(\mathcal{C}_I)$ where $T' = \left\lfloor \frac{T}{n_I} \right\rfloor$. The next result, establish which of these two families of codes have better distance bounds under the same conditions:

Theorem 1. Let $\mathcal{C}_{MSR}$ be a MSR convolutional code and C_{Conc}, $\mathcal{C}_O$ and C_I be a concatenated, convolutional and rank metric codes, respectively. Over a rank-deficiency sliding window channel $\mathcal{CH}(S, W)$, with fixed rate $k/n = k_O k_I / n_O n_I$ and delay T, then

$$d_H^{j'}(\mathcal{C}_O) d_{rank}(\mathcal{C}_I) < d_{SR}^{j-1}(\mathcal{C}_{MSR})$$

where $j' = \left\lfloor \frac{j-1}{n_I} \right\rfloor$ with $1 \leq j \leq T$.

Note that in the theorem above, we compare the corresponding column distance after receiving the same amount of shots. Since the bound established for $\mathcal{CH}(S, W)$ cannot be achieved by the concatenated codes, MSR convolutional codes are the only optimal codes, but huge finite fields are necessary to ensure their existence. To build a (n, k, μ) MSR convolutional code, where μ is the memory of the code, the field required for the construction presented in Mahmood et al. (2015) is $\mathbb{F}_{q^M}$ with $M = q^{n(\mu+2)-1}$. For example, to obtain the codes $(3, 1, 2)$ and $(2, 1, 2)$ the fields $\mathbb{F}_{2^{2048}}$ and $\mathbb{F}_{2^{128}}$ are needed.

This last condition is an issue from the practical point of view, since the memory required for storage and usage of these codes are enormous. For this reason, it makes sense to restrict the size of the fields for the construction of codes used in networks described as above. Taking this into account, we have two possibilities: a) to look for an alternative family of codes which achieves or improve the bounds of the Rank-Deficient Sliding Window

Network CH(S,W) over fields of minimum size or b) to find a construction for MSR codes for smaller fields.

With this in mind, an alternative family of codes for this sort of channel are the concatenated codes. Despite the fact that their distance is significant smaller that the one of MSR codes (as indicated in Theorem 1) it is important to note that the distribution of the deficiencies within the window is crucial for recovering the missing packets. For instance, suppose that in the first t instances we send $x_0, \ldots, x_t$ and received $y_0, \ldots, y_t$. In order to recover x_0 at time instant t with the MSR code, we need to have less than $d_{SR}^{j-1}(\mathcal{C}_{MSR})$ deficiencies for some $j = 0, 1, \ldots, t$ independently of the distribution of these deficiencies within the intervals. However, if we use a concatenated code then depending on the distribution of the deficiencies within the windows, the inner rank metric code gives very different erasures patterns to the outer code.

4. COMPLEXITY

In this section we compare the complexity of the decoding performance of both, the concatenated codes and the MSR convolutional codes. In Mahmood et al. (2015), it is said that the complexity of the decoding method, over a window of length $j-1$, for the MSR convolutional codes is $\mathcal{O}(((j-1)k)^3)$ over $\mathbb{F}_{q^M}$. This is due to the decoding method can be reduced to the inversion of a square matrix of this size.

In order to obtain the complexity of the decoding performance of the concatenated codes over a window of length $j-1$ we have to observe that it can be divide into two parts. First, the MRD code corrects the rank deficiency errors or give an erasure. Second, once all the packets are processed by the MRD code, the convolutional code corrects all the erasures in the window by solving a linear system. The performance of the MRD code over the window has complexity $\mathcal{O}((j-1)(k_I)^3)$ over $\mathbb{F}_{q^m}$, while the second part has $\mathcal{O}((n_I d_H^j(C_O))^2)$, since the convolutional code correct up to $d_H^j(C_O)$ packets that contains n_I elements over the field $\mathbb{F}_{q^{mk_I}}$. Thus the complexity of the decoding performance of the concatenated code is $\mathcal{O}((j-1)(k_I)^3)$ over $\mathbb{F}_{q^m}$. By considering, $M = m$ in order to compare comparable complexities, we have $\mathcal{O}(j(k_I)^3) \leq \mathcal{O}((jk)^3)$ which means that, exponentially, the decoding for the concatenated codes is faster.

5. CONCLUSION

In this paper we have discussed the difference in the performance of both MSR convolutional codes and concatenated codes under the same channel. We can say that the concatenated codes are faster by correcting the rank deficiencies and they correct a considerable amount of rank deficiencies with high probability. These codes can be constructed for fields of a more affordable size than the required for the existence of MSR codes.

There are some open problems that arise from this discussion. One of them is to find a construction of rank-metric convolutional codes with greater correction capability than the concatenated codes over a same size field or develop a construction for MSR codes for limited field size. In this sense, in Alfarano et al. (2020), a construction for optimal codes for Hamming column distance is presented. One last open question emerges, the search for new concatenated codes that improve the bounds presented in Napp et al. (2018) due to the flexibility of concatenation technique.

Abstract: We introduce a new class of hybrid Lur'e dynamical systems where a sector nonlinearity may affect both the continuous-time evolution and the reset map acting on suitable closed-loop states, under a time-regularization mechanism ensuring dwell time of solutions. For this class of systems we characterize Lyapunov-based exponential stability conditions exploiting homogeneity of the closed loop. In particular, we show that, with quadratic Lyapunov certificates these conditions can be cast as linear matrix inequalities. We then focus on the control design problem, where both the feedback gains acting on the continuous evolution and the reset action must be designed, in addition to the sets where such resets are triggered, expressed by sign-indefinite quadratic forms. For this control design problem we also show that the synthesis can be performed by solving a set of linear matrix inequalities.

Keywords: Reset control systems, Lur'e systems, Lyapunov theory, exponential stability

1. INTRODUCTION

Reset control systems (see, for example, Goebel et al. (2009, 2012), Prieur et al. (2018), Le and Teel (2021) and references therein) is a specific class of hybrid dynamical systems wherein continuous motion of the plant-controller dynamics is equipped with resetting rules inducing instantaneous re initializations of certain controller states, whenever the so-called reset conditions are satisfied. Beyond the fact that this class of systems allows to deal with a broad range of applications, as automotive systems, power systems and biological systems, they can overcome the limitation of classical continuous control law and achieve desired behavior as for example robustness, performance improvement (see, e.g., Hespanha and Morse (1999); Prieur (2005), Safaei et al. (2010), Aangenent et al. (2010); Beker et al. (2001); Goebel and Teel (2009); Hespanha et al. (2003); Prieur and Astolfi (2003); Nešić et al. (2008, 2011), Prieur et al. (2011, 2013)).

In this paper, a new class of hybrid Lur'e dynamical systems is introduced, where a sector nonlinearity may affect both the continuous-time evolution and the reset map acting on suitable closed-loop states. In other words, we consider reset control systems with Lur'e non-linearity, consisting in the interconnection between a linear plant and a non-linearity through a feedback loop. The nonlinearity verifies a cone bounded sector condition Khalil (2002), Castelan et al. (2008). Lyapunov-based exponential stability conditions exploiting homogeneity of the closed loop are proposed by adapting results issued from Goebel et al. (2012); Nešić et al. (2008); Zaccarian et al. (2011). Following the ideas presented in Fichera et al. (2016a), Fichera et al. (2016b), with quadratic Lyapunov certificates these conditions can be cast as linear matrix inequalities (LMIs). We then focus on the control design problem, where we must design 1) the state feedback gains acting on the continuous evolution and the reset action and 2) the shape of the sets where such resets are triggered, expressed as sign-indefinite quadratic forms. For this control design problem we also show that the synthesis can be performed by solving a set of linear matrix inequalities. The contribution of the current note can be viewed as complementary to the results developed in Fiacchini et al. (2012) dealing with quadratic stability problem for hybrid systems with nested saturations.

The extended abstract is organized as follows: Section 2 introduces the class of hybrid systems under consideration and states the problems at stake. Section 3 presents theoretical results dealing with the stability analysis. Section 4 then expands the stability analysis results in order to handle the control design problem. Finally, some concluding remarks are given in Section 5.

Notation. The notation is standard. The Euclidean norm of a vector is denoted by $|\cdot|$. If $\mathcal{A}$ is a compact set, the notation $|x|_{\mathcal{A}} = \min\{|x-y| : y \in \mathcal{A}\}$ indicates the distance of the vector x from the set $\mathcal{A}$. If $\mathcal{A}$ is the origin then $|x|_{\mathcal{A}} = |x|$. For any $s \in \mathbb{R}$, the function $\mathrm{dz} : \mathbb{R} \to \mathbb{R}$ is defined by $\mathrm{dz}(s) = 0$ if $|s| \leq 1$ and $\mathrm{dz}(s) = \mathrm{sign}(s)(|s|-1)$ if $|s| \geq 1$. Given a matrix Q, $\mathrm{He}(Q) = Q + Q^\top$. Moreover, $\lambda_{min}(Q)$ (respectively, $\lambda_{max}(Q)$) denotes the minimum (respectively, the maximum) eigenvalue of Q.

2. PROBLEM STATEMENT

Consider the following hybrid system, including an input nonlinearity ϕ,

$$\begin{cases} \dot{x} = A_F x + B_F \phi(u_F), \\ \dot{\tau} = 1 - \mathrm{dz}\left(\dfrac{\tau}{\rho}\right) \end{cases} \qquad (x,\tau) \in \mathcal{C} \qquad (1a)$$

$$\begin{cases} x^+ = A_J x + B_J \phi(u_J) \\ \tau^+ = 0, \end{cases} \qquad (x,\tau) \in \mathcal{D} \qquad (1b)$$

where $x \in \mathbb{R}^n$ is the physical state, $\tau \in \mathbb{R}$ is a dwell-time logic (with $\rho > 0$), and $u_F \in \mathbb{R}^m$ and $u_J \in \mathbb{R}^m$ are suitable

control inputs to be designed. The flow and jump sets $\mathcal{C}$ and $\mathcal{D}$ are defined as follows:

$$\begin{aligned}\mathcal{C} &:= \{(x,\tau) : x \in \mathcal{F} \text{ or } \tau \in [0,\rho]\} \\ &= \{(x,\tau) : x \in \mathcal{F}\} \cup \{(x,\tau) : \tau \in [0,\rho]\} \qquad (2)\\ \mathcal{D} &:= \{(x,\tau) : x \in \mathcal{J} \text{ and } \tau \in [\rho,2\rho]\} \\ &= \{(x,\tau) : x \in \mathcal{J}\} \cap \{(x,\tau) : \tau \in [\rho,2\rho]\} \qquad (3)\end{aligned}$$

with $\mathcal{F}$ and $\mathcal{J}$ symmetric cones defined by a symmetric (typically not sign definite) matrix $M = M^\top \in \mathbb{R}^{n\times n}$ as

$$\begin{aligned}\mathcal{F} &:= \{x \in \mathbb{R}^n : x^\top M x \le 0\} \\ \mathcal{J} &:= \{x \in \mathbb{R}^n : x^\top M x \ge 0\}.\end{aligned} \qquad (4)$$

The nonlinearity ϕ affecting the system input is a known, continuous, decentralized cone bounded nonlinearity (see, for example, Khalil (2002), Castelan et al. (2008)) as stated in the following assumption.

Assumption 1. The nonlinearity $\phi : \mathbb{R}^m \to \mathbb{R}^m$ is a known, continuous and decentralized function, which verifies the following generic cone bounded sector condition for any diagonal positive definite matrix $S \in \mathbb{R}^{m\times m}$:

$$\phi^\top(\zeta)\, S\, (\phi(\zeta) - \Omega\zeta) \le 0 \quad \forall \zeta \in \mathbb{R}^m \qquad (5)$$

Matrix $\Omega \in \mathbb{R}^{m\times m}$ is a positive definite diagonal matrix defining the sector $[0, \Omega_{i,i}]$, where each component ϕ_i of ϕ lies.

In this note, the inputs of the flow and jump maps are selected as linear static state feedbacks:

$$u_F = K_F x \text{ and } u_J = K_J x, \qquad (6)$$

with $K_F \in \mathbb{R}^{m\times n}$, $K_J \in \mathbb{R}^{m\times n}$. Then the closed loop (1)-(6) can be rewritten as

$$\begin{cases}\dot{x} = A_F x + B_F \phi(K_F x) \\ \dot{\tau} = 1 - \mathrm{dz}\left(\dfrac{\tau}{\rho}\right),\end{cases} \quad (x,\tau) \in \mathcal{C} \qquad (7a)$$

$$\begin{cases}x^+ = A_J x + B_J \phi(K_J x) \\ \tau^+ = 0,\end{cases} \quad (x,\tau) \in \mathcal{D}, \qquad (7b)$$

where the flow and jumps sets $\mathcal{C}$ and $\mathcal{D}$ are defined in equation (2) and (3), respectively.

Remark 1. Note that in the closed-loop system (7), the two nonlinearities $\phi(K_F x)$ and $\phi(K_J x)$ satisfy Assumption 1. Therefore, the generic relation (5) can be particularized for both $\phi(K_F x)$ and $\phi(K_J x)$ as follows

$$\phi(K_F x)^\top\, S_F\, (\phi(K_F x) - \Omega_F K_F x) \le 0 \quad \forall x \in \mathbb{R}^n \qquad (8)$$

$$\phi(K_J x)^\top\, S_J\, (\phi(K_J x) - \Omega_J K_J x) \le 0 \quad \forall x \in \mathbb{R}^n, \qquad (9)$$

which holds for any diagonal positive matrices $S_F \in \mathbb{R}^{m\times m}$, $S_J \in \mathbb{R}^{m\times m}$ and where $\Omega_F \in \mathbb{R}^{m\times m}$ and $\Omega_J \in \mathbb{R}^{m\times m}$ are suitable positive definite diagonal matrices. Matrices Ω_F and Ω_J are supposed to be known.

In this note we address 1) the stability analysis of system (1)-(6), or equivalently system (7), when K_F are K_J are given, and 2) the design problem where K_F are K_J must be designed.

These two complementary problems can be summarized as follows.

Problem 1. Given the gains K_F are K_J, devise conditions to guarantee that the compact set $\mathcal{A}$ defined as

$$\mathcal{A} = \{0\} \times [0, 2\rho] \subset \mathbb{R}^n \times [0, 2\rho] \qquad (10)$$

is globally asymptotically stable for the closed loop (1)-(6) (equivalently, system (7)).

Problem 2. Design the gains K_F are K_J in (4) such that the compact set $\mathcal{A}$ defined as in (10) is globally asymptotically stable for the closed loop (1)-(6) (equivalently system (7)).

3. STABILITY ANALYSIS RESULTS

In this section, theoretical results addressing Problem 1 are proposed by exploiting some ingredients provided in Fichera et al. (2016a), Prieur et al. (2018).

Recall that due to the dwell-time, the solutions (x,τ) to system (7) may flow outside the flow set as emphasized for example in Zaccarian et al. (2005),Prieur et al. (2018). Hence, to deal with the effects of dwell-time on trajectories and in order to allow for more design flexibility consider the following definitions,

$$\tilde{\mathcal{F}} = \{x \in \mathbb{R}^n : x^\top \tilde{M} x \le 0\} \qquad (11)$$

$$\tilde{\mathcal{F}}_\epsilon = \{x \in \mathbb{R}^n : x^\top \tilde{M} x - \epsilon x^\top x \le 0\} \qquad (12)$$

with $\tilde{M} = \tilde{M}^\top \in \mathbb{R}^{n\times n}$ and $\epsilon > 0$ to be designed.

Note that (12) is the ϵ-inflated version of (11), therefore the inclusion $\tilde{\mathcal{F}} \subset \tilde{\mathcal{F}}_\epsilon$ is always satisfied.

Stability conditions to solve Problem 1 are first proposed by focusing on a generic Lyapunov function, and then they are specialized to a quadratic Lyapunov function, thus leading to a convenient formulation involving convex linear matrix inequalities (LMI).

Theorem 1. Consider system (7) and the sets defined in (11) and (12). Assume that there exist a continuously differentiable function $V : \mathbb{R}^n \to \mathbb{R}_{\ge 0}$, positive real scalars $\alpha_1, \alpha_2, \alpha_3$ and a nonnegative scalar $\underline{\rho}$ satisfying

$$\alpha_1 |x|^2 \le V(x) \le \alpha_2 |x|^2, \qquad \forall x \in \mathbb{R}^n, \qquad (13)$$

$$\begin{aligned}&\langle \nabla V(x), A_F x + B_F \phi_F \rangle + \alpha_3 V(x) \\ &\quad - 2\phi_F^\top S_F (\phi_F - \Omega_F K_F x) < 0, \quad \forall x \in \tilde{\mathcal{F}}_\epsilon \setminus \{0\}\end{aligned} \qquad (14)$$

$$\begin{aligned}&V(A_J x + B_J \phi_J) - \exp(\alpha_3 \underline{\rho}) V(x) \\ &\quad - 2\phi_J^\top S_J (\phi_J - \Omega_J K_J x) \le 0, \quad \forall x \in \mathcal{J}\end{aligned} \qquad (15)$$

$$x^+ \in \tilde{\mathcal{F}}, \qquad \forall x \in \mathcal{J} \qquad (16)$$

$$\mathcal{F} \subset \tilde{\mathcal{F}}_\epsilon \qquad (17)$$

with ϕ_F and ϕ_J being shorthands for $\phi(K_F x)$ and $\phi(K_J x)$, respectively. Then there exists $\bar{\rho} > \underline{\rho}$ such that, for any $\rho \in (\underline{\rho}, \bar{\rho})$, the set $\mathcal{A} := \{0\} \times [0, 2\rho] \subset \mathbb{R}^n \times [0, 2\rho]$ is globally asymptotically stable for the hybrid closed-loop system (7).

Proof. The proof is omitted in this extended abstract. However, the key ingredients of the proof emerge from a careful expansion of the proof of Theorem 5.1 in Prieur et al. (2018) to the case of system (7) subject to the nonlinearities $\phi(K_F x)$ and $\phi(K_J x)$ satisfying the cone-bounded conditions (8) and (9), respectively. □

An interesting way to particularize Theorem 1 is to select a quadratic Lyapunov function $V(x) = x^\top P x$, in order to derive LMI-based conditions. Then, the following result can be stated in the context of Problem 1.

Proposition 1. Given System (7) and positive scalars $\alpha_3 > 0$, $\underline{\rho} > 0$, assume that there exist matrices $P = P^\top > 0$, $\tilde{M} = \tilde{M}^\top$, S_F, S_J and $\tilde{S}_J$ diagonal positive definite matrices, non-negative scalars τ_S, τ_R, $\tilde{\tau}_C$, $\tilde{\tau}_F$ and a positive scalar ϵ such that the following inequalities hold,

$$\begin{pmatrix}\mathrm{He}(PA_F) + \alpha_3 P - \tau_S(\tilde{M} - \epsilon I) & PB_F + K_F^\top \Omega_F S_F \\ B_F^\top P + S_F \Omega_F K_F & -2S_F\end{pmatrix} < 0 \qquad (18)$$

$$\begin{pmatrix} A_J^\top P A_J - \exp(\alpha_3 \rho) P + \tau_R M & A_J^\top P B_J + K_J^\top \Omega_J S_J \\ B_J^\top P A_J + S_J \Omega_J K_J & B_J^\top P B_J - 2 S_J \end{pmatrix} \leq 0 \tag{19}$$

$$\begin{pmatrix} A_J^\top \tilde{M} A_J + \tilde{\tau}_C M & A_J^\top \tilde{M} B_J + K_J^\top \Omega_J \tilde{S}_J \\ B_J^\top \tilde{M} A_J + \tilde{S}_J \Omega_J K_J & B_J^\top \tilde{M} B_J - 2 \tilde{S}_J \end{pmatrix} \leq 0 \tag{20}$$

$$\tilde{M} - \tilde{\tau}_F M \leq \epsilon I. \tag{21}$$

Then there exists $\bar{\rho} > \rho$ such that for any $\rho \in (\rho, \bar{\rho})$ the set $\mathcal{A}$ is globally asymptotically stable for the hybrid closed-loop system (7).

Proof. We only present a sketch of the proof, which consists in rewriting the conditions of Theorem 1 fpr the case where $V(x) = x^\top P x$. Indeed, let us consider the case of relation (14), which reads

$$\begin{aligned} 2x^\top P(A_F x + B_F \phi_F) + \alpha_3 x^\top P x \\ -2\phi_F^\top S_F(\phi_F - \Omega_F K_F x) < 0, \forall x \in \tilde{\mathcal{F}}_\epsilon \setminus \{0\} \end{aligned}$$

with ϕ_F the shorthands for $\phi(K_F x)$. We can handle the fact that the condition has to be satisfied for any $x \in \tilde{\mathcal{F}}_\epsilon \setminus \{0\}$ by using the S-procedure (see Boyd et al. (1994)) and the definition (12), which leads to

$$\begin{aligned} 2x^\top P(A_F x + B_F \phi_F) + \alpha_3 x^\top P x \\ -2\phi_F^\top S_F(\phi_F - \Omega_F K_F x) - -\tau_S x^\top (\tilde{M} - \epsilon I) x < 0 \end{aligned}$$

with $\tau_S \geq 0$. Hence, if relation (18) is verified then the above inequality and therefore condition (14) are satisfied.

The same reasoning holds for relation (15). In the case of condition (16), since ϕ_J is involved, one has to consider that this relation holds for ϕ_J satisfying the cone-bounded condition (9). This leads to relation (20). □

Remark 2. The inequalities presented in Proposition 1 are not LMIs in the matrix decision variables P, $\tilde{M}$, S_F, S_J, $\tilde{S}_J$ and the scalar decision variables τ_S, τ_R, $\tilde{\tau}_C$, $\tilde{\tau}_F$, ϵ due to the product between certain scalar and matrix decision variables. These products can be eliminated, thereby transforming the conditions into authentic LMIs, when multiplying by τ_S inequalities (20) and (21), and performing the following change of variables:

$$\bar{M} = \tau_S \tilde{M}, \bar{\epsilon} = \tau_S \epsilon, \bar{\tau}_C = \tau_S \tilde{\tau}_C, \bar{\tau}_F = \tau_S \tilde{\tau}_F, \tau_S \tilde{S}_J = \bar{S}_J.$$

so that the emerging conditions become linear in the transformed decision variables P, $\bar{M}$, S_F, S_J, $\bar{S}_J$, τ_R, $\bar{\tau}_C$, $\bar{\tau}_F$ and $\bar{\epsilon}$.

It still is required to fix a priori the two scalars α_3 and ρ but we emphasize that these quantities should be selected small enough for the construction to be effective and this helps in an iterative selection.

4. DESIGN RESULTS

In this section we take inspiration from Proposition 1 and Remark 2, to propose sufficient conditions to solve Problem 2. Recall that the matrices Ω_F and Ω_J involved in relations (8) and (9) are supposed to be known.

Proposition 2. Given System (7) and positive scalars $\alpha_3 > 0$ and $\rho > 0$, if there exist matrices $P = P^\top > 0$, $\bar{M} = \bar{M}^\top$, $\bar{K}_F$, $\bar{K}_J$, diagonal matrices $S_F > 0$ and $S_J > 0$, non-negative scalars $\bar{\tau}_F, \bar{\tau}_C, \tau_R \in \mathbb{R}_{\geq 0}$ and positive scalar $\bar{\epsilon}$ such that the following inequalities hold,

$$\begin{pmatrix} A_F^\top P + P A_F + \alpha_3 P - \bar{M} + \bar{\epsilon} I & P B_F + \bar{K}_F^\top \\ B_F^\top P + \bar{K}_F & -2 S_F \end{pmatrix} < 0 \tag{22}$$

$$\begin{pmatrix} A_J^\top P A_J - \exp(\alpha_3 \rho) P + \tau_R M & A_J^\top P B_J + \bar{K}_J^\top \\ B_J^\top P A_J + \bar{K}_J & B_J^\top P B_J - 2 S_J \end{pmatrix} \leq 0 \tag{23}$$

$$\begin{pmatrix} A_J^\top \bar{M} A_J + \bar{\tau}_C M & A_J^\top \bar{M} B_J + \bar{K}_J^\top \\ B_J^\top \bar{M} A_J + \bar{K}_J & B_J^\top \bar{M} B_J - 2 S_J \end{pmatrix} \leq 0 \tag{24}$$

$$\bar{M} - \bar{\tau}_F M \leq \bar{\epsilon} I, \tag{25}$$

Then there exists $\bar{\rho} > 0$ such that for any $\rho \in (\rho, \bar{\rho})$ the set $\mathcal{A}$ is globally exponentially stable for the hybrid closed-loop system (7) with the gains $K_F = S_F^{-1} \Omega_F^{-1} \bar{K}_F$ and $K_J = S_J^{-1} \Omega_J^{-1} \bar{K}_J$.

Proof. The proof follows the same lines as in the proof of Proposition 1 by modifying the conditions thanks to the change of variables suggested in Remark 2. Furthermore, one can also use the change of variables $\bar{K}_F = S_F \Omega_F K_F$ and $\bar{K}_J = S_J \Omega_J K_J$, allowing to recover the gains K_F and K_J because matrices S_F, S_J, Ω_F and Ω_J are all diagonal positive definite and therefore nonsingular. □

5. CONCLUSION

This note introduced a new class of hybrid Lur'e dynamical systems where a sector nonlinearity may affect both the continuous-time evolution and the reset map acting on suitable closed-loop states, under a time-regularization mechanism ensuring dwell time of solutions. For this class of systems, both the stability analysis and the control design problems have been addressed by exploiting Lyapunov-based stability conditions and homogeneity of the closed loop. By selecting a quadratic Lyapunov certificate these conditions can be cast as linear matrix inequalities. In the control design problem, both the feedback gains acting on the continuous evolution and the reset action can be designed. For this control design problem the synthesis can also be performed by solving a set of linear matrix inequalities.

The studies proposed are preliminary but pave the way for future directions of research including addressing regional stability properties and taking into account nonlinearities affecting also the shape of the flow and jump sets. Another interesting problem could be to study how the conditions change if the flow and jump maps are subject to different input-nonlinearities, with independent sector bounds.

Abstract: For a symmetric Lie algebra $\mathfrak{g} = \mathfrak{k} \oplus \mathfrak{p}$ we consider a class of bilinear or more general control-affine systems on $\mathfrak{p}$ defined by a drift vector field X and control vector fields ad_{k_i} which gain fast and full control on the adjoint orbits of the corresponding compact group $\mathbf{K}$. We show that under quite general assumptions on X such a control system is essentially equivalent to a natural reduced system on a maximal Abelian subspace $\mathfrak{a} \subseteq \mathfrak{p}$, and likewise to related differential inclusions defined on $\mathfrak{a}$.

Keywords: Control-affine Systems; Differential Inclusions; Symmetric Lie algebras; Adjoint Orbits

1. INTRODUCTION

We consider control systems that admit fast controllability on certain degrees of freedom, represented by a Lie group action. The goal is to define an associated (reduced) control system on the remaining degrees of freedom, and to show that the two systems are essentially equivalent (in a sense which will be specified later). Of course, this idea is not new and has been applied, e.g., in a seminal work by [Khaneja et al. (2001)] to compute time-optimal controls in certain low-dimensional closed quantum systems. The success of their approach is based on the symmetric space structure of the resulting quotient manifold, i.e. of the manifold which results from factoring out the orbits of the fast controllable dynamics. This method was further exploited by Khaneja and Yuan to characterise the reachable sets of certain bilinear systems, cf. [Yuan et al. (2018)].

In contrast, our subsequent framework is motivated by open quantum dynamics, where for certain experimental settings with switchable noise (i.e. fast controllable coupling to an environment [Chen et al. (2014); Wong et al. (2019)], described in [Bergholm et al. (2016)]) one can assume fast and full control on the unitary orbits in the state space of all density matrices. The drift vector field then usually describes relaxation or, more generally, interaction of the system with some environment. In [Dirr et al. (2019)] a simplified model for such systems was studied, where the state space could be restricted to diagonal density matrices (due to some invariance condition on the drift vector field) and unitary orbits therefore collapsed to a discrete Weyl group action (of permutation matrices). However, without the said invariance condition one is led to factor out the full unitary dynamics. This approach has been pursued in [Rooney et al. (2018)] yet under an additional boundedness condition, which is superfluous as we will show in Thm. 2.

Our general setting will be as follows: Let $\mathfrak{g} = \mathfrak{k} \oplus \mathfrak{p}$ be a semisimple, orthogonal, symmetric Lie algebra defined by its Cartan-like decomposition. This means that $\mathfrak{g}$ is a semisimple Lie algebra, where $\mathfrak{k}$ and $\mathfrak{p}$ are the $+1$ and -1 eigenspaces of some involutive Lie algebra automorphism θ of $\mathfrak{g}$. We will set $\mathbf{K} := \mathrm{Int}_{\mathfrak{g}}(\mathfrak{k})$, the subgroup, generated by $\mathfrak{k}$, of the group of inner automorpisms of $\mathfrak{g}$. Then $\mathbf{K}$ is a compact Lie group and we can endow $\mathfrak{p}$ with a $\mathbf{K}$-invariant inner product. By $\mathfrak{a}$ we denote a choice of maximal Abelian subspace of $\mathfrak{p}$, and by $\mathbf{W} = N(\mathfrak{a})/Z(\mathfrak{a})$ the Weyl group acting on $\mathfrak{a}$, where $N(\mathfrak{a})$ and $Z(\mathfrak{a})$ denote the normalizer and centralizer of $\mathfrak{a}$ in $\mathbf{K}$. The Weyl group is a finite reflection group, and it admits a (closed) Weyl chamber $\mathfrak{w} \subset \mathfrak{a}$. One can show that $\mathfrak{w} \cong \mathfrak{a}/\mathbf{W} \cong \mathfrak{p}/\mathbf{K}$ are canonically isometric. For further details we refer to, e.g., [Helgason (1978)].

Example 1. (Eigenvalue decomposition). Consider the symmetric Lie algebra $\mathfrak{sl}(n, \mathbb{C}) = \mathfrak{su}(n) \oplus \mathfrak{herm}_0(n, \mathbb{C})$, where $\mathfrak{herm}_0(n, \mathbb{C})$ denotes the traceless Hermitian matrices. The corresponding Lie algebra automorphism is $\theta(x) := -x^*$. Then a convenient choice of a maximal Abelian subspace of $\mathfrak{herm}_0(n, \mathbb{C})$ is the set $\mathfrak{diag}_0(\mathbb{R})$ of real traceless diagonal matrices. The Weyl group is isomorphic to the symmetric group S_n acting by permutation of the diagonal entries of the elements of $\mathfrak{diag}_0(\mathbb{R})$, and a natural choice of a Weyl chamber is given by the real traceless diagonal matrices with diagonal elements in weakly decreasing order.

⋆ The project was supported i.a. by Excellence Network of Bavaria under ExQM and is part of *Munich Quantum Valley* of the Bavarian State Government with funds from Hightech Agenda *Bayern Plus*.

Example 2. Consider the symmetric Lie algebra $\mathfrak{su}(n) = \mathfrak{so}(n,\mathbb{R}) \oplus i\mathfrak{sym}_0(n,\mathbb{R})$ corresponding to the compact Riemannian symmetric space $\mathrm{SU}(n)/\mathrm{SO}(n)$. Here $\mathfrak{sym}_0(n,\mathbb{R})$ denotes the traceless real symmetric matrices. This symmetric Lie algebra is isomorphic to the symmetric Lie algebra $\mathfrak{sl}(n,\mathbb{R}) = \mathfrak{so}(n,\mathbb{R}) \oplus \mathfrak{sym}_0(n,\mathbb{R})$, which now corresponds to the non-compact Riemannian symmetric space $\mathrm{SL}(n,\mathbb{R})/\mathrm{SO}(n)$. Such a duality holds for all symmetric Lie algebras. Note that the latter example corresponds to the orthogonal diagonalization of (traceless) real symmetric matrices.

In fact many common matrix diagonalizations, e.g. the singular value decomposition, and also some uncommon ones, can be rephrased in the setting of symmetric Lie algebras [Kleinsteuber (2006)].

After these preliminaries we can define the class of control-affine systems on $\mathfrak{p}$ that we want to study in the sequel. Given a vector field $X \in \mathfrak{X}(\mathfrak{p})$, and a set of control directions $k_1, \dots, k_m \in \mathfrak{k}$ satisfying $\langle k_1, \dots, k_m \rangle_{\mathsf{Lie}} = \mathfrak{k}$, we consider the control system

$$\dot{p}(t) = X(p(t)) + \sum_{i=1}^{m} u_i(t)\,\mathrm{ad}_{k_i}(p(t)),\ p(0) = p_0 \in \mathfrak{p} \quad \text{(A)}$$

where ad_x denotes the adjoint operator of x, that is, $\mathrm{ad}_x(y) := [x,y]$. The control functions $u_i : [0,T] \to \mathbb{R}$ are required to be locally integrable. A solution $p : [0,T] \to \mathfrak{p}$ is an absolutely continuous function satisfying (A) almost everywhere. Obviously (A) reduces to a bilinear system [Elliott (2009)] if X is linear.

Since the control directions k_i generate the entire Lie algebra $\mathfrak{k}$, and since we do not impose any bounds (neither of L^∞ nor of L^1 type) on the control functions, we can move within the $\mathbf{K}$-orbits of $\mathfrak{p}$ from any starting point to any desired target point arbitrarily quickly [Jurdjevic and Sussmann (1972)]. We say that we have fast and full control on the Lie group $\mathbf{K}$ and consequently on any $\mathbf{K}$-orbit of $\mathfrak{p}$. In particular we can move into the maximal Abelian subspace $\mathfrak{a}$ at any time. This motivates us to define a reduced control system on $\mathfrak{a}$. To this end we first introduce some useful concepts.

For every $K \in \mathbf{K}$, we define the *induced vector field*

$$X_K := \Pi_{\mathfrak{a}} \circ \mathrm{Ad}^\star_K(X) \in \mathfrak{X}(\mathfrak{a}),$$

where $\Pi_{\mathfrak{a}}$ is the orthogonal projection in $\mathfrak{p}$ on $\mathfrak{a}$. By Ad_K we denote the adjoint action of $\mathbf{K}$ on $\mathfrak{p}$ and by $\mathrm{Ad}^\star_K$ its pullback action, i.e.,

$$\mathrm{Ad}^\star_K(X) = \mathrm{Ad}_K^{-1} \circ X \circ \mathrm{Ad}_K\,.$$

If X is linear, then so are all X_K. Furthermore we define the set of *achievable derivatives* at $a \in \mathfrak{a}$ by

$$\Lambda(a) = \{X_K(a) : K \in \mathbf{K}\} \subset T_a\mathfrak{a} \cong \mathfrak{a}.$$

Since $\mathbf{K}$ is compact, $\Lambda(a)$ is also compact for all a. We can interpret $\Lambda : \mathfrak{a} \to \mathcal{P}(\mathfrak{a})$ as a set valued function. It turns out that if X is Lipschitz, e.g. if it is linear, then the set valued function Λ is also Lipschitz. This means that for all $x, y \in \mathfrak{a}$,

$$\Lambda(x) \subseteq \Lambda(y) + L\|x-y\|B_1$$

for some (global) Lipschitz constant $L > 0$ and where B_1 denotes the closed unit ball in $\mathfrak{a}$.

Now we can define the *reduced control* system by

$$\dot{a}(t) = X_{U(t)}(a(t)), \quad a(0) = a_0 \in \mathfrak{a}, \qquad \text{(Q)}$$

where the control function $U : [0,T] \to \mathbf{K}$ has to be measurable [1]. Again, a solution $a : [0,T] \to \mathfrak{a}$ is absolutely continuous and satisfies (Q) almost everywhere. We can also define a corresponding *differential inclusion*

$$\dot{a}(t) \in \Lambda(a(t)), \quad a(0) = a_0 \in \mathfrak{a}, \qquad \text{(I)}$$

where a solution $a : [0,T] \to \mathfrak{a}$ needs to be absolutely continuous and satisfy (I) almost everywhere. In fact, if X is continuous, (Q) and (I) are equivalent, i.e. they have the same solutions, see Thm. 2.3 in [Smirnov (2002)]. Often it will be convenient to consider a relaxed version of the differential inclusion given by

$$\dot{a}(t) \in \mathrm{conv}(\Lambda(a(t))), \quad a(0) = a_0 \in \mathfrak{a}, \qquad \text{(R)}$$

where conv denotes the convex hull. This will slightly enlarge the set of solutions, however, if X is Lipschitz, every solution of (R) can still be approximated uniformly (on compact time intervals) by solutions to (I), see Ch. 2.4, Thm. 2 in [Aubin et al. (1984)].

If X is Lipschitz, then Λ is Lipschitz with compact values, which implies some convenient properties of the relaxed control system (R), see Ch. 4 in [Smirnov (2002)].

Proposition 1. Let X be Lipschitz and let $a_0 \in \mathfrak{a}$. It holds that:

(i) The set $S_{[0,T]}(a_0)$ of solutions to (R) is path connected in the AC-topology [2];
(ii) If Λ is bounded, then $S_{[0,T]}(a_0)$ is compact in the standard C-topology of uniform convergence;
(iii) If $a \in S_{[0,T]}(a_0)$ is a solution to (R) with $a(T) \in \partial\mathsf{reach}_{[0,T]}(a_0)$, then $a(t) \in \partial\mathsf{reach}_{[0,t]}(a_0)$ for all $t \in [0,T]$;
(iv) If Λ is bounded, then there exist time-optimal solutions to (R) starting in a given compact set and ending in a given closed set, if any such solution exists;
(v) If X is Lipschitz with global Lipschitz constant L, then the map $S_{[0,T]} : \mathfrak{a} \to AC([0,T],\mathfrak{a})$ is Lipschitz with global Lipschitz constant $1 + TLe^{TL}$.

2. MAIN RESULTS

Our main results describe the equivalence of the control-affine system (A) on $\mathfrak{p}$ and the reduced control system (Q) on $\mathfrak{a}$. Detailed proofs will be presented in the MTNS-talk and published in a subsequent journal paper. Here – due to page constraints – we focus on a sketch of the key ideas.

First we show a local equivalence result which illustrates why the definition of the reduced control system is reasonable. For this we need the following fact: if $p : [0,T] \to \mathfrak{p}$ is differentiable at $t \in [0,T]$, then there is some $a : [0,T] \to \mathfrak{a}$ differentiable at t satisfying $\pi \circ p = \pi \circ a$. Furthermore this derivative is well defined up to a Weyl group action on the pair $(a(t), \dot{a}(t))$. [3] Hence we can define the set

[1] Due to the compactness of $\mathbf{K}$, the control function U is automatically bounded, and hence in L^∞.

[2] By $AC([0,T],\mathfrak{a})$ we denote the Banach space of absolutely continuous functions $a : [0,T] \to \mathfrak{a}$ with the norm $\|a\|_{AC} = |a(0)| + \int_0^T |\dot{a}(t)|dt$.

[3] In the case of unitary diagonalization of Hermitian matrices (Example 1), this is a well-known result, see Ch. I.§5, Thm. 1 in [Rellich (1969)]. We extended the result to all semisimple, orthogonal, symmetric Lie algebras.

$$\tilde{\Lambda}(a) = \{\dot{b}(t) : b : [0,T] \to \mathfrak{a} \text{ differentiable at } t, b(t) = a, \\ \pi \circ b = \pi \circ p, \text{ and } p : [0,T] \to \mathfrak{p} \text{ solves (A)}\},$$

which is the set of all possible derivatives in $\mathfrak{a}$ of solutions to (A). Recall that $\mathbf{K}_a$ and $\mathbf{W}_a$ denote the stabilizers of a in $\mathbf{K}$ and $\mathbf{W}$ respectively.

Proposition 2. (Local equivalence). It holds that

$$\tilde{\Lambda}(a) \subseteq \Lambda(a) = \bigcup_{v \in \tilde{\Lambda}(a)} \operatorname{conv}(\mathbf{W}_a v) \subseteq \operatorname{conv}(\tilde{\Lambda}(a)),$$

and in particular,

$$\operatorname{conv}(\Lambda(a)) = \operatorname{conv}(\tilde{\Lambda}(a)).$$

Proof. [Sketch of proof] The first inclusion follows from a computation as in the proof of the following theorem. For the first equality a computation shows that (we replace a by b for clarity)

$$\begin{aligned}\Lambda(b) &= \bigcup_{[K] \in \mathbf{K}/\mathbf{K}_b} \{(\Pi_{\mathfrak{a}} \circ \operatorname{Ad}_{\tilde{K}}^{-1} \circ \operatorname{Ad}_K^\star(X))(b) : \tilde{K} \in \mathbf{K}_b\} \\ &= \bigcup_{[K] \in \mathbf{K}/\mathbf{K}_b} \operatorname{conv}(\mathbf{W}_b \cdot (\pi_b \circ \Pi_b \circ \operatorname{Ad}_K^\star(X))(b)),\end{aligned}$$

where the second transformation uses Kostant's convexity theorem applied to the symmetric Lie subalgebra of $\mathfrak{g}$ given by the commutant of b. Here Π_b denotes the orthogonal projection onto the commutant of b in $\mathfrak{p}$, and $\pi_b : \mathfrak{p}_b \to \mathfrak{p}_b/\mathbf{K}_b$ denotes the quotient map. The rest is straightforward.

Now we will prove a global equivalence result. The first direction, projecting from $\mathfrak{p}$ to $\mathfrak{a}$ is the easier one. In the following we denote by $\pi : \mathfrak{p} \to \mathfrak{w} \cong \mathfrak{p}/\mathbf{K}$ the quotient map, where $\mathfrak{w}$ is some choice of Weyl chamber.

Theorem 1. Let $p : [0,T] \to \mathfrak{p}$ be a solution to the control-affine system (A). Then $a = \pi \circ p$ is a solution to the reduced control system (Q).

Proof. [Sketch of proof] The quotient map π is non-expansive, and hence a is absolutely continuous. On the subset $J \subseteq [0,T]$ where both p and a are differentiable, it holds that there is some $K : J \to \mathbf{K}$ such that $a = \operatorname{Ad}_K^{-1}(p)$ and $\dot{a} = \operatorname{Ad}_K^{-1} \circ \Pi_p(\dot{p})$. Then a computation shows that $\dot{a} = X_K(a)$ on J, and hence (as J clearly has full measure) a satisfies the differential inclusion (I) almost everywhere.

More delicate is the other direction, lifting from $\mathfrak{a}$ to $\mathfrak{p}$.

Theorem 2. Assume that X is Lipschitz and real analytic. Let $a : [0,T] \to \mathfrak{a}$ be a solution to the reduced control system (Q) with control function $U : [0,T] \to \mathbf{K}$. Then, for every $\varepsilon > 0$ there exists a solution $p : [0,T] \to \mathfrak{p}$ to the control-affine system (A) satisfying $\|\operatorname{Ad}_k(a) - p\|_\infty \leq \varepsilon$. In particular $\|\pi \circ p - \pi \circ a\|_\infty \leq \varepsilon$.

Proof. [Sketch of proof] Using standard L^1-approximation results we may assume that U is real analytic and that $a(0)$ is regular [4], see Sec. 2.8 Thm. 1 in [Sontag (1998)]. Hence a is real analytic and regular with finitely many exceptions. Now we define an ideal lift q of a by $q = \operatorname{Ad}_U(a)$. Moreover we define an approximating solution p by $\dot{p} = (\operatorname{ad}_h + X)p$ and $p(0) = q(0)$, where h contains the derivative of U as well as the part of $X(q)$ tangential to the $\mathbf{K}$ orbit, outside of an ε region around the singular points of a. By definition h is bounded and hence p is well-defined. Then one can use Gronwall's inequality to bound the difference $p - q$ and one finds that p approximates q uniformly as $\varepsilon \to 0$. Finally, by standard techniques from control theory, cf. [Liu (1997)], one can uniformly approximate p using solutions to (A).

The problems occur at the points where the stabilizers in $\mathbf{K}$ or $\mathbf{W}$ respectively are not minimal. When projecting, this generally reduces the regularity. To deal with this we generalized several known results for Hermitian matrices to the setting of semisimple, orthogonal, symmetric Lie algebras. In particular, although the quotient map $\pi : \mathfrak{p} \to \mathfrak{w}$ is not differentiable at the singular points, it still preserves absolute continuity, and at the points where the projected path is differentiable, we can give an explicit expression for the derivative. When lifting, the control functions might need to diverge at these points. Intuitively this happens because the orbits of the corresponding stabilizers become arbitrarily small, and so the control in these directions becomes increasingly ineffective. In [Rooney et al. (2018)] the control system on the eigenvalue simplex was defined with the additional condition that such a divergence was not allowed to occur. We showed that this assumption is unnecessary, by approximating the solutions in a neighborhood of the singular points.

Example 3. To see that the approximation cannot be avoided in general, consider a system where $X(0) \neq 0$. Then $p \equiv 0$ is not a solution of (A), but $a \equiv 0$ is a solution of (Q). Indeed, by Kostant's convexity theorem [Kostant (1973)], and assuming that $X(0) \in \mathfrak{a}$, we see that

$$\Lambda(0) = \{\Pi_{\mathfrak{a}} \circ \operatorname{Ad}_K(X(0)) : K \in \mathbf{K}\} = \operatorname{conv}(\mathbf{W}(X(0)))$$

and hence $\Lambda(0)$ contains the convex combination

$$\frac{1}{|\mathbf{W}|} \sum_{w \in \mathbf{W}} w \cdot X(0),$$

which equals 0, the unique fixed point of a Weyl group action. Thus $a \equiv 0$ is a solution to (Q).

Finally, the above findings suggest to formalize the notion of equivalence [5] of control systems as follows:

Definition 1. Let X and Y be two (state) spaces on which are defined two control systems whose solutions are absolutely continuous functions. Let $\pi : X \to Y$ be a (at least Lipschitz-continuous) surjection. We say that the two control systems are equivalent if

(i) whenever $x : [0,T] \to X$ is a solution on X, then $\pi \circ x$ is a solution on Y;
(ii) whenever $y : [0,T] \to Y$ is a solution on Y, there exist solutions $x_n : [0,T] \to X$ such that $\pi \circ x_n$ uniformly approximates y as $n \to \infty$.

Then the equivalence between the control-affine and the reduced system follows immediately from Theorem 1 and Theorem 2. Moreover, their proofs reveal the following equivalence between their reachable sets:

Theorem 3. Assume that X is Lipschitz and real analytic. Then for each $T > 0$ and $p \in \mathfrak{p}$ one has

[4] Recall that $a \in \mathfrak{a}$ is called regular if it has trivial stabilizer in W, or equivalently, if it lies in the interior of a Weyl chamber.

[5] Note that this definition does not yield an equivalence relation.

$$\mathsf{reach}_T(p) \subseteq \mathrm{Ad}_{\mathbf{K}}(\mathsf{reach}_T(\pi(p))) \subseteq \overline{\mathsf{reach}_T(p)},$$

where the reachable sets refer the the control-affine system (A) on $\mathfrak{p}$ and the relaxed control system (R) on $\mathfrak{a}$.

3. CONCLUSION

We have shown that for a class of control systems defined on symmetric Lie algebras and with fast control on the corresponding compact Lie group (examples of which appear naturally in quantum control theory), one can define a reduced control system whose state space has a much lower dimension. The equivalence theorem shows that this reduction does not incur any loss of information. Hence this method yields a new perspective on these control systems, and in some cases allows to visualize properties of the system due to the reduction in dimension. Furthermore the new control system can be represented by a differential inclusion with nice properties, and thus allows for many new methods to be applied to the system.

Abstract: Gas transport in one-dimensional pipe networks can be described as an abstract dissipative Hamiltonian system, for which quantitative stability bounds can be derived by means of relative energy estimates for subsonic flow. This allows to establish convergence to the parabolic limit problem in the practically relevant high friction regime. The stability estimates carry over almost verbatim to a mixed finite element approximations with an implicit Euler time discretization, leading to order optimal convergence rates that are uniform the high friction limit. All results are proven in detail for the flow on a single pipe, but by the port-Hamiltonian formalism, they naturally extend to pipe networks.

Keywords: port-Hamiltonian systems, relative energy estimates, asymptotic preserving schemes

1. INTRODUCTION

We consider dynamical systems modelling the transport of gas in long pipes and pipe networks. On each pipe, identified with the interval $(0,\ell)$, the flow is modelled by the barotropic Euler equations which after transformation and rescaling are given by

$$a\partial_\tau \rho + \partial_x(a\rho w) = 0, \tag{1}$$

$$\varepsilon^2 \partial_\tau w + \partial_x\big(\frac{\varepsilon^2}{2} w^2 + P'(\rho)\big) = -\gamma |w| w. \tag{2}$$

Here a is the cross-sectional area of the pipe, ρ the gas density, τ, w and γ the rescaled time, velocity and friction coefficient, $P(\rho)$ the pressure potential, and ε a scaling parameter, proportional to the Mach number.

Of particular interest for the operation of gas transportation networks is the low-Mach, respectively, high friction limit $\varepsilon \to 0$, which describes to the practically relevant setting of long length and time scales; see Brouwer et al. (2011) for details. In this case, one can expect smooth solutions bounded away from vacuum, which is important in practice and therefore assumed in the following.

By formally setting $\varepsilon = 0$ in the system (1)–(2), and eliminating the velocity w via (2), one obtains a doubly nonlinear parabolic model for gas transport which is widely used in practice and which has also been studied intensively in the mathematical literature. Existence of weak solutions, uniform bounds, and converging discretization methods have been established for this models; see e.g. Bamberger et al. (1979); Schöbel-Kröhn (2020).

2. ABSTRACT HAMILTONIAN FORMULATION.

The functions ρ, w in (1)–(2) are the *state variables* of the system, and we define corresponding *co-state variables* by

$$h := \tfrac{\varepsilon^2}{2} w^2 + P'(\rho), \qquad m := a\rho w, \tag{3}$$

which have the physical interpretation of the total specific enthalpy and mass flux, respectively. These auxiliary functions are linked via $ah = \frac{\delta \mathcal{H}}{\delta \rho}$ and $\varepsilon^2 m = \frac{\delta \mathcal{H}}{\delta w}$ to the variational derivatives of the associated energy functional

$$\mathcal{H}(\rho, w) := \int_0^\ell a\big(\frac{\varepsilon^2}{2}\rho w^2 + P(\rho)\big)\, dx. \tag{4}$$

Multiplying (1)–(2) with suitable test functions, integrating over $(0,\ell)$, and applying integration-by-parts in the second equation leads to

$$(a\partial_\tau \rho, q) + (\partial_x m, q) = 0, \tag{5}$$

$$(\varepsilon^2 \partial_\tau w, r) - (h, \partial_x r) = -(\gamma |w| w, r) - hr\big|_0^\ell, \tag{6}$$

which hold for all smooth test functions q and v, and for all points in time. We use $(u,v) = \int_0^\ell uv\, dx$ for abbreviation. By construction, any smooth solution of (1)–(2) satisfies these variational identities.

The system (5)–(6) can further be written as an abstract dissipative Hamiltonian system of the form

$$\mathcal{C}\partial_\tau \boldsymbol{u} + \big(\mathcal{J} + \mathcal{R}(\boldsymbol{u})\big)\boldsymbol{z}(\boldsymbol{u}) = \mathcal{B}_\partial \boldsymbol{z}(\boldsymbol{u}), \tag{7}$$

with $\boldsymbol{u} = (\rho, w)$ and $\boldsymbol{z}(\boldsymbol{u}) = \mathcal{C}^{-1}\mathcal{H}'(\boldsymbol{u}) = (h, m)$ denoting the state and co-state variables, and with appropriate

operators $\mathcal{C}$, $\mathcal{J}$, $\mathcal{R}$, $\mathcal{B}_\partial$. Note that $\mathcal{C}$ is positive definite, $\mathcal{J}$ skew-symmetric, and $\mathcal{R}(\boldsymbol{u})$ positive. From the abstract form of the problem, we immediately deduce the following energy identity or inequality for smooth solutions of (7)

$$\begin{aligned}\frac{d}{d\tau}\mathcal{H}(\boldsymbol{u}) &= \langle \partial_\tau \boldsymbol{u}, \mathcal{H}'(\boldsymbol{u})\rangle \\ &= -\langle \mathcal{R}(\boldsymbol{u})\boldsymbol{z}(\boldsymbol{u}), \boldsymbol{z}(\boldsymbol{u})\rangle + \langle \mathcal{B}_\partial \boldsymbol{z}(\boldsymbol{u}), \boldsymbol{z}(\boldsymbol{u})\rangle\end{aligned} \tag{8}$$

where $\langle\cdot,\cdot\rangle$ denotes the duality product. This shows that the change in the total energy of the system over time is caused only by dissipation due to friction at pipe walls and by flux over the boundary.

3. ASYMPTOTIC STABILITY

In the following, we further investigate the dependence of solutions to (1)–(2) on the scaling parameter. To do so, we use the concept of *relative energy*, which is defined by

$$\mathcal{H}(\boldsymbol{u}|\hat{\boldsymbol{u}}) = \mathcal{H}(\boldsymbol{u}) - \mathcal{H}(\hat{\boldsymbol{u}}) - \langle \mathcal{H}'(\hat{\boldsymbol{u}}), \boldsymbol{u} - \hat{\boldsymbol{u}}\rangle. \tag{9}$$

For appropriately bounded subsonic states $\boldsymbol{u}$ and $\hat{\boldsymbol{u}}$, the relative energy introduces a distance measure which is equivalent to an ε-weighted L^2-norm; see Dafermos (2005); Egger and Giesselmann (2020) for details.

Now let $\boldsymbol{u} = (\rho, w)$, $\hat{\boldsymbol{u}} = (\hat\rho, \hat w)$ be solutions of (1)–(2) for different scaling parameters ε, $\hat\varepsilon$. Further assume that the pressure potential $P(\rho)$ is smooth and strictly convex, that the flow subsonic, and that the solutions are uniformly bounded and sufficiently smooth. Then we can show that

$$\begin{aligned}&\|\rho(\tau) - \hat\rho(\tau)\|^2_{L^2(0,\ell)} + \varepsilon^2 \|w(\tau) - \hat w(\tau)\|^2_{L^2(0,\ell)} \\ &\quad + \int_0^\tau \|w(s) - \hat w(s)\|^3_{L^3(0,\ell)} \le C e^{c\tau} |\varepsilon^2 - \hat\varepsilon^2|\end{aligned} \tag{10}$$

with constants c, C only depending on bounds for the solutions and parameters; see Egger and Giesselmann (2020) for the details. Let us note that this result holds in particular for $\hat\varepsilon = 0$, and thus yields asymptotic convergence towards the parabolic limit problem.

4. ASYMPTOTIC PRESERVING DISCRETIZATION

For discretization of the variational identities (5)–(6), we use a mixed finite element method in space together with an implicit Euler method in time. Then ρ_h^n and m_h^n denote the piecewise constant resp. piecewise linear approximations for ρ and m, while $w_h = w(\rho_h, m_h)$ and $h_h = h(\rho_h, m_h)$ are defined explicitly as functions of these functions. This amounts to a generalization of standard approximation schemes for related linear wave propagation problems Joly (2003). By formally setting $\varepsilon = 0$, we also obtain a viable numerical method for the parabolic limit problem, i.e., the scheme is *asymptotic preserving*.

Since the abstract Hamiltonian structure (7) of the problem is inherited by this variational discretization approach, also the stability analysis via relative energy estimates transfers directly. This allows us to prove error estimates

$$\begin{aligned}&\|\rho(\tau^n) - \rho_h^n\|^2_{L^2(0,\ell)} + \varepsilon^2 \|m(\tau^n) - m_h^n\|^2_{L^2(0,\ell)} \\ &\quad + \sum_{k=1}^n \Delta\tau \|m(\tau^k) - m_h^k\|^3_{L^3(0,\ell)} \le C(\Delta\tau^2 + h^2)\end{aligned} \tag{11}$$

with a uniform constant C being independent of ε; see Egger et al. (2021) for details. Let us emphasize that the error estimate remains valid in the asymptotic limit $\varepsilon = 0$ and thus also covers the parabolic limit problem. Further note that similar arguments were also employed for the analysis of numerical methods for the compresible Navier-Stokes equations; see Feireisl et al. (2018).

5. EXTENSION TO NETWORKS

Based on the variational framework employed in our analysis, all results presented for a single pipe can be generalized quite naturally to pipe networks, which are described by finite, directed and connected graphs. On every edge of the graph, representing a pipe of the network, the equations (1)–(2) are assumed to hold. Additional coupling conditions now have to be imposed in order to guarantee conservation of mass and energy across pipe junctions; see Reigstad (2015) for details. The weak formulation of this problem again leads to a system of the abstract form (7), such that all stability and convergence results derived for a single pipe carry over to the network almost immediately. Also the numerical scheme as well as its stability and convergence analysis via relative energy estimates hold almost verbatim.

Abstract: We present and develop tools to analyze stability properties of discrete-time switched linear systems driven by shuffled switching signals. A switching signal is said to be shuffled if all modes of the system are activated infinitely often. We establish a notion of joint spectral radius related to these systems: the shuffled joint spectral radius (SJSR) which intuitively measures the impact of shuffling on the decay rate of the system's state. We show how this quantity relates to stability properties of such systems. Specifically, from the SJSR, we can build a lower bound on the minimal shuffling rate in order to stabilize an unstable system. Then, we present several methods to approximate the SJSR, mainly by computing lower and upper bounds using Lyapunov methods and some automata theoretic techniques.

Keywords: Switched Systems, Lyapunov Functions, Exponential Stability, Formal Languages and Automata.

1 INTRODUCTION

Switched systems are dynamical systems with several modes of operations where the active mode is determined by a switching signal. Early works focus on proving stability of switched systems driven by arbitrary switching signals or by switching signals with dwell-time conditions [Liberzon (2003); Sun (2006); Lin and Antsaklis (2009)]. More recent works have considered systems with constrained switching signals where the switching signals are generated by labeled graphs [Lee and Dullerud (2007); Dai (2012); Athanasopoulos and Lazar (2014); Philippe et al. (2016); Pepe (2018)]. Shuffled switching signals is also a class of constrained switching signals that has been considered in the literature [Gurvits (1995); Wang et al. (2017); Girard and Mason (2019)]. A switching signal is said to be shuffled if all the modes of the switched systems are activated infinitely often. In this paper, we focus on the discrete-time switched linear systems driven by shuffled switching signals.

It is well known that the question of stability of discrete-time switched systems with arbitrary switching can be answered efficiently with the notion of the joint spectral radius (JSR) (see Jungers (2009) and the references therein). Intuitively the JSR represents the maximal asymptotic growth rate of products of matrices taken in a set. Computing the JSR is not an easy task but several techniques exist to approximate it. With a similar approach, it is possible to define a joint spectral radius related to the shuffled switched systems: the shuffled joint spectral radius (SJSR).

In this talk, we will present the notion of shuffled switched systems, we will also introduce the SJSR and investigate its properties. Then we will relate this quantity with the stability of such systems and finally we will describe numerical techniques for the SJSR approximation. Also, we mention that the proofs of theoretical results and numerical examples can be found in the preprint [Aazan et al. (2021)].

2 SHUFFLED JOINT SPECTRAL RADIUS

In this section, we present the concept of shuffled switched systems, then we introduce the notion of the ρ-SJSR, also we state a theorem that relates this quantity with the shuffled switched systems trajectories. Finally we present a resulting corollary that relates the system stabilizability with the ρ-SJSR.

2.1 Definition

We consider a discrete-time switched linear system described by the following equation

$$x(t+1) = A_{\theta(t)}x(t), \tag{1}$$

where $t \in \mathbb{N}$, $x(t) \in \mathbb{R}^n$ is the state and $\theta : \mathbb{N} \to \mathcal{I}$ is the switching signal belonging to a particular class of arbitrary switching signals: the shuffled switching signals. $\mathcal{I} = \{1, \cdots, m\}$, with $m \geq 2$ is the finite set of *modes* and $\mathcal{A} = \{A_i \in \mathbb{R}^{n\times n} | i \in \mathcal{I}\}$ is a finite set of matrices indexed by the modes. For a switching signal θ, let $\mathbb{A}_{\theta,0} = I_n$, and

⋆ This work was supported in part by the Agence Nationale de la Recherche (ANR) under Grant HANDY ANR-18-CE40- 0010.

$$\mathbb{A}_{\theta,T} = \prod_{t=0}^{T-1} A_{\theta(t)} = A_{\theta(T-1)} \cdots A_{\theta(0)},\ \forall T \geq 1.$$

Given an initial state $x_0 \in \mathbb{R}^n$, the trajectory defined by (1) with $x(0) = x_0$ is denoted $\mathbf{x}(.,x_0,\theta)$, it satisfies for all $t \in \mathbb{N}$, $\mathbf{x}(t,x_0,\theta) = \mathbb{A}_{\theta,t}x_0$.

Formally, the shuffled switching signal is defined as in [Girard and Mason (2019)]:

Definition 1. A switching signal $\theta : \mathbb{N} \to \mathcal{I}$ is *shuffled* if

$$\forall i \in \mathcal{I}, \forall T \in \mathbb{N}, \exists t \geq T :\ \theta(t) = i.$$

Following the previous definition, it is natural to define the following quantities related to a shuffled switching signal θ:

- The sequence of *shuffling instants* $(\tau_k^\theta)_{k\in\mathbb{N}}$ is defined by $\tau_0^\theta = 0$ and for all $k \in \mathbb{N}$,
$$\tau_{k+1}^\theta = \min\left\{ t > \tau_k^\theta \;\middle|\; \begin{array}{c} \forall i \in \mathcal{I}, \exists s \in \mathbb{N} : \\ \tau_k^\theta \leq s < t \text{ and } \theta(s) = i \end{array} \right\}.$$
- The *shuffling index* $\kappa^\theta : \mathbb{N} \to \mathbb{N}$ is given by
$$\kappa^\theta(t) = \max\{k \in \mathbb{N} |\ \tau_k^\theta \leq t\}.$$
- The *shuffling rate* γ^θ is defined as
$$\gamma^\theta = \liminf_{t\to+\infty} \frac{\kappa^\theta(t)}{t}.$$

Let $\mathcal{S}_s(\mathcal{I})$ be the set of all shuffled switching signals taking values in $\mathcal{I}$.

Now we are in a good position to define the ρ-SJSR. Given a finite set of matrices $\mathcal{A} \subseteq \mathbb{R}^{n\times n}$, let $\boldsymbol{\rho}(\mathcal{A})$ be its joint spectral radius (JSR), we recall that the JSR of a set of matrices $\mathcal{A} \subseteq \mathbb{R}^{n\times n}$ is defined as following:

$$\boldsymbol{\rho}(\mathcal{A}) = \lim_{k\to+\infty} \left(\sup \left\{ \left\| \prod_{j=1}^{k} A_j \right\|^{1/k} \;\middle|\; \begin{array}{c} A_j \in \mathcal{A}, \\ j = 1,\dots,k \end{array} \right\} \right).$$

We define the ρ-SJSR as following:

Definition 2. For all $\rho > \boldsymbol{\rho}(\mathcal{A})$, the Shuffled Joint Spectral Radius relative to $(\mathcal{A},\rho)$ (ρ-SJSR for short) is defined as

$$\boldsymbol{\lambda}(\mathcal{A},\rho) = \limsup_{k\to+\infty} \left(\sup_{\theta\in\mathcal{S}_s(\mathcal{I})} \left(\frac{\left\|\mathbb{A}_{\theta,\tau_k^\theta}\right\|}{\rho^{\tau_k^\theta}} \right)^{1/k} \right). \quad (2)$$

It is useful to say that the *limsup* in the above definition can be replaced by a simple limit. Due to the norm equivalence, one can replace the norm in (2) by any submultiplicative matrix norm.

2.2 Shuffled switched systems and ρ-SJSR

Now, when $\boldsymbol{\lambda}(\mathcal{A},\rho) > 0$, we bring out the relation between the system's trajectories and the ρ-SJSR. Then, we will derive a sufficient condition for stabilization based on the minimal shuffling rate and the ρ-SJSR. The following theorem clarifies the relationship between the ρ-SJSR and the behavior of the trajectories of (1).

Theorem 1. For all $\rho > \boldsymbol{\rho}(\mathcal{A})$, for all $\lambda \in (\boldsymbol{\lambda}(\mathcal{A},\rho), 1]$, there exists $C \geq 1$ such that

$$\begin{aligned} \|\mathbf{x}(t,x_0,\theta)\| \leq & C\rho^t\lambda^{\kappa^\theta(t)}\|x_0\|, \\ & \forall\theta \in \mathcal{S}_s(\mathcal{I}),\ \forall x_0 \in \mathbb{R}^n,\ \forall t \in \mathbb{N}. \end{aligned} \quad (3)$$

Conversely, if there exists $C \geq 1$, $\rho \geq 0$ and $\lambda \in [0,1]$ such that (3) holds, then either $\rho > \boldsymbol{\rho}(\mathcal{A})$ and $\lambda \geq \boldsymbol{\lambda}(\mathcal{A},\rho)$, or $\rho = \boldsymbol{\rho}(\mathcal{A})$ and $\lambda \geq \sup_{\rho'>\boldsymbol{\rho}(\mathcal{A})} \boldsymbol{\lambda}(\mathcal{A},\rho')$.

A remarkable result from the previous theorem is a sufficient condition for stabilization based on the minimal shuffling rate.

Corollary 1. Assume $\boldsymbol{\lambda}(\mathcal{A},\rho) > 0$ for every $\rho > \boldsymbol{\rho}(\mathcal{A})$. Let $\theta \in \mathcal{S}_s(\mathcal{I})$, if there exists $\rho > \boldsymbol{\rho}(\mathcal{A})$ such that $\gamma^\theta > -\frac{\ln(\rho)}{\ln(\boldsymbol{\lambda}(\mathcal{A},\rho))}$, then

$$\lim_{t\to+\infty} \|\mathbf{x}(t,x_0,\theta)\| = 0, \quad \forall x_0 \in \mathbb{R}^n. \quad (4)$$

The proof of this corollary follows from the previous theorem and from the shuffling rate definition.

3 APPROXIMATION OF THE ρ-SJSR

We have seen in the previous section that the ρ-SJSR plays an important role in the stability analysis of shuffled switched systems. However, like the JSR, this quantity is difficult to calculate. In this section, we will consider the problem of approximating the ρ-SJSR. In the following, we will give an explicit expression for a lower bound based on the JSR of a set constructed from $\mathcal{A}$, we will show that this lower bound is asymptotically tight, moreover an exact expression for the ρ-SJSR will be given under certain conditions. Next, an approach to find upper bounds will be given based on multiple Lyapunov functions and automata theoretic techniques.

3.1 Lower bounds computation

Let $\mathcal{N}_\mathcal{I}$ be the set of products of matrices where all modes in $\mathcal{I}$ appear exactly once, formally:

$$\mathcal{N}_\mathcal{I} = \left\{ \prod_{k=1}^{m} A_{j_k} \;\middle|\; \begin{array}{c} j_1,\dots,j_m \in \mathcal{I}, \\ \forall i \in \mathcal{I}, \exists k \in \{1,\dots,m\}, j_k = i \end{array} \right\}.$$

The following theorem gives an explicit expression of a lower bound for the ρ-SJSR based on the JSR of $\mathcal{N}_\mathcal{I}$. Also, it shows that this lower bound is asymptotically tight, moreover, under certain conditions, it reveals an explicit expression of the ρ-SJSR.

Theorem 2. The following results hold true.

(i) For all $\rho > \boldsymbol{\rho}(\mathcal{A})$,
$$\boldsymbol{\lambda}(\mathcal{A},\rho) \geq \frac{\boldsymbol{\rho}(\mathcal{N}_\mathcal{I})}{\rho^m}. \quad (5)$$

(ii) We have the asymptotic estimate
$$\lim_{\rho\to+\infty} \rho^m \boldsymbol{\lambda}(\mathcal{A},\rho) = \boldsymbol{\rho}(\mathcal{N}_\mathcal{I}). \quad (6)$$

(iii) If there exists a norm $\|\cdot\|_*$ that is extremal [1] for $\mathcal{N}_\mathcal{I}$, then there exists $R \geq \boldsymbol{\rho}(\mathcal{A})$ such that for all $\rho \geq R$,
$$\boldsymbol{\lambda}(\mathcal{A},\rho) = \frac{\boldsymbol{\rho}(\mathcal{N}_\mathcal{I})}{\rho^m}. \quad (7)$$

Remark: If $\mathcal{A}$ consists of invertible matrices only, an explicit expression of R can be given.

In the next section, we give a method for computing upper bounds using Lyapunov theory.

[1] An induced norm $\|.\|_*$ is said to be extremal for a set of matrices $\mathcal{A}$, if it satisfies $\boldsymbol{\rho}(\mathcal{A}) = \max_{A\in\mathcal{A}} \|A\|_*$.

3.2 Upper bounds computation

This section details a method for computing upper bounds on the JSR and the ρ-SJSR.

Theorem 3. If there exist $V : (2^{\mathcal{I}} \setminus \{\mathcal{I}\}) \times \mathbb{R}^n \to \mathbb{R}_0^+$, $\alpha_1, \alpha_2, \rho > 0$ and $\lambda \in [0, 1]$ such that the following inequalities hold true for every $x \in \mathbb{R}^n$

$$\alpha_1 \|x\|^2 \leq V(J, x) \leq \alpha_2 \|x\|^2, \qquad \forall J \subsetneq \mathcal{I} \tag{8}$$

$$V(J \cup \{i\}, A_i x) \leq \rho^2 V(J, x), \qquad \text{if } J \cup \{i\} \neq \mathcal{I} \tag{9}$$

$$V(\emptyset, A_i x) \leq \rho^2 \lambda^2 V(J, x), \qquad \text{if } J \cup \{i\} = \mathcal{I} \tag{10}$$

then the bound (3) holds. Conversely, if the matrices A_i are invertible, for all $i \in \mathcal{I}$ and the bound (3) holds for some $\rho > 0$, $\lambda \in [0, 1]$ and $C \geq 1$, then there exists a function $V : (2^{\mathcal{I}} \setminus \{\mathcal{I}\}) \times \mathbb{R}^n \to \mathbb{R}_0^+$ such that the inequalities (8), (9) and (10) are satisfied.

The proof of the direct result relies on a finite state automaton whose states corresponds to subsets of $\mathcal{I}$, where each time the switching signal shuffles, there will be a transition to the automaton's initial state which corresponds to the empty set, therefore, based on the automaton, it is not hard to construct the conditions of the theorem. The proof of the converse result relies on a multiple Lyapunov function (each corresponds to a state) which can be seen as the supremum of trajectories norm that lead from the corresponding state to a specific state.

By combining the result of the previous theorem with Theorem 1, one can easily compute upper bounds on the ρ-SJSR and the JSR using some LMIs.

4 CONCLUSION

In this work, we have defined the ρ-SJSR, a special kind of JSR related to shuffled switched systems. We successfully related this notion to the stabilization of such systems. Also, we provided some theoretical tools for approximation using automata theoretic techniques and Lyapunov functions. Some interesting numerical examples can be found in [Aazan et al. (2021)] and will be presented in the talk.

The current work opens several research directions for the future. First, the development of numerical and theoretic techniques to compute tighter bounds on the ρ-SJSR. Secondly since our approach is based on automata theoretic techniques, it is natural to think that one can derive stability conditions by working directly on the Büchi, Rabin or Muller automaton specifying the ω-regular language.

** *Dept. of Mathematics, Diponegoro University, Indonesia.*

Abstract: We propose a model reduction approach for singular linear switched systems in discrete time with a fixed mode sequence based on a balanced truncation reduction method for linear time-varying discrete-time systems. The key idea is to use the one-step map to find an equivalent time-varying system with an identical input-output behavior, and then adapt available balance truncation methods for (discrete) time-varying systems. The proposed method is illustrated with a low-dimensional academic example.

Keywords: singular linear switched systems, time-varying systems, reachability and observability Gramians and balanced truncation.

1. INTRODUCTION

In this paper we consider singular linear switched systems (SLSSs) in discrete time of the form

$$S_\sigma : \begin{cases} E_{\sigma(k)}x(k+1) = A_{\sigma(k)}x(k) + B_{\sigma(k)}u(k), \\ y(k) = C_{\sigma(k)}x(k), \ k \in \mathbb{N}, \end{cases} \tag{1}$$

where $x(k) \in \mathbb{R}^n$ is the state at time $k \in \mathbb{N}$ and $\sigma : \mathbb{N} \to Q = \{0, 1, 2, \cdots, \mathtt{m}\}$, $\mathtt{m} \in \mathbb{N}$, is the switching signal with the switching times $0 < s_1 < s_2 < \cdots < s_\mathtt{m}$ in the bounded interval $[k_0, k_f) := \{k_0, k_0 + 1, \ldots, k_f - 1\}$ of interest. The system matrices are $E_i, A_i \in \mathbb{R}^{n\times n}$, $B_i \in \mathbb{R}^{n\times m}$, $C_i \in \mathbb{R}^{p\times n}$, where $i \in Q$. The matrices E_i are in general singular, which is related to the presence of (mode-dependent) algebraic constraints. We assume that the i-th mode is active in the interval $[s_i, s_{i+1})$, for $i = 0, 1, \cdots, \mathtt{m}$ (where $s_0 := 0$) and define the duration of the i-th mode as $\tau_i = s_{i+1} - s_i$. Since we will be interested in the input-output behavior of S_σ we assume in the following that $x(0) = 0$.

Control problems governed by SLSSs arise in a variety of practical applications including circuit simulation, computational electromagnetics, fluid dynamics, mechanical and chemical engineering; see Luenberger (1977); Xia et al. (2008). In some cases, these systems lead to analyzing large-scale and complex dynamical systems. Although, the computational speed and performance of the modern computers are increasing; simulation, optimization or real time controller design for such large-scale systems are still difficult due to extra memory requirements and additional computational complexity. Model order reduction (MOR) is a useful tool for dealing with such complexity, wherein one seeks a simpler model that can then be used as an efficient surrogate model to the original model. There are already some existing results on MOR for switched ODEs, see e.g. Schulze and Unger (2018); Gosea et al. (2020) for continuous time case, and Baştuğ et al. (2016, 2014); Shaker and Wisniewski (2012); Birouche et al. (2012) for discrete time case. However, in contrast to the existing literature, we view here the SLSS (1) as a *time-varying* linear systems, in particular, the reduction in general depends on the specifically given switching signal and results in a time-varying reduced model.

The remaining paper is structured as follows. We discuss the problem formulation and some preliminaries for singular system in Section 2. Section 3 provides the computation procedure of time-varying balanced realization in discrete time. In Section 4, we present time-varying balanced truncation method for SLSS. Finally, some numerical results are presented in Section 5.

2. PRELIMINARIES AND PROBLEM STATEMENT

In this section, it is shown that the solutions of a SLSS can equivalently be expressed in terms of a time-varying system. For the existence and uniqueness of solutions of SLSSs the following assumption is needed.

Assumption 1. The SLSS (1) is *jointly index-1*, i.e.

$$\mathcal{S}_i \oplus \ker E_j = \mathbb{R}^n, \quad \forall i, j \in Q,$$

where $\mathcal{S}_i = A_i^{-1}(\operatorname{im} E_i)$. ◇

Under the jointly index-1 assumption, the solution of SLSS (1) with $x(0) = 0$ exists. This solution is unique and satisfies the following lemma.

Lemma 1. (Cf. Anh et al. (2019)) Assume the SLSS (1) is jointly index-1. For a given switching signal σ, there exist corresponding matrices $\widetilde{A}_k$, $\widetilde{B}_k$ and $\widetilde{F}_k$, such that all solutions of (1) with $x(0) = 0$ satisfy

$$x(k+1) = \widetilde{A}_k x(k) + \widetilde{B}_k u(k) + \widetilde{F}_k u(k+1), \quad k \in \mathbb{N}. \tag{2}$$

⋆ Email Addresses: s.hossain@rug.nl; s.sutrisno[@rug.nl, @live.undip.ac.id]; s.trenn@rug.nl;

Proof. Let $\sigma(-1) := \sigma(0)$ and, for $k \in \mathbb{N}$,

$$\widetilde{A}_k := V_{\sigma(k)} \begin{bmatrix} \bar{A}^1_{\sigma(k),\sigma(k-1)} & 0 \\ -\bar{A}^2_{\sigma(k+1),\sigma(k)}\bar{A}^1_{\sigma(k),\sigma(k-1)} & 0 \end{bmatrix} V^{-1}_{\sigma(k-1)}, \quad (3a)$$

$$\widetilde{B}_k := V_{\sigma(k)} \begin{bmatrix} \bar{B}^1_{\sigma(k),\sigma(k-1)} \\ -\bar{A}^2_{\sigma(k+1),\sigma(k)}\bar{B}^1_{\sigma(k),\sigma(k-1)} \end{bmatrix}, \quad (3b)$$

$$\widetilde{F}_k := V_{\sigma(k)} \begin{bmatrix} 0 \\ -\bar{B}^2_{\sigma(k+1),\sigma(k)} \end{bmatrix}, \quad (3c)$$

where

$$\begin{bmatrix} \bar{A}^1_{i,j} & 0 \\ -\bar{A}^2_{i,j} & I_{n_2} \end{bmatrix} = V_i^{-1} G_{i,j}^{-1} A_i V_j, \quad \begin{bmatrix} \bar{B}^1_{i,j} \\ \bar{B}^2_{i,j} \end{bmatrix} = V_i^{-1} G_{i,j}^{-1} B_i,$$

$$G_{i,j} = E_i + A_i Q_{i,j}, \quad Q_{i,j} = V_j \begin{bmatrix} 0 & 0 \\ 0 & I_{n_2} \end{bmatrix} V_i^{-1},$$

$V_i = [g_i^1, ..., g_i^{n_1}, h_i^{n_1+1}, ..., h_i^n]$, $g_i^1, ..., g_i^{n_1}$ are the bases of $\mathcal{S}_i$, and $h_i^{n_1+1}, ..., h_i^n$ are the bases of $\ker E_i$. The remaining proof is similar to the proof of (Anh et al., 2019, Thm. 5.1) and therefore omitted. ■

Remark 2. The one-step map from $x(k)$ to $x(k+1)$ depends on the modes at time $k-1$, k and $k+1$. This concludes that the allowed space of consistent initial values also depends on the choice of $\sigma(-1)$, here we assume that $\sigma(-1) = \sigma(0)$. As pointed out in (Anh et al., 2019, Rem. 5.2), the effect of a different choice $\sigma(-1)$ is not yet fully understood, and is still under investigation; nevertheless, since we restrict our attention to the initial condition $x(0) = 0$, this is of no further concern to us here.

Motivated by Lemma 1, we consider the following time-varying surrogate system for (1) with given switching signal σ:

$$\widetilde{S}_\sigma : \begin{cases} x(k+1) = \widetilde{A}_k x(k) + \begin{bmatrix} \widetilde{B}_k & \widetilde{F}_k \end{bmatrix} \widetilde{u}(k), \\ y(k) = C_k x(k), \ k \in \mathbb{N}, \end{cases} \quad (4)$$

where $x(0) = 0$, $\widetilde{u}(k) = \begin{bmatrix} u(k) \\ u(k+1) \end{bmatrix}$, $C_k := C_{\sigma(k)}$ and $\widetilde{A}_k$, $\widetilde{B}_k$, $\widetilde{F}_k$ are given by (3). Writing $\tilde{u} = \begin{bmatrix} I \\ \mathcal{T}_1 \end{bmatrix} u$, where $\mathcal{T}_1\{u\}(k) := u(k+1)$ denotes the time-shift operator, by Lemma 1, (1) and (4) have the same input-output behaviour.

Note that the solution of jointly index-1 SLSS (1) does not exist for any initial value $x(0) \in \mathbb{R}^n$. In fact, the consistency space of jointly index-1 (1), under the assumption $\sigma(-1) = \sigma(0)$, is $\operatorname{im} V_{\sigma(0)} \begin{bmatrix} I & 0 \\ -\widehat{A}^2_{\sigma(0),\sigma(0)} & \widehat{B}^2_{\sigma(0),\sigma(0)} \end{bmatrix}$. This has some implications on the relationship between system S_σ and $\widetilde{S}_\sigma$ in terms of observability and reachability. Here, observability means that if the input and output are identically zero on $[k_0, k_f)$ also the state has to be zero; reachability means, that for each $x_f \in \mathbb{R}^n$, there exists an input such that the corresponding solution satisfies $x(k_f - 1) = x_f$. Clearly, a reachable SLSS S_σ implies a reachable time varying surrogate system $\widetilde{S}_\sigma$ whereas an observable SLSS S_σ does not imply that its surrogate system $\widetilde{S}_\sigma$ is observable. However, an observable $\widetilde{S}_\sigma$ implies that S_σ is also observable.

Our goal is to find for the time-varying system (4) a reduced size time-varying system

$$\widehat{S}_\sigma : \begin{cases} \widehat{x}(k+1) = \widehat{A}_k \widehat{x}(k) + \begin{bmatrix} \widehat{B}_k & \widehat{F}_k \end{bmatrix} \begin{bmatrix} u(k) \\ u(k+1) \end{bmatrix}, \\ \widehat{y}(k) = \widehat{C}_k \widehat{x}(k), \ k \in \mathbb{N}. \end{cases} \quad (5)$$

with reduced system matrices $\widehat{A}_i \in \mathbb{R}^{r \times r}$, $\widehat{B}_i, \widehat{F}_i \in \mathbb{R}^{r \times m}$, $\widehat{C}_i \in \mathbb{R}^{p \times r}$ and $r \ll n$, such that $\widehat{y} \approx y$ for a large class of inputs u. Due to the input-output equivalence between (1) and (4), the reduced system (5) will then also be good surrogate model for the original SLSS.

3. TIME-VARYING BALANCED REALIZATIONS

3.1 Time-varying Gramians

Consider a time-varying discrete time system of the form

$$\begin{aligned} x(k+1) &= A_k x(k) + B_k u(k), \quad k \in [k_0, k_f) \\ y(k) &= C_k x(k). \end{aligned} \quad (6)$$

Definition 3. The time-varying reachability and observability Gramians of (6) are defined recursively as

$$P(k) = A_{k-1} P(k-1) A_{k-1}^\top + B_{k-1} B_{k-1}^\top, \quad (7)$$

$$Q(k) = A_k^\top Q(k+1) A_k + C_k^\top C_k, \quad (8)$$

with some positive semi-definite initial/final values $P(k_0) = P_0$ and $Q(k_f) = Q_f$

Note that the reachability Gramian is constructed *forward* in time, while the observability Gramians evolves *backward* in time.

Remark 4. The choice of the initial/final Gramians is crucial in the sense that they play an important role for the magnitude of all other subsequent Gramians. At this moment the best choice of the initial/final Gramians is not clear. In the context of time-varying case, two versions can be proposed for the initial/final Gramians. One choice could be to assume that the first mode is active in the past, i.e. $(-\infty, k_0]$, and the Gramians of the first mode is considered as the initial reachability Gramian. Similarly, by assuming that the last mode will be active in the future, i.e. $[k_f, \infty)$, and the Gramian of the last is considered as the final value for observability Gramian. However, in this choice, the computation of infinite Gramians is only possible for stable modes; here, we do not assume stability of each mode. On the other hand, a second choice could be the identity matrix which would not affect the direction of the states which are difficult to control and difficult to observe. By scaling the identity matrix with a smaller magnitude, one can restrict the influence of these artificial initial/final Gramians relatively to the time-varying Gramians and also for the bounded time-varying coordinate transformation matrices.

Note that, $P(k)$ and $Q(k)$ are both symmetric and positive semidefinite for all $k \in [k_0, k_f]$ if P_0 and Q_f are positive definite. It is assumed that the input-output balancing with respect to the reachability and observability Gramians is defined over specific time intervals. Hence, no assumption is needed with regard to the stability of the system.

Applying any time-varying coordinate transformation

$$x(k) = T(k)\overline{x}(k)$$

to (6) results in an equivalent system

$$\overline{x}(k+1) = \overline{A}_k\overline{x}(k) + \overline{B}_k u(k)$$
$$y(k) = \overline{C}_k x(k),$$

with $\overline{A}_k := T(k+1)^{-1}A_kT(k)$, $\overline{B}_k := T(k+1)^{-1}B_k$, $\overline{C}_k := C_kT(k)$. It is easily seen, the corresponding Gramians satisfy

$$\overline{P}(k) = T(k)^{-1}P(k)T(k)^{-\top},$$
$$\overline{Q}(k) = T(k)^{\top}Q(k)T(k),$$

if the initial/final values satisfy $\overline{P}_0 = T(0)^{-1}P_0T(0)^{-\top}$ and $\overline{Q}_f = T(k_f)^{\top}Q_fT(k_f)$. In particular,

$$\overline{P}(k)\overline{Q}(k) = T(k)^{-1}P(k)Q(k)T(k).$$

This shows that, under such transformation, the eigenvalues of the product of Gramians are invariant.

The key idea of balanced truncation is to find a coordinate transformation such that the corresponding Gramians become equal and diagonal. How to achieve such a balancing transformation is given in the following lemma.

Lemma 5. Assume that Gramiens $P(k)$ and $Q(k)$ of the time-varying system (6) are nonsingular on $[k_0, k_f)$. Then, there exists a transformation $T : [k_0, k_f] \to \mathbb{R}^{n\times n}$ such that

$$T(k)^{-1}P(k)T(k)^{-\top} = T(k)^{\top}Q(k)T(k) = \Xi(k), \qquad (9)$$

for all $k \in [k_0, k_f]$ and $\Xi(k) = \{\xi_1(k), \ldots, \xi_n(k)\}$ is a diagonal matrix. In fact, the transformation matrices are given by

$$T(k) = R(k)U(k)\Xi(k)^{-1/2},$$
$$T(k)^{-1} = \Xi(k)^{-1/2}V(k)^{\top}L(k)^{\top},$$

where $U(k)\Xi(k)V(k)^{\top}$ is the singular value decomposition of $R(k)^{\top}L(k)$, and where $R(k)R(k)^{\top} = P(k)$ and $L(k)L(k)^{\top} = Q(k)$ are the Cholesky decompositions of P and Q, respectively.

Proof. The proof is similar to the proof of (Hossain and Trenn, 2020, Lemma 11) and therefore omitted. ■

4. MODEL REDUCTION

We now combine the above results to propose a model reduction method for SLSS (1) based on balanced truncation. By Assumption 1, we can instead consider system (4) and we can construct the corresponding time-varying reachability/observability Gramians $\widetilde{P}(k)$ and $\widetilde{Q}(k)$ for $(\widetilde{A}_k, [\widetilde{B}_k, \widetilde{F}_k], \widetilde{C}_k)$ for some initial/final Gramians $\widetilde{P}_0, \widetilde{Q}_f$. Now an assumption is needed for model reduction methods.

Assumption 2. Assume a transformation $\widetilde{T}$ such that the balanced Gramians are obtained by

$$\widetilde{T}(k)^{-1}\widetilde{P}(k)\widetilde{T}(k)^{-\top} = \widetilde{T}(k)^{\top}\widetilde{Q}(k)\widetilde{T}(k) = \widetilde{\Xi}(k)$$

and let, the (uniformly) partitioned form $\widetilde{\Xi}(k) = \begin{bmatrix}\widehat{\Xi}(k) & 0\\ 0 & \overline{\Xi}(k)\end{bmatrix}$, where all diagonal entries in $\overline{\Xi}(k)$ are significantly smaller than those in $\widehat{\Xi}(k)$. ◇

With the Assumption 2, the singular value decomposition is then given by

$$\widetilde{R}(k)^{\top}\widetilde{L}(k) = \begin{bmatrix}\widehat{U}(k) & \overline{U}(k)\end{bmatrix}\begin{bmatrix}\widehat{\Xi}(k) & 0\\ 0 & \overline{\Xi}(k)\end{bmatrix}\begin{bmatrix}\widehat{V}(k) & \overline{V}(k)\end{bmatrix}^{\top}$$

where $\widetilde{R}(k)\widetilde{R}(k)^{\top} = \widetilde{P}(k)$ and $\widetilde{L}(k)\widetilde{L}(k)^{\top} = \widetilde{Q}(k)$ are obtained by a Cholesky decomposition. According to this splitting, let $\widetilde{T}(k) = [\widehat{\Pi}_R(k), *]$ and $\widetilde{T}(k)^{-1} = [\widehat{\Pi}_L(k), *]^{\top}$, and define

$$\widehat{A}_k := \widehat{\Pi}_L(k+1)\widetilde{A}_k\widehat{\Pi}_R(k),$$
$$\begin{bmatrix}\widehat{B}_k & \widehat{F}_k\end{bmatrix} := \widehat{\Pi}_L(k+1)\begin{bmatrix}\widetilde{B}_k & \widetilde{F}_k\end{bmatrix},$$
$$\widehat{C}_k := \widetilde{C}_k\widehat{\Pi}_R(k),$$

which results in our proposed reduced system (5), where the left- and right-projectors are calculated as

$$\widehat{\Pi}_R(k) := \widetilde{R}(k)\widehat{U}(k)\widehat{\Xi}(k)^{-1/2} \in \mathbb{R}^{n\times r},$$
$$\widehat{\Pi}_L(k) := \widehat{\Xi}(k)^{-1/2}\widehat{V}(k)^{\top}\widetilde{L}(k)^{\top} \in \mathbb{R}^{r\times n}.$$

5. NUMERICAL RESULTS

This section illustrates the proposed method by providing an example.

Example 6. Consider a SLSS with two modes

$$(E_0, A_0, B_0, C_0) = \left(\begin{bmatrix}1&0&0&0\\1&1&0&0\\0&0&1&0\\0&0&0&0\end{bmatrix}, \begin{bmatrix}1&0&0&0\\1&0&1&0\\1&1&1&0\\0&0&0&1\end{bmatrix}, \begin{bmatrix}0.02\\2\\1\\0.2\end{bmatrix}, \begin{bmatrix}-0.1\\0.1\\0.1\\2\end{bmatrix}^{\top}\right),$$
$$(E_1, A_1, B_1, C_1) = \left(\begin{bmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&0\end{bmatrix}, \begin{bmatrix}1&0&0&0\\0&1&1&0\\1&0&1&0\\0&0&0&1\end{bmatrix}, \begin{bmatrix}0.01\\2\\0.5\\0.1\end{bmatrix}, C_0\right),$$

Consider a switching signal $\sigma : [0, 9) \to \{0, 1\}$,

$$\sigma(k) = \begin{cases}0 & : k \in [0, 4) \cup [7, 9),\\ 1 & : k \in [4, 7).\end{cases}$$

It can easily be verified that the pairs (E_0, A_0) and (E_1, A_1) are jointly index-1. Hence, by Lemma 1, the time-varying system (4) is obtained with the following system matrices

$$(\widetilde{A}_k, \widetilde{B}_k) = \begin{cases}\left(\begin{bmatrix}1&0&0&0\\0&0&1&0\\1&1&1&0\\0&0&0&0\end{bmatrix}, \begin{bmatrix}0.02\\1.98\\1\\0\end{bmatrix}\right) & : k = 0, 1, 2, 3, 7, 8,\\ \left(\begin{bmatrix}1&0&0&0\\0&1&1&0\\1&0&1&0\\0&0&0&0\end{bmatrix}, \begin{bmatrix}0.01\\2\\0.5\\0\end{bmatrix}\right) & : k = 4, 5, 6,\end{cases}$$
$$\widetilde{F}_k = \begin{cases}\begin{bmatrix}0\\0\\0\\-0.2\\0\end{bmatrix} & : k = 0, 1, 2, 6, 7, 8,\\ \begin{bmatrix}0\\0\\0\\-0.1\end{bmatrix} & : k = 3, 4, 5.\end{cases}$$

The corresponding reachability and observability Gramians are calculated respectively, $\widetilde{P}(k)$ and $\widetilde{Q}(k)$ for $k \in [0, 9)$ with initial/final values $\widetilde{P}_0 = 0.002I$ and $\widetilde{Q}_f = 0.002I$. The corresponding HSVs are depicted in Figure 1 and it is apparent that the last two HSVs are significantly smaller than the first two. Hence, a two dimensional reduced system is obtained which approximates the time-varying system (4) and hence, the original SLSS.

The computed two dimensional reduced systems at each time steps are given by $(\widehat{A}_k, [\widehat{B}_k, \widehat{F}_k], \widehat{C}_k) =$

$$\left(\begin{bmatrix}0.9206 & -0.0051\\ -0.0107 & 0.0012\end{bmatrix}\begin{bmatrix}-1.8615 & 0.0046\\ -0.0535 & 0.6305\end{bmatrix}\begin{bmatrix}-0.1410\\ -0.6334\end{bmatrix}^{\top}\right),$$
$$\left(\begin{bmatrix}0.9761 & -0.0071\\ -0.0058 & -0.0076\end{bmatrix}\begin{bmatrix}-1.0832 & 0.0074\\ -0.0603 & 0.6287\end{bmatrix}\begin{bmatrix}-0.2387\\ -0.6332\end{bmatrix}^{\top}\right),$$
$$\left(\begin{bmatrix}0.9887 & -0.0116\\ -0.0027 & -0.0071\end{bmatrix}\begin{bmatrix}-0.7265 & 0.0117\\ -0.0445 & 0.8861\end{bmatrix}\begin{bmatrix}-0.3859\\ -0.4449\end{bmatrix}^{\top}\right),$$

$$\left(\begin{bmatrix} 1.1336 & -0.0155 \\ -0.4762 & -0.0398 \end{bmatrix} \begin{bmatrix} -0.3934 & 0.0143 \\ -0.0311 & 0.4016 \end{bmatrix} \begin{bmatrix} -0.7193 \\ -0.4515 \end{bmatrix}^\top\right),$$
$$\left(\begin{bmatrix} 0.9856 & -0.0335 \\ -0.0019 & 0.1912 \end{bmatrix} \begin{bmatrix} -0.2249 & 0.0206 \\ -0.0536 & 0.4158 \end{bmatrix} \begin{bmatrix} -1.0114 \\ -0.4262 \end{bmatrix}^\top\right),$$
$$\left(\begin{bmatrix} 0.9719 & -0.0475 \\ -0.0036 & 0.0701 \end{bmatrix} \begin{bmatrix} -0.1850 & 0.0286 \\ -0.0047 & 0.2986 \end{bmatrix} \begin{bmatrix} -1.3323 \\ -0.5423 \end{bmatrix}^\top\right),$$
$$\left(\begin{bmatrix} 0.8014 & -0.0770 \\ -0.8119 & 0.0689 \end{bmatrix} \begin{bmatrix} -0.1249 & 0.0523 \\ 0.1196 & -0.5938 \end{bmatrix} \begin{bmatrix} -1.4777 \\ 0.5432 \end{bmatrix}^\top\right),$$
$$\left(\begin{bmatrix} 0.9471 & 0.0834 \\ -0.0047 & 0.0125 \end{bmatrix} \begin{bmatrix} -0.1026 & 0.1118 \\ -0.0261 & 0.4245 \end{bmatrix} \begin{bmatrix} -2.8391 \\ -0.1943 \end{bmatrix}^\top\right).$$

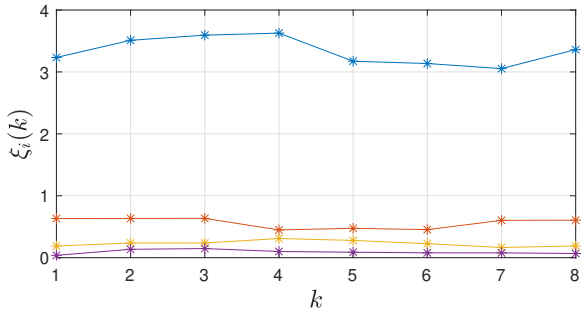

Fig. 1. Hankel singular values of balanced Gramians at each time instance.

Consider randomly generated input $u(\cdot)$ with $u(0) = 0$, and the input-output behavior is calculated for the system (4) and its reduced system with relative errors. Figure 2 displays the output, the input signal, and the relative error for the original system and the proposed two dimensional reduced system. Clearly, both outputs match nicely and the relative error is less then 6%.

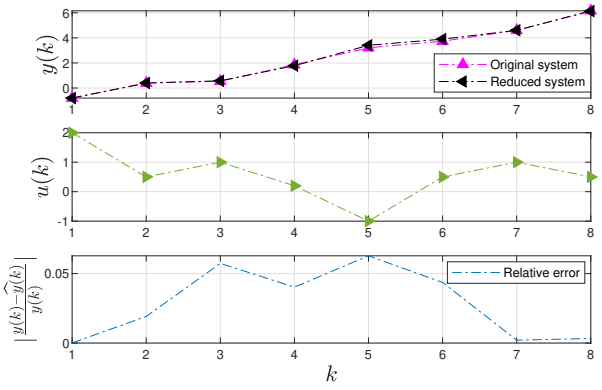

Fig. 2. Outputs and the relative error of the original system (4) and the proposed 2^{nd} order approximation.

Next, another initial /final value of the Gramians is considered by increasing the magnitudes as $\widetilde{P}_0 = 0.5I$ and $\widetilde{Q}_f = 0.5I$. With the same input sequence as in Figure 2, the input-output behavior with the relative error is depicted in Figure 3, which shows that the choice of the initial /final values of Gramians plays an important role in the error analysis. Therefore, it is concluded that taking small magnitude with identity matrix could be the best choice for the initial /final values of the Gramians.

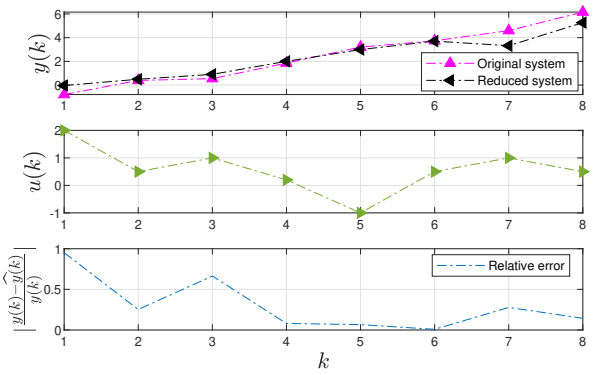

Fig. 3. Outputs and relative errors of the original system (4) and the proposed 2nd order approximation with initial/final values $\widetilde{P}_0 = 0.5I$, $\widetilde{Q}_f = 0.5I$.

6. CONCLUSION

In this paper, we have presented a time-varying approach for proposing a reduced system for singular linear switched systems. The key novelty is the viewpoint of the SLSS as a piecewise-constant time-varying system. At first, we have focused on input-extended time-varying ODEs, which gives identical input-output behavior as the original index-1 SLSSs. Then, by applying the well known time-varying balanced truncation method for the discrete time case, we find a good approximation of the time-varying system.

Abstract: Finding the minimum distance of linear codes is an NP-hard problem. Traditionally, this computation has been addressed by means of the design of algorithms that find, by a clever exhaustive search, a linear combination of some generating matrix rows that provides a codeword with minimum weight. Therefore, as the dimension of the code or the size of the underlying finite field increase, so it does exponentially the run time. In this work, we prove that, given a generating matrix, there exists a column permutation which leads to a reduced row echelon form containing a row whose weight is the code distance. This result enables the use of permutations as representation scheme, in contrast to the usual discrete representation, which makes the search of the optimum polynomial time dependent from the base field. In particular, we have implemented genetic and CHC algorithms using this representation as a proof of concept. Experimental results have been carried out employing codes over fields with two and eight elements, which suggests that evolutionary algorithms with our proposed permutation encoding are competitive with regard to existing methods in the literature. As a by-product, we have found and amended some inaccuracies in the Magma Computational Algebra System concerning the stored distances of some linear codes.

Keywords: linear codes, minimum distance, genetic algorithms

1. INTRODUCTION

This talk is based in some results published in Cuéllar et al. (2021).

The computation of a word with minimum weight for a linear code is not an easy task. Vardy showed in Vardy (1997) that the decision problem associated to the computation of the minimum distance of a binary linear code is NP-complete. Hence, unless P = NP, we cannot expect to find a general polynomial time exact algorithm to compute the distance of an arbitrary linear code. This feature has been used to develop Code-based Cryptography, see D. J. Bernstein (2009), as one of main research lines looking for a possible new standard concerning Post-quantum Cryptography.

We can find different approaches in the literature to overcome the distance calculation. One is to design the linear code $\mathcal{C}$ subject to certain constraints using higher algebraic structures, to guarantee a lower bound for the distance $d(\mathcal{C})$. These approaches do not tackle the problem of finding the true distance, which remains unknown, although they ensure an error correction capability given by its precalculated lower bound.

Another kind of approaches focuses on finding the true distance using exact algorithms. Here, the problem is considered as a search procedure over a solution space, using heuristics to guide the search and to reduce the computational time of the algorithms. The most known algorithm was designed by Brouwer and Zimmermann, see Betten et al. (2006), and later extended by Lisonek and Trummer (2016), and it essays to build information sets from a generating matrix. The main drawback is that the efficiency of these methods is still non-polynomial, since the whole solution space has to be explored in the worst case. They have been successfully applied over small binary codes, but their computational time increases exponentially with the length of the code and the bit-size of the underlying finite field.

A third class of attemtps focuses on providing approximate methods to find lower and/or upper bounds of the distance. In this category, one of the first algorithms was provided in Leon (1988). Metaheuristics have also been used to solve the problem. Here, the methodology consists on finding an optimal solution $m^* \in \mathcal{A}^k$ that minimizes the fitness $f(m^*) = min_m\{w(mG)\}$ subject to the restriction $f(m^*) > 0$ (or equivalently, $m^* \neq 0$), where w denotes the Hamming weight. These methods provide an upper bound of $d(\mathcal{C})$. Some proposals we have found in the literature to tackle the problem were Genetic Algorithms, see Dontas

and De Jong (1990), Simulated Annealing, see Muxiang and Fulong (1994), Ant Colony Optimization, see Bland (2007) and Bouzkraoui et al. (2018), for example.

One of the main limitations in many of the approximate methods is the high selective pressure over the non-valid trivial message $s = (0, 0, \ldots, 0)$, which leads to the fitness $f(s) = 0$. This problem has been highlighted and studied by some authors, as for instance in Berkani et al. (2015), and more recently in Berkani et al. (2017).

In this work we propose to address this problem from a completely new perspective. We prove that, given a generating matrix, there exists a column permutation which leads to a reduced row echelon form containing a row whose weight is the code distance. This result allows us to provide a novel problem statement and, therefore, new search mechanisms could be applied to provide a problem solution. In our case, we propose to use a permutation representation of the solution space to search the minimum distance. Hence a Generational Genetic Algorithm (GGA) and a Cross generational elitist selection, Heterogeneous recombination, and Cataclysmic mutation algorithm (CHC) are designed for solving the problem.

This has allowed us to discover some inaccuracies in the Magma Computational Algebra System concerning the stored distances of some linear codes.

2. PERMUTATION-BASED SCHEME

Let $0 < k \leq n$ be two non negative integers, and $\mathbb{F}_q$ the field with q elements. Our new perspective to compute the minimum distance relies in the the following result:

Theorem 1. Let G be a $k \times n$ generating matrix of a $[n, k]_q$-linear code $\mathcal{C}$ over the finite field $\mathbb{F}_q$. There exists a permutation $\sigma \in \mathcal{S}_n$ such that the RREF, R, of GP_σ, where P_σ is the permutation matrix of σ, satisfies that the Hamming weight of some of its rows reaches the minimum distance of $\mathcal{C}$. Consequently, if b is a row of R verifying such property, then bP_σ^{-1} is a non zero codeword of $\mathcal{C}$ with minimal weight.

By Theorem, finding the minimum distance of an $[n, k]_q$-linear code is reduced to find the minimum of the map $\mathfrak{d} : \mathcal{S}_n \to \mathbb{N}$ defined by

$$\mathfrak{d}(\sigma) = \min\{\mathrm{w}(b) \mid b \text{ is a row of the RREF of } GP_\sigma\} \quad (1)$$

for any $\sigma \in \mathcal{S}_n$. This encoding is then invariant with respect to the base field. Obviously, the computation of $\mathfrak{d}(\sigma)$, for some permutation σ, does depend on q and n.

3. ALGORITHMS

The Generational Genetic Algorithm (GGA) follow the classic genetic algorithm with elitism and reinitialization Back et al. (1997).

By Theorem 1, we are looking for permutations in order to compute the weights of the rows in the RREF of the permuted generating matrix. The algorithm works as follows: A population $P(t) \subseteq \mathcal{S}_n$ is initialized and evaluated with N random solutions at iteration $t = 0$. Then, the main loop of the algorithm is executed until a stopping condition is met. In this paper, the stopping criterion is to evaluate a maximum number of solutions so that the algorithms can be compared in performance. In order to test the algorithms, an additional stopping criterion has been included when a solution in the population reaches a previously known lower bound of the distance.

The loop of the algorithms start by selecting N parents according to the binary tournament selection operator Blickle and Thiele (1997). A crossover operator is applied to two parents to generate a pair of new solutions with probability p_c. If they are not combined, the mutation operator acts on the parents to generate two mutated solutions. All the N new solutions generated by either crossover or mutation form the population at the next iteration $P(t + 1)$. Finally, the solutions in $P(t + 1)$ are evaluated. An elitism component is included before the next iteration starts: If no solution in $P(t+1)$ has a fitness equal or better than the best in $P(t)$, then then worst in $P(t + 1)$ is replaced with the best in $P(t)$. Also, we include a reinitialization of $P(t + 1)$ with N new random solutions after $MaxReinit$ solution evaluations with no improvement in the fitness of the best solution found.

The CHC algorithm is an evolutionary algorithm whose initial version was proposed for binary encoding Eshelman (1991). This algorithm holds a balance between genotypic diversity in the solutions of the population, and convergence to local optima. It is based on four main components: elitist selection, the HUX solution recombination operator, an incest prevention check to avoid the recombination of similar solutions, and a population reinitialization method when a local optimum is found. Later versions of this algorithm are proposed for real and permutation encoding in Eshelman and Schaffer (1993); Cordón et al. (2006); Simões and Costa (2011). The adaptation of this algorithm it is mainly inspired in the proposals of Cordón et al. (2006); Simões and Costa (2011).

The distance between two solutions x, y in the population is computed using the Hamming distance, and the decrement dec of the crossover is updated as a percentage τ of the maximum Hamming distance between individuals in the population, where $\tau \in [0, 1]$ is an update rate, an input parameter to the algorithm.

The algorithm starts by initializing a population $P(t) \subseteq \mathcal{S}_n$ with N random solutions. Then, the average and maximum distances between all solutions are computed. The crossover threshold d is assigned to the average distance, and a threshold update rate dec is initialized to τ multiplied by the maximum distance. The main loop of the algorithm finishes when the aforementioned stopping condition is met. It works as follows: Firstly, the solutions in $P(t)$ are randomly shuffled and matched by pairs. These pairs of solutions are the parents to be combined. Then, the crossover operator is applied to each pair of parents to generate two offsprings, only if the distance between the two parents is not under the distance threshold d. If so, the offsprings are evaluated, and the population at the next iteration $P(t + 1)$ is created containing the best N solutions coming from $P(t)$ and the new generated solutions by crossover. If $P(t+1)$ is the same as $P(t)$, the crossover threshold d is decreased by dec. Only when d is zero or under zero, the population is reinitialized. In our

work, the reinitialization procedure replaces $P(t+1)$ with $N-1$ randomly generated solutions, and the best solution in $P(t)$. The values d and dec are recalculated for this new population.

4. EXPERIMENTATION

The parameters used in the experimentation are shown in Table 1. The row *Mutation probability by gene* describes the probability of mutation of each coordinate in a solution. The row *Evaluations* stands for the main stopping criterion of each algorithm (i.e. to reach a maximum number of evaluations). The row *Reinitialization* shows the number of solutions evaluated with no improvements required to reinitialize the population in GGA proposals. A secondary stopping criterion was set for all algorithms: if the true known distance of the code being evaluated (or a lower bound) is found, the algorithm stops even if the main stopping criterion is not satisfied yet.

Parameter	GGA-Order	CHC-Order
Population size	400	400
Crossover	AX_2	AX_2
Mutation	2-swap	–
Crossover probability	0.8	–
Mutation probability by gene	–	–
Evaluations	500000	500000
Reinitialization	100000	–

Table 1. Algorithms' parameters for experimentation with codes over $\mathbb{F}_8$

Tables 2 and 3 show the results obtained for each dataset containing a code over $\mathbb{F}_8$. The columns **Dataset** display the parameters of the corresponding best known linear codes according to Grassl (2007). Columns **B** describe the minimum weight found by each algorithm, and the subindices indicate the number of experiments that provided such result. Columns **W** introduce the worst minimum weight obtained. Columns **M** show the average of the minimum weights obtained in the 100 experiments. Finally, Columns **T/E** print the average time in seconds of each experiment, together with the average number of evaluations required to finish it.

5. ANALYSIS OF THE CODE $(75, 45, 17-27)$ OVER $\mathbb{F}_8$

According to Grassl (2007) and Bosma et al. (1997), the best known linear code over $\mathbb{F}_8$ with length 75 and dimension 45 is $(75, 45, 17-27)$ as it can be verified executing the first 7 lines of the MAGMA source code in Figure 1. However, our algorithms obtain the column permutation in (2), which provides a matrix whose RREF contains a row whose weight is 15. A codeword with this weight is exhibited in (3). MAGMA source code to verify our findings is set in lines 9 to 13 in Figure 1, which can be tested in the online version of MAGMA at the URL `http://magma.maths.usyd.edu.au/calc/`. Thus, the minimum distance is less or equal to 15, which is below of the lower bound provided by MAGMA.

$$(53, 11, 58, 36, 17, 27, 44, 8, 73, 24, 20, 71, 69, 46, 10, 43, 26, 61, 29, 57, 23, 6, 5, 67, 14, 4, 50, 45, 72, 59, 18, 25, 47, 28, 51, 68, 22, 48, 52, 42, 60, 21, 38, 64, 16, 34, 2, 3, 31, 33, 49, 63, 74, 54, 62, 19, 7, 1, 0, 15, 13, 66, 39, 65, 41, 30, 12, 37, 32, 70, 56, 40, 55, 9, 35) \quad (2)$$

$$(a^2+a, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, a, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, a, 0, 0, 0, 0, 0, 0, a^2+a, a^2, 0, a^2+a+1, 1, 0, a+1, 0, 0, a, 0, 0, 0, 0, 0, a^2+a+1, 0, 0, 0, a+1, 1, 0, 0, 0, 0, 0, a^2+a+1, 0, 0, 0, 0, 0, 0, a+1, 0, 0, 0, 0) \quad (3)$$

According to Grassl (2007), the linear code $(75, 45, 17-27)$ is constructed from the code with parameters $(77, 46, 18)$ described in Xing and Ling (2000). By additional experi-

Weight(c);
```

ments we have found a codeword of weight 15 in this code. Additional tests were performed for other codes considered in Xing and Ling (2000). More specifically, we calculated permutations for the codes $(75, 44, 18)$ and $(76, 45, 18)$, respectively, which helps us finding the corresponding codewords both with weight 15.

Abstract: We investigate the scenario where a perturbed nonlinear system communicates its output measurements to a remote observer via a network. The sensors are grouped into N nodes and each of these nodes decides when its measured data is transmitted over the network independently. Given a (continuous-time) observer, we present an approach to design local (dynamic) transmission policies to obtain accurate state estimates, while only sporadically using the communication network. We prove a practical convergence property to the origin for the estimation error and we show there exists a uniform strictly positive minimum inter-event time for each local triggering rule under mild conditions on the plant. The analysis relies on hybrid Lyapunov tools. The efficiency of the proposed techniques is illustrated on a numerical case study of a flexible robotic arm.

Preamble: *This extended abstract is based on the journal submission Petri et al. (2022), which is in agreement with the conference policy.*

While digital networks exhibit a range of benefits for control applications in terms of ease of installation, maintenance and reduced weight and volume, they also require adapted control theoretical tools to cope with the induced communication constraints (e.g., sampling, delays, packet drops, scheduling, quantization), see e.g., Hespanha et al. (2007); Heemels and Van De Wouw (2010). In this work, we concentrate on the state estimation of nonlinear systems over a digital channel and we focus on the effect of sampling. In particular, we consider state estimation where the plant is nonlinear, perturbed and communicates its measurements over a digital network to a remote observer, whose goal is to estimate the plant state, see Fig. 1.

The communication schedule is very important to guarantee good estimation performance. An option is to generate the transmission instants based on time, in which case we talk of time-triggered strategies for which various results are available in the literature, see, e.g., Postoyan and Nešić (2011); Li et al. (2017); Ferrante et al. (2016); Mazenc et al. (2015); Dačić and Nešić (2008). However, this paradigm may generate (significantly) more transmissions over the network than necessary to fulfil the estimation task, thereby leading to a waste of the network resources. As a potential and promising solution, one can use event-triggered transmissions to overcome this drawback, see e.g., Heemels et al. (2012) and references therein. In this case, an event-based triggering rule monitors the plant measurement and/or the observer state and decides when an output transmission is needed.

Various event-triggered techniques are available in the literature for estimation, see, e.g., Scheres et al. (2021); Li et al. (2010); Shi et al. (2014); Li and Lemmon (2011); Trimpe (2014); Yu et al. (2021); Song et al. (2021); Shi et al. (2016); Huang et al. (2019); Sijs and Lazar (2012); Hu et al. (2020); Etienne and Di Gennaro (2016); Etienne et al. (2017a,b); Tong et al. (2020); Niu et al. (2020). A dominant approach consists in implementing a copy of the observer within the sensor and then use its information to define the transmission instants, see e.g., Scheres et al. (2021); Li et al. (2010); Shi et al. (2014); Li and Lemmon (2011); Trimpe (2014); Yu et al. (2021); Song et al. (2021). A possible drawback then is that it may require significant computation capabilities on the sensors, especially in the case of large-scale systems, or highly nonlinear dynamics, which may be unavailable. Another possible solution is to follow an event-triggered strategy, which is only based on a static condition involving the measured output and its

⋆ This work was funded by Lorraine Université d'Excellence LUE, HANDY project ANR-18-CE40-0010-02, the France Australian collaboration project IRP-ARS CNRS and the Australian Research Council under the Discovery Project DP200101303.

past transmitted value(s) see, e.g., Shi et al. (2016); Huang et al. (2019); Sijs and Lazar (2012); Hu et al. (2020); Etienne et al. (2017a); Etienne and Di Gennaro (2016); Etienne et al. (2017b); Tong et al. (2020). Consequently, it is not necessary to implement a copy of the observer in the sensors and thus the sensors are not required to have significant computation capabilities. However, such static triggering rules may generate a lot of transmissions, moreover the results in Shi et al. (2016); Huang et al. (2019); Sijs and Lazar (2012); Hu et al. (2020); Etienne and Di Gennaro (2016); Etienne et al. (2017a,b); Tong et al. (2020) only apply to specific classes of systems and a centralized scenario, where all sensors communicate simultaneously over the network, with the exception of Shi et al. (2016) and Hu et al. (2020).

In this work, we adopt an event-triggered approach based only on the measured output and the last transmitted output value. This strategy keeps monitoring the plant output, and thereby may lead to less transmissions compared to a self-triggering approach, and it does not require a copy of the observer, which simplifies the implementation and requires less computation capability on the sensor. The main novelties are, first, the design of a new triggering rule, which involves an auxiliary scalar variable for each sensor node, that will have several benefits. Second, the proposed results apply to general, perturbed nonlinear systems contrary to the vast majority of works in the literature, which concentrates on specific classes of systems, see e.g., Li et al. (2010); Shi et al. (2014); Li and Lemmon (2011); Trimpe (2014); Yu et al. (2021); Song et al. (2021); Shi et al. (2016); Huang et al. (2019); Sijs and Lazar (2012); Hu et al. (2020); Etienne and Di Gennaro (2016); Etienne et al. (2017a,b); Tong et al. (2020); Niu et al. (2020). Third, the triggering strategies are decentralized. Indeed, we consider the scenario with N sensor nodes, where each node decides independently when to transmit its local data to the observer via a digital network. Consequently, each sensor node has its own triggering rule and several nodes are allowed to communicate at the same time instant. The considered setup is depicted in Fig. 1.

Our design is following an emulation-based approach in the sense that the observer is first designed ignoring the effects of the communication network. In particular, we assume that the observer has been designed in continuous-time in such a way that it satisfies an input-to-state stability property, that holds for many observer design techniques of the literature, see e.g., Astolfi et al. (2021); Shim and Liberzon (2015) and the references therein. Afterwards, we take the network into account and consequently the observer knows only the networked version of the output, which is generated using a zero-order-hold device between two successive transmission instants. We then design a triggering rule for each sensor node to approximately preserve the original properties of the observer. As already stated, the triggering rules are dynamic in the sense that they involve a local scalar auxiliary variable, which essentially filters an absolute threshold type condition, see e.g., Etienne et al. (2017a,b); Etienne and Di Gennaro (2016); Tong et al. (2020). This is a new in the context of estimation, to the best of the authors knowledge, and is inspired by related event-triggering control techniques, see e.g., Girard (2014); Tanwani et al. (2015); Tabuada (2007). Importantly, there is no need to implement a copy of the observer at each sensor node, which has clear computational advantages. Indeed, each sensor just needs to know the difference between its current output and its last transmitted output value and its local auxiliary scalar variable. We model the overall system as an hybrid system using the formalism of Goebel et al. (2012); Heemels et al. (2021), where a jump corresponds to a transmission of the current output measured by one of the sensor nodes to the observer.

To design the event-triggered estimation scheme, we provide easily usable conditions on the triggering rules, which ensure that the estimation error system satisfies a global practical stability property. The analysis relies on hybrid Lyapunov tools, see Goebel et al. (2012). Note that, we do not guarantee an asymptotic stability property, but only a practical one in general, which is a consequence of the absence of a copy of the observer in the triggering mechanism. Afterwards, we prove that there exists a uniform strictly positive minimum time between any two successive transmissions for each local triggering rule under mild boundedness conditions on the plant state and its input, thereby excluding the Zeno phenomena. Moreover, we provide explicit conditions under which the proposed event-triggered observer stops transmitting, which it is a clear advantage against time-triggered strategies. The proposed results can then be extended in various ways (to be robust to additive measurement noise, to the case where the plant input is also triggered etc.). Finally, we will illustrate the efficiency of the approach in a numerical case study of a flexible robotic arm.

This work is an extension of the preliminary conference paper Petri et al. (2021), where only linear time-invariant systems and a centralized transmission strategy were considered.

Abstract: We study tree-like networks of leaderless Kuramoto-like non-identical oscillators having time-varying natural frequencies taking values in a compact set. We interconnect the oscillators via a novel class of hybrid coupling rules inducing uniform global practical asymptotic stability of the synchronization set, thereby ensuring global uniform convergence. Moreover, we show that the synchronization set is uniformly globally finite-time stable whenever the coupling function is discontinuous at the origin. Numerical simulation results illustrate the advantage of the proposed model with respect to non-uniform behavior typically found with classical Kuramoto models.

Keywords: Synchronization, hybrid dynamical systems, multi-agent systems, finite-time stability, Lyapunov methods.

This extended abstract presents the results given in the paper "Leaderless uniform global asymptotic and finite-time synchronization of Kuramoto-like oscillators" (Mariano et al. (2021)) submitted to Automatica for publication, as allowed by the conference guidelines.

Oscillatory behaviours and their studies have always been a topic of interest in engineering and science in general. To address this problem, the Kuramoto model (Kuramoto (1975)), while being proposed originally as a model to describe chemical and biological oscillators, has found widespread applications to describe a broad family of oscillatory behaviours Acebron et al. (2005). In Kuramoto (1975), the evolution of an "all-to-all" network, i.e., a fully connected graph, of n phase-coupled (possibly) heterogeneous oscillators is described as

$$\dot{\theta}_i = \omega_i + \frac{\kappa}{n} \sum_{j \in \mathcal{V}_i} \sin(\theta_j - \theta_i) \qquad i \in \{1, \dots, n\} \quad (1)$$

where $\theta_i \in \mathbb{R}$ is the phase of the i-th oscillator, $\mathcal{V}_i := \{1, \dots, n\} \setminus \{i\}$, $\omega_i \in \mathbb{R}$ is its natural frequency and $\kappa > 0$ is the gain of the coupling action between each pair of oscillators. Neuroscience (Tass (2003); Cumin and Unsworth (2007)), chemistry (Forrester (2015)) and electrical engineering (Dörfler and Bullo (2012)), to cite a few, are examples of contexts where the Kuramoto model has been successfully used. The control community has taken an active interest in the Kuramoto model and in the last two decades has provided rigorous guarantees of its synchronization properties in various settings, see, e.g., Jafarpour and Bullo (2019); Jadbabaie et al. (2004); Chopral and Spong (2009); Dörfler and Bullo (2011); Leonard et al. (2012); Aokii (2015); Sepulchre et al. (2007); Aeyels and Rogge (2004).

Among the phenomena characterizing oscillating systems, collective synchronization plays a key role. However, the results in the existing literature come with several shortcomings preventing this phenomenon from occurring. First, when the network comprises oscillators with the same natural frequency, i.e., when $\omega_i = \omega$ for all $i \in \{1, \dots, n\}$ in (1), it is now well-known that a system of Kuramoto oscillators admits, in addition to stable equilibria coinciding with the synchronization set, equilibria that are unstable (see, e.g., Strogatz (2000); Sepulchre et al. (2007)). The downside of this result is that the closer a solution is initialized to an unstable equilibrium, the longer it will take for phase synchronization to arise: we talk of *non-uniform* convergence Sepulchre et al. (2007). While non-uniform synchronization may naturally characterize certain physical (Oud (2006)) and biological systems, in general it is not a desirable property for engineering applications, for which we have the freedom to design the interconnection rules. Indeed, as a first drawback, the lack of uniformity may induce arbitrarily slow convergence to the attractor set and poor robustness properties (Miller and Pachter (1997)). Secondly, it may occur in the classical Kuramoto model that the angular phase mismatch between adjacent oscillators remains constant and different from zero indefinitely: in this case we talk of *phase locking* (Aeyels and Rogge (2004)), which hampers the capability to reach asymptotic collective synchronization. Thirdly, in critical applications, finite-time convergence, instead of only asymptotic synchronization, may be a mandatory requirement (Polyakov (2011)). To the authors' best knowledge, the case of finite-time synchronization of Kuramoto oscillators has been studied only in (Wu and

⋆ Work supported by the ANR under grant HANDY ANR-18-CE40-0010

Li (2018)), where the authors propose a multiplex control to synchronize non-identical oscillators in fixed-time. Finally, contrary to the case of non-identical oscillators with constant natural frequencies, which has been widely investigated in the literature (Dörfler and Bullo (2014)), oscillators with time-varying natural frequencies have been studied only in the settings of second order Kuramoto models, see, e.g., Dörfler and Bullo (2012), as far as we know.

In this context, we propose novel hybrid rules to interconnect oscillators, by exploiting the periodicity of phases. We consider an undirected tree graph $\mathcal{G}_u = (\mathcal{V}, \mathcal{E}_u)$ with $n = |\mathcal{V}|$ nodes and $m = |\mathcal{E}_u|$ edges and we assign an arbitrary orientation to $\mathcal{G}_u$, which leads to the oriented tree $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. The continuous dynamics of each oscillator, represented by a node in $\mathcal{G}$, is defined as

$$\dot{\theta}_i = \omega_i(\mathfrak{t}) + \kappa \sum_{j \in \mathcal{O}_i} \sigma(\theta_j - \theta_i + 2q_{ij}\pi) - \kappa \sum_{j \in \mathcal{I}_i} \sigma(\theta_i - \theta_j + 2q_{ji}\pi), \qquad x \in C, \qquad (2)$$

where the sets $\mathcal{I}_i \cup \mathcal{O}_i := \mathcal{V}_i$ represent the *in-neighbors* and *out-neighbors* of node i. We consider each phase θ_i, $i \in \mathcal{V}$, evolving on $[-\pi - \delta, \pi + \delta]$, with $\delta \in (0, \pi)$. Variable q_{ij}, $(i, j) \in \mathcal{E}$, is a logic state, taking values in $\{-1, 0, 1\}$. The role of q_{ij} is to unwind the difference between the two phases θ_j and θ_i through jumps while it remains constant along flows. The time-varying parameter $\omega_i(\mathfrak{t}) \in [\omega_m, \omega_M]$ in (2) is the instantaneous frequency of oscillator i while the strictly positive gain $\kappa \in \mathbb{R}_{>0}$ scales the coupling between oscillators. The coupling action is expressed by σ, which is piecewise continuous on $\operatorname{dom}\sigma := [-\pi - \delta, \pi + \delta]$, and is selected such that $\sigma(s) = -\sigma(-s)$ for any $s \in \operatorname{dom}\sigma$ and that $\operatorname{sgn}(s)\sigma(s) \geq \alpha(|s|)$ for any $s \in \operatorname{dom}\sigma \setminus \{0\}$ and for some function α positive definite and non-decreasing. Examples of suitable functions σ are depicted in Figure 2, together with the sine function used in (1), for the sake of comparison (additional selections can be found in Mariano et al. (2021)). The state x collects all the q_{ij}, $(i, j) \in \mathcal{E}$, and θ_i, $i \in \mathcal{V}$. The flow set C in (2) is selected as the closed complement of the jump set D. Through jumps we ensure that the proposed model is well-defined: We design a first set of jump rules to guarantee that the argument $\theta_j - \theta_i + 2q_{ij}\pi$ of σ in (2) belongs to $\operatorname{dom}\sigma = [-\pi - \delta, \pi + \delta]$ when flowing. A second set of jump rules is introduced for when one of the oscillators $i \in \mathcal{V}$ reaches $|\theta_i| = \pi + \delta$. In this case, a jump of 2π is enforced so that the phase is mapped into $(-\pi - \delta, \pi + \delta)$ while remaining the same modulo 2π.

The novel class of hybrid coupling rules proposed to interconnect the oscillators induces uniform global practical asymptotic stability of the synchronization set, defined as

$$\mathcal{A} := \{x \in C \cup D : \theta_i = \theta_j + 2k_{ij}\pi, \forall (i, j) \in \mathcal{E}\}, \qquad (3)$$

thereby ensuring global uniform convergence, while still locally preserving the original behavior of Kuramoto oscillators for suitable selections of σ. The practical stability results can be summarized in the following theorems, whose proofs are given in Mariano et al. (2021).

Theorem 1. Given set $\mathcal{A}$ in (3), the following holds.

(i) All maximal solutions of the considered hybrid model are $\mathfrak{t}-$complete, i.e., their continuous time domain is unbounded;

(ii) there exists a class $\mathcal{KL}$ function $\beta_\circ$ and a class $\mathcal{K}$ gain $\gamma_\circ$, both of them independent of κ, such that, for any $\kappa > 0$, all solutions x satisfy

$$|x(\mathfrak{t}, \mathfrak{j})|_{\mathcal{A}} \leq \beta_\circ(|x(0, 0)|_{\mathcal{A}}, \kappa\mathfrak{t}) + \gamma_\circ((\kappa)^{-1}(|\omega_M - \omega_m|)), \quad (4)$$

for all $(\mathfrak{t}, \mathfrak{j}) \in \operatorname{dom} x$, where $\omega_M - \omega_m$ is the maximum mismatch of the instantaneous frequency of two adjacent oscillators. ■

In view of item (i) of Theorem 1, item (ii) of Theorem 1 provides an insightful bound (4) illustrating the trend of the continuous time evolution of the hybrid solutions to our model, and the role of κ in speeding up their transient and reducing their asymptotic disagreement. Hence, Theorem 1 implies that the oscillator phases uniformly converge to any desired neighborhood of $\mathcal{A}$ by taking κ sufficiently large, thus the practical nature of the result. A useful outcome of the mild regularity conditions that we require from σ is that defining σ to be discontinuous at the origin, as in the staircase function represented in Fig. 2, leads to a desirable sliding-like behavior of the solutions in the attractor $\mathcal{A}$. This sliding property induces interesting advantages of the behavior of solutions. A first advantage is that, even with non-uniform natural frequencies, we prove uniform global $\mathcal{KL}$ asymptotic stability of $\mathcal{A}$ for a large enough coupling gain κ, due to the well-known ability of sliding-mode mechanisms of dominating unknown additive bounded disturbances acting on the dynamics. A second advantage is that we can guarantee a finite-time convergence. Finally, by taking κ sufficiently large, we actually prove prescribed finite-time convergence (see Song et al. (2017)). These properties are formalized in the theorem below.

Theorem 2. If σ is discontinuous at the origin, then set $\mathcal{A}$ in (3) is prescribed finite-flowing-time stable, i.e., for each $T > 0$ there exists $\kappa^\star > 0$ such that for each $\kappa \geq \kappa^\star$:
(i) there exists $\beta \in \mathcal{KL}$ such that all solutions x satisfy $|x(\mathfrak{t}, \mathfrak{j})|_{\mathcal{A}} \leq \beta(|x(0, 0)|_{\mathcal{A}}, \mathfrak{t} + \mathfrak{j}), \quad \forall (\mathfrak{t}, \mathfrak{j}) \in \operatorname{dom} x$;

(ii) all solutions x satisfy, $x(\mathfrak{t}, \mathfrak{j}) \in \mathcal{A}$ for all $(\mathfrak{t}, \mathfrak{j}) \in \operatorname{dom} x$ with $\mathfrak{t} \geq T$. ■

Simulations are provided to illustrate the theoretical guarantees and demonstrate the potential strength of hybrid theoretical tools to overcome fundamental limitations of continuous-time networked systems as the non-uniform behavior typically found with classical Kuramoto models.

In a first set of simulations, to illustrate the uniform asymptotic and finite-time synchronization property, we consider a tree-like network of $n = 20$ heterogeneous oscillators with time-varying natural frequency and we initialize solutions far away from the synchronization set, in a neighbourhood of one of the unstable equilibria of the classical Kuramoto oscillator (Strogatz (2000)).

The phase evolution is reported [1] in Fig. 3, for different selections of σ, and $\kappa = 1$. When σ is defined as the quadratic or the sine function, practical synchronization is achieved, as shown in Fig. 3. We note that using the

[1] The simulations have been carried out using the Matlab toolbox HyEQ (Sanfelice et al. (2013)).

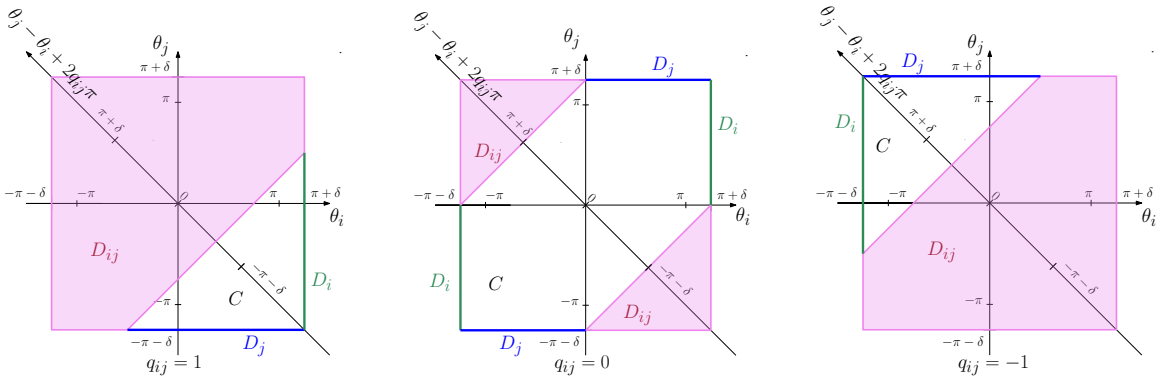

Fig. 1. Projection of the flow and jump sets on (θ_i, θ_j) for each value of q_{ij} (Mariano et al. (2021)).

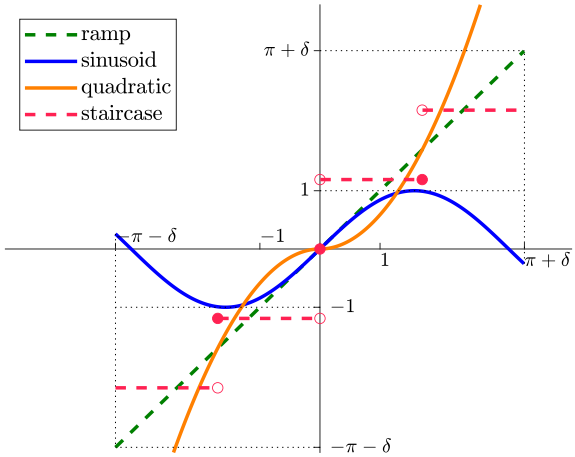

Fig. 2. Examples of suitable functions σ satisfying, together with the sine function used in the classical Kuramoto model.

sinusoidal σ, as in the classical Kuramoto oscillators, leads to a slower convergence due to the non-uniform synchronization property, as compared to the quadratic and the staircase functions. On the other hand, the staircase function, which is discontinuous at 0, leads also to a finite-time synchronization property, in agreement with Theorem 2.

In a second set of simulations, we consider $n = 5$ oscillators, $\kappa = 1$ and $\frac{\kappa}{n} = 1$ in (1), so that the coupling gains are the same and $\omega_i = 1$, $i \in \{1, \ldots, 5\}$. Simulation results for an "all-to-all" network are provided in Fig.4 where we see that the phases generated by our model show a richness of converging behaviors (asymptotic and finite time convergence compared to the exponential one of the classical Kuramoto model) for relatively large initial phase mismatch (left column). For larger initial errors (right column), our designed hybrid coupling induces uniform synchronization, whereas slow transients are generated by (1) (top row). Similar results have been obtained in the case where the interconnection graph is a tree. Even though our main results in Theorems 1 and 2 require tree-like networks, Fig.4 shows that our solution may provide desirable uniform synchronization also with more general "all-to-all" networks.

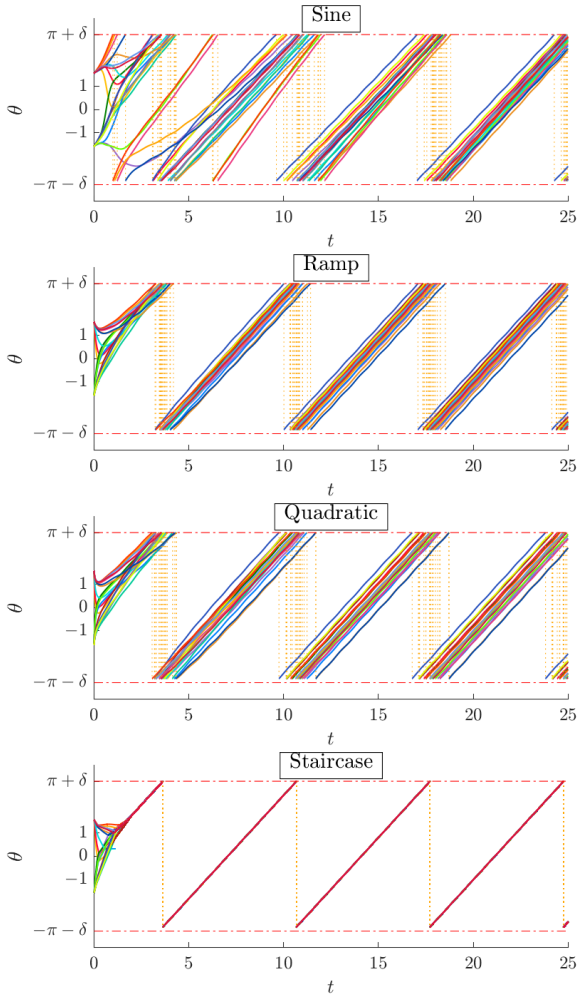

Fig. 3. Phase evolution for $\kappa = 1$ and different selections of σ (from top to bottom: sine, ramp, quadratic and staircase functions).

Abstract: We deal with evolutionary game-theoretic learning processes for population games on networks with dynamically evolving communities. Specifically, we propose a novel framework in which a deterministic, continuous-time replicator equation on a community network is coupled with a closed migration process between the communities, in turn governed by an environmental feedback mechanism resulting in co-evolutionary dynamics. Through a rigorous analysis of the system of differential equations obtained, we characterize the equilibria of the coupled dynamical system. Moreover, for a class of population games —matrix games— a Lyapunov argument is used to establish an evolutionary folk theorem that guarantees convergence to the evolutionary stable states of the game. Numerical simulations are provided to illustrate and corroborate our theoretical findings.

Keywords: Game theory, evolutionary games, flows in graphs.

1. INTRODUCTION

The literature on evolutionary game theory usually relies on the assumption that individuals interact on a homogeneous time-invariant all-to-all communication structure. However, this assumption is quite simplistic in many real-world scenarios Easley and Kleinberg (2010). To address this limitation, in particular for the class of learning mechanisms regulated by pairwise interactions and imitation dynamics, some recent efforts toward incorporating a mesoscopic network structure into learning protocols have been made. In these frameworks, it is assumed that the players are divided into communities that determine their possible interactions with other players. For example, in Hofbauer and Sandholm (2009); Sandholm (2010), communities are introduced as fully mixed and isolated populations, where players do not interact across communities, but the communities themselves are coupled through a common payoff function. For such a model, global convergence results have been established for several classes of games. In Barreiro-Gomez et al. (2017), some convergence results have been extended to populations in which the the action played by an individual determines their community and thus, ultimately, their pattern of interactions. In Como et al. (2021), imitation dynamics on community networks have been formalized, in which players belong to different communities who interact on a network structure. Some convergence results have been established, including global convergence for potential games.

[1] This work was partially supported by the Wallenberg AI, Autonomous Systems and Software Program (WASP) funded by the Knut and Alice Wallenberg Foundation.

In the aforementioned works, it is assumed that the communities are fixed a priori Como et al. (2021); Hofbauer and Sandholm (2009); Sandholm (2010) or determined by the individuals' actions Barreiro-Gomez et al. (2017). This relies on an assumption of time-scale separation, in which a dynamical co-evolution of the communities at the same time-scale as the learning process is neglected.

In this work, we address this gap by proposing a novel dynamic coupling of two mechanisms. On the one hand, evolutionary dynamics on community networks with closed migration processes as in Kelly (2011).On the other, environmental feedback, which has previously been modeled for evolutionary game frameworks *without* community structure in Tilman et al. (2020). Here, we model a scenario where individuals of a community can move to other communities in response to environmental changes. This means that we augment the system of ordinary differential equations (ODEs) that characterizes the replicator equation on community networks from Como et al. (2021) with a set of ODEs that describes the evolution of the community densities.

Notation: The sets of real and non-negative real numbers are denoted by $\mathbb{R}$ and $\mathbb{R}_+$, respectively. For finite sets $\mathcal{A}$ and $\mathcal{B}$, $\mathbb{R}^{\mathcal{A}\times\mathcal{B}}$ denotes the set of real matrices whose entries are indexed by the elements of $\mathcal{A}\times\mathcal{B}$. The transpose of a matrix $\boldsymbol{x}$ is denoted by $\boldsymbol{x}^\top$. The j-th column (row) of matrix $\boldsymbol{x}$ is denoted by $\boldsymbol{x}_j$ ($\boldsymbol{x}_{j'}$) and the ij-th element by x_{ij}. The i-th element of a vector $\boldsymbol{y}$ is denoted by y_i and the 2-norm of the vector as $||\boldsymbol{y}||$ The vector of all ones is denoted by $\mathbf{1}$ and the sign function is denoted by sgn. For a non-negative matrix W in $\mathbb{R}^{n\times n}$ the associated graph is

defined as $(\mathcal{N}, \mathcal{E}_W)$, with node set $\mathcal{N} := \{1, 2, \dots, n\}$ and edge set $\mathcal{E}_W := \{(i,j) \in \mathcal{N} \times \mathcal{N} : W_{ij} > 0\}$.

2. MODEL

We consider a continuum of individuals structured into communities that interact with each other through instantaneous, random, pairwise encounters with varying strengths, both within and between the communities in the population. In each pairwise encounter individuals use an action from a finite and common action set, which, together with the action of the opponent, results in a reward. Evolutionary dynamics describe how the frequency of actions change under the influence of the pairwise encounters. Here, we consider a replicator equation on community networks in which the frequency of actions is assumed to be proportional to the expected reward and performance of the actions in the population. The novel aspect is that individuals can move freely between the communities. The communities are connected by a dynamic flow network whose flow rates change in response to the frequencies of actions in the communities and, possibly, an exogenous process. Since the movement of individuals changes the rate at with which pairwise encounters occur, a feedback process is established that describes a coevolutionary process of strategic interaction and migration at a community and population level. In the following, the formal definitions of the various concepts are provided.

2.1 Population game

Given a finite action set the *population state* $\boldsymbol{y}$ is a vector in the unitary simplex over $\mathcal{A}$ defined as $\mathcal{Y} := \{\boldsymbol{y} \in \mathbb{R}_+^{\mathcal{A}} : \mathbf{1}^\top \boldsymbol{y} = 1\}$. The elements y_i of the population state $\boldsymbol{y}$ denotes the fraction of players in the population that use action i in $\mathcal{A}$ (i-players). A population state $\boldsymbol{y}$ in $\mathcal{Y}$ is said to support action i in $\mathcal{A}$ if a non-zero fraction of the population uses it. The set of $\mathcal{S}_{\boldsymbol{y}} := \{i \in \mathcal{A} : y_i > 0\}$ is called the *support* of $\boldsymbol{y}$. Given a population state expected rewards $r_i(\boldsymbol{y})$ are determined by the reward functions $r_i : \mathcal{Y} \to \mathbb{R}$ for i in $\mathcal{A}$. A *population game* then refers to the pair $(\mathcal{Y}, r)$.

2.2 Community network

Individuals are structured into a finite set $\mathcal{H}$ of communities. We refer to the proportion of the population in community h in $\mathcal{H}$ as the *community density* and denote it by η_h. The fraction of i-players in community h is denoted by x_{ih} and make up the elements of the *system state* matrix $\boldsymbol{x}$ in $\mathbb{R}_+^{\mathcal{A}\times\mathcal{H}}$. The columns of the system state matrix are referred to as the *community state* vectors $\boldsymbol{x}_h$ in $\mathbb{R}_+^{\mathcal{A}}$ for h in $\mathcal{H}$. Similar as before, the support of a community state is $\mathcal{S}_{\boldsymbol{x}_h} := \{i \in \mathcal{A} : x_{ih} > 0\}$ and $\cup_{h\in\mathcal{H}} \mathcal{S}_{\boldsymbol{x}_h} = \mathcal{S}_{\boldsymbol{y}}$. The density of the population is assumed to be constant and given by

$$\boldsymbol{\eta}\mathbf{1} = \mathbf{1}^\top \boldsymbol{x}\mathbf{1} = \mathbf{1}^\top \boldsymbol{y} = 1, \tag{1}$$

which results in the set of admissible system states $\mathcal{X} = \{\boldsymbol{x} \in \mathbb{R}^{\mathcal{A}\times\mathcal{H}} : (1)\}$. The strength of interactions between communities is determined by a constant non-negative matrix W in $\mathbb{R}_+^{\mathcal{H}\times\mathcal{H}}$. Together with the fraction of i-players this determines the rate $x_{ih}W_{hk}x_{jk} \geq 0$, for i, j in $\mathcal{A}$ and h, k in $\mathcal{H}$, at which i-players in community h meet j-players in community k in a pairwise encounter. We refer to the triplet $(\mathcal{H}, W, \boldsymbol{\eta})$ as a community network. Throughout the extended abstract the following assumption is made.

Assumption 1. W is non-negative and irreducible with a strictly positive diagonal. That is, the graph $(\mathcal{H}, \mathcal{E}_W)$, associated to the community network is connected and has self-loops.

2.3 Evolutionary dynamics

Although the results that we will describe in section 3.1 can be generalized to a broader class of evolutionary imitation dynamics, here we focus on the replicator equation due to its prominence in evolutionary game theory Cressman et al. (2003); Cressman and Tao (2014) and control applications of population games Quijano et al. (2017). The replicator equation on a community network is a matrix valued equation $\boldsymbol{f}(\boldsymbol{x})$ in $\mathbb{R}_+^{\mathcal{H}\times\mathcal{H}}$ whose elements Como et al. (2021)

$$f_{ih}(\boldsymbol{x}) = \eta_h \sum_{k\in\mathcal{H}} x_{ik}W_{hk}r_i(\boldsymbol{y}) - x_{ih}\sum_{j\in\mathcal{A}}\sum_{k\in\mathcal{H}} x_{jk}W_{hk}r_j(\boldsymbol{y}). \tag{2}$$

describe how the proportion of i-players in community h changes under the influence of selection. We remark that, if there is a community h in $\mathcal{H}$ such that $\eta_h = 1$, then (2) reduces to the more familiar form of the classic replicator equation Cressman and Tao (2014) given by $f_i(\boldsymbol{x}) = x_i\left(r_i(\boldsymbol{x}) - \sum_{j\in\mathcal{A}} x_j r_j(\boldsymbol{x})\right)$ for $x_i = W_{hh}x_{ih}$.

Assumption 2. Expected rewards are positive.

This assumption is born out of a technical necessity that is not confining: because the restricted Nash equilibria of (2) are invariant to the addition of a constant, negative rewards can always be changed to positive ones without changing the set of equilibrium points.

2.4 Dynamic flow process

We assume individuals of a community have an intrinsic tendency for movement that is described by a constant non-negative matrix Λ in $\mathbb{R}_+^{\mathcal{H}\times\mathcal{H}}$ with elements λ_{hk}. Given a system state $\boldsymbol{x}$ in $\mathcal{X}$ these intrinsic tendencies may be amplified or reduced by a non-negative environmental function. $\boldsymbol{\phi} : \mathcal{X} \to \mathbb{R}_+^{\mathcal{H}\times\mathcal{H}}$. The environmental response function may also depend on a subset of community state vectors or an exogenous variable. It may also be governed by positive system dynamics. As in the closed migration processes of (Kelly, 2011, Chapter 2), we assume scaling is multiplicative such that the dynamic rate at which individuals move from community h to community k is $\lambda_{hk}\phi_{hk}(\boldsymbol{x})$ in $\mathbb{R}_+$. The changes in community densities induced by these movements are described by the dynamic flow process

$$\dot{\eta}_h = \sum_{k\in\mathcal{H}} \lambda_{kh}\phi_{kh}(\boldsymbol{x})\eta_k - \eta_h \sum_{k\in\mathcal{H}} \lambda_{hk}\phi_{hk}(\boldsymbol{x}). \tag{3}$$

This preserves the population density (1) because the system is closed. Moreover, non-negativity of the environmental function $\boldsymbol{\phi}$ and movement matrix Λ ensures the solutions of (3) remain well-defined densities.

This can, for example, model density-limiting effects, which are an important consideration in ecological and population models. Increased pressures on resources can lower reproductive rates Cressman and Garay (2003) and increase out-migration Isard (1960); Masanori et al. (2015). The latter can, for example, be captured by considering a dynamic environmental response that is uniform in the *outflows* of a community:

$$\dot{\phi}_{hk} = (\phi_{hk} - m)\left(1 - \frac{\eta_h}{\kappa_h}\right)\phi_{hk}, \tag{4}$$

where $m > 0$ is a constant maximum environmental response and $\kappa_h > 0$ the carrying capacity of community h. Clearly, its solutions $\phi_h(t)$ of the above differential equation exist in $\mathbb{R}_+$ as required for well-defined community densities. Moreover, if a community is overcrowded $\eta_h > \kappa_h$ and out-migration increases. This example may be generalized to account for a dependency of the carrying capacity on the community state vector x_h akin to density games Novak et al. (2013).

When the dynamic movement rates are frequency dependent, but action independent, the proportion of actions in the outflows of a community are distributed according to the corresponding community state vector. Thus, when (2) is interconnected with (3), the closed-loop system state dynamics read as

$$\begin{aligned}\dot{x}_{ih} &= \sum_{k\in\mathcal{H}} \lambda_{kh}\phi_{kh}(\boldsymbol{x})x_{ik} - x_{ih}\sum_{k\in\mathcal{H}} \lambda_{hk}\phi_h(\boldsymbol{x}) \\ &+ \eta_h \sum_{k\in\mathcal{H}} x_{ik}W_{hk}r_i(\boldsymbol{y}) - x_{ih}\sum_{j\in\mathcal{A}}\sum_{k\in\mathcal{H}} x_{jk}W_{hk}r_j(\boldsymbol{y}).\end{aligned} \tag{5}$$

Definition 1. The combination of a population game, a community network and an environmental function, define the population game on a community network with dynamic densities as the tuple $\Gamma = (\mathcal{Y}, r, \mathcal{H}, W, \Lambda, \boldsymbol{\phi})$.

3. RESULTS

3.1 A dynamic system state-density balance

We next characterize the asymptotic relation between the population state, the community state and dynamic community densities of a connected community network. For our first result, no further restrictions are imposed on the size of the finite action set, or the structure of the reward functions and environmental function.

Theorem 1. Consider a population game on a community network with dynamic densities Γ that satisfies Assumptions 1-2. Let $\boldsymbol{\eta}(t)$ and $\boldsymbol{x}(t)$ be the solutions of the dynamics (3) and (5), respectively. If $\lim_{t\to\infty} \boldsymbol{x}(t)\mathbf{1} = \boldsymbol{y}^*$, then $\boldsymbol{y}^*$ is a restricted Nash equilibrium and, for all h in $\mathcal{H}$ such that $\liminf_{t\to\infty} \eta_h(t) > 0$, it holds that

$$\lim_{t\to\infty} \frac{x_{ih}(t)}{\eta_h(t)} = y_i^* \quad \forall i \in \mathcal{A}. \tag{6}$$

In the degenerate cases $\eta_k(t) = 0$, $x_{ik}(t) = 0$ for all i in $\mathcal{A}$.

The proof is based on W being non-negative and irreducible, together with the dynamic flow process being closed and non-negative. Using this, it can be shown that the ratio x_{ih}/η_h is constant and equal for all communities if the population state $\boldsymbol{y}$ is at an equilibrium. By Assumption 2, this must be a restricted Nash equilibrium. Details can be found in Govaert et al. (2022).

Theorem 1 shows that the dynamic system state-density balance in(6) is achieved even when the dynamic flow process (3) is non-convergent, i.e. $\lim_{t\to\infty} \boldsymbol{\eta}(t)$ does not exist. Otherwise, the following corollary is an immediate consequence of Theorem 1.

Corollary 1.1. If the dynamic flow process (3) converges to $\lim_{t\to\infty} \boldsymbol{\eta}(t) = \boldsymbol{\eta}^*$ and $\lim_{t\to\infty} \boldsymbol{x}(t)\mathbf{1} = \boldsymbol{y}^*$, then the system state matrix converges to the equilibrium $\lim_{t\to\infty} \boldsymbol{x}(t) = \boldsymbol{y}^*\boldsymbol{\eta}^{*\top}$.

3.2 Evolutionary stability

Next, we focus on the relation between the population state vector and evolutionarily stable states. For this result, we restrict our attention to binary action sets and linear rewards functions of the form

$$r(\boldsymbol{y}) = \begin{bmatrix} a & b \\ c & d \end{bmatrix}\boldsymbol{y} \quad a, b, c, d > 0, \tag{7}$$

that satisfy Assumption 2. These rewards can also be interpreted as the payoffs of a player in a two-by-two symmetric matrix game played against the mixed strategy $\boldsymbol{y}$. Consider the following definition of an evolutionarily stable state from Hofbauer and Sigmund (1998).

Definition 2. (Evolutionarily stable state). A population state vector $\hat{\boldsymbol{y}}$ in $\mathcal{Y}$ is an evolutionarily stable state if there exists $\delta > 0$ such that $\hat{\boldsymbol{y}} \cdot A\boldsymbol{y} > \boldsymbol{y} \cdot A\boldsymbol{y}$, for all $\boldsymbol{y} : 0 < ||\boldsymbol{y} - \hat{\boldsymbol{y}}|| < \delta]$.

The following result shows the importance of evolutionarily stable states also for the replicator equation on networks with dynamic communities when the underlying interaction network is undirected. Its proof, omitted due to space constraints, is based on a Lyapunov argument.

Theorem 2. Consider Γ that satisfies Assumption 1 and additionally $W = W^\top$. The action set is binary and reward functions are linear and symmetric. Then,

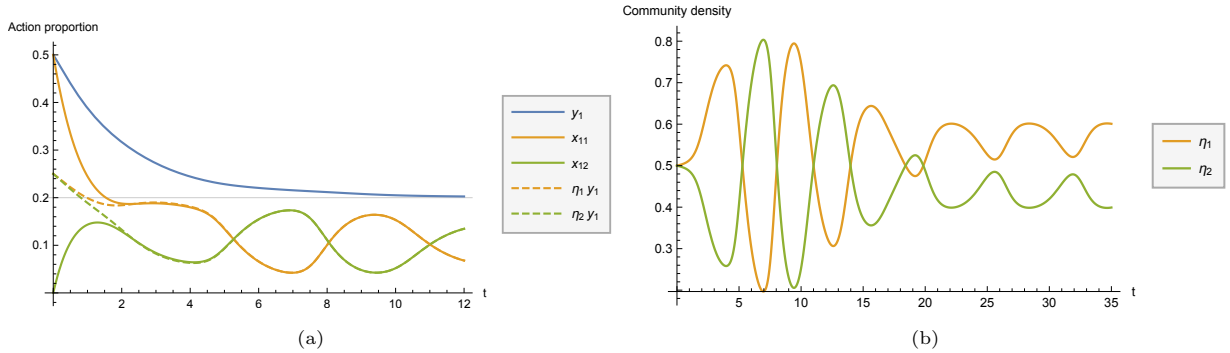
(1) An evolutionarily stable state $\hat{\boldsymbol{y}}$ in $\mathcal{Y}$ is locally asymptotically stable.
(2) If an evolutionarily stable state $\hat{\boldsymbol{y}}$ exists in the interior of $\mathcal{Y}$ then all interior trajectories converge to it.

The proof is based on a Lyapunov argument, where the strict local Lyapunov function $P(\boldsymbol{y}) := \prod_{i\in\mathcal{S}_{\hat{y}}} y_i^{\hat{y}_i}$ is combined with the assumption that W is connected and symmetric. Details can be found in Govaert et al. (2022).

The combination of Theorems 1 and 2 characterizes the asymptotic behavior at a population and community level and shows the important role of evolutionarily stable states. We now illustrate this with a brief case study on carrying capacities that exhibit periodic behaviors under the influence of geographically distributed seasonal changes or cyclic socio-economic parameters. We illustrate this for two communities with a sinusoidally varying carrying capacities Banks (1993):

$$\kappa_1(t) = \gamma\,\sin(t) + \rho, \quad \kappa_2(t) = \gamma\,\sin(t + \pi) + \rho, \tag{8}$$

with $0 < \gamma < \rho$ to ensure they are positive. The phase shift between the two communities represents a geographical



(a) (b)

Fig. 1. Numerical solutions of the dynamic flow process (3) and the closed-loop system (5) for two communities with the dynamic environmental function (4) with sinusoidal varying carrying capacities (8). Notice in (b) that the community densities oscillate periodically from $t = 22$, while the population state in (a) converges to an equilibrium and a dynamic balance system state is achieved asymptotically. Parameters values are as follows. Carrying capacity: $\gamma = 0.25$, $\rho = 0.5$. Pairwise rewards: $a = 1$, $b = 7$, $c = 5$, $d = 6$. Interaction matrix: $W_{11} = 0.7$, $W_{12} = W_{21} = W_{22} = 0.3$. Movement matrix: $\lambda_{aa} = \lambda_{bb} = 1$, $\lambda_{ba} = 0.8$, $\lambda_{ab} = 0.5$. Initial conditions not shown in the figure: $\phi_{12}(0) = \phi_{21}(0) = 0.05$.

difference in seasonal changes or socio-economic parameters. The sinusoidally varying carrying capacities can be combined with the dynamic environmental function (4). A closed system of differential equations is then obtained with the dynamic flow process (3) and the evolutionary dynamic (5) with rewards (7). Even for just two communities a full analysis is challenging. However, with the theory developed here, some critical insights at both a population and community level can be obtained. As Theorem 2 predicts, the population state converges asymptotically to the evolutionarily stable state indicated by the horizontal line in Fig. 1a. The interesting behavior occurs at a community level that shows persistent oscillations due to the sinusoidally varying carrying capacities as in Fig. 1b. The effect of Theorem 1 is then seen by the trajectories that converge to each other in Fig. 1a: the proportion of players in the communities converge asymptotically to the product of the oscillating community densities and the evolutionarily stable state.

4. CONCLUSION

In this work, we have proposed a novel framework for evolutionary game dynamics on networks with dynamic communities. Specifically, our framework couples a learning dynamics on a community network with closed migration processes and an environmental feedback, which coevolve at comparable time scales. Under some reasonable assumptions on the structure of the networks and on the reward functions, we have provided a characterization of the equilibria of the dynamical system. Moreover, for matrix games on undirected networks, we have established a convergence result to the evolutionary stable states of the system.

Abstract: Recently, there has been a large interest in the theory of optimal transport and its connections to the Schrödinger bridge problem. In this work we generalize some of these results to multi-marginal optimal transport problems when the cost function decouples according to a tree structure. In particular, the entropy regularized multi-marginal optimal transport problem can be seen as a Schrödinger bridge problem on the same tree. Moreover, based on this, we extend efficient algorithms for the bi-marginal problem to the multi-marginal setting where the cost function decouples according to a tree structure. Such problems appear in several applications of interest such as barycenter and tracking problems. A common approach for solving these problems is by utilizing pairwise regularization. However, we show that the multi-marginal regularization introduces less diffusion, which is favorable in many applications.

Keywords: Optimal transport, Schrödinger bridge, Graph signal processing, Multi-marginal problems, Entropy regularization

1. MULTI-MARGINAL OPTIMAL TRANSPORT

An optimal transport problem is to find a transport plan that minimizes the cost of moving mass from one distribution to another, see, e.g., Villani (2008). Historically this problem has been important in economics and operations research, but as a result of recent progress it has become a popular tool in a wide range of fields such as signal processing, computer vision, automatic control, and machine learning (see, e.g., Elvander et al. (2020); Dominitz and Tannenbaum (2010); Solomon et al. (2015); Chen et al. (2016c); Adler et al. (2017)). An extension to the standard optimal transport framework is multi-marginal optimal transport, see, e.g., Pass (2015), which seeks a transport plan between not only two, but several distributions.

In this extended abstract, which is based on Haasler et al. (2021), we consider discrete multi-marginal optimal transport problems. In this setting, the marginal distributions are described by nonnegative vectors $\mu_j \in \mathbb{R}^n_+$, for $j = 1, \dots, J$, and we seek a nonnegative J-mode mass transport tensor $\mathbf{M} \in \mathbb{R}^{n\times n\cdots\times n}_+$ that minimizes the transportation cost between the marginals. In particular, the element $\mathbf{M}_{i_1,\dots,i_J}$ of $\mathbf{M}$ denotes the amount of transported mass associated with the tuple $(i_1, \dots, i_J)$, where $i_j \in \{1, \dots, n\}$ describes the location on the j-th marginal, and the tensor $\mathbf{M}$ is thus a transport plan between the marginals $\mu_j \in \mathbb{R}^n_+$, for $j = 1, \dots, J$, if its projections satisfy $P_j(\mathbf{M}) = \mu_j$, for $j = 1, \dots, J$, where

$$P_j(\mathbf{M}) = \sum_{i_1,\dots,i_{j-1},i_{j+1},\dots,i_J} \mathbf{M}_{i_1,\dots,i_{j-1},i_j,i_{j+1},\dots,i_J}.$$

The cost for transporting mass is described by the nonnegative J-mode cost tensor $\mathbf{C} \in \mathbb{R}^{n\times n\cdots\times n}_+$, where $\mathbf{C}_{i_1,\dots,i_J}$ assigns a cost to the tuple $(i_1, \dots, i_J)$. The total cost is thus $\langle \mathbf{C}, \mathbf{M}\rangle = \sum_{i_1,\dots,i_J} \mathbf{C}_{i_1,\dots,i_J}\mathbf{M}_{i_1,\dots,i_J}$, and the problem of finding an optimal transport plan $\mathbf{M}$ can therefore be formulated as a linear program. However, in many practical applications this linear program is impossible to solve directly due to the large number of variables, n^J. In Cuturi (2013) these computational limitations have been alleviated for the bi-marginal setting by introducing an entropy regularization. Following the same approach, we formulate the entropy regularized multi-marginal optimal transport problem (see also Benamou et al. (2015); Elvander et al. (2020)) as

$$\begin{aligned} &\underset{\mathbf{M}\in\mathbb{R}^{n\times\cdots\times n}_+}{\text{minimize}} \ \langle \mathbf{C}, \mathbf{M}\rangle + \epsilon H(\mathbf{M}) \\ &\text{subject to } P_j(\mathbf{M}) = \mu_j, \ \text{for } j \in \Gamma, \end{aligned} \tag{1}$$

where $\epsilon > 0$ is a regularization parameter, the normalized entropy of $\mathbf{M}$ is defined as

$$H(\mathbf{M}) := \sum_{i_1,\dots,i_J} \left(\mathbf{M}_{i_1,\dots,i_J} \log\left(\mathbf{M}_{i_1,\dots,i_J}\right) - \mathbf{M}_{i_1,\dots,i_J} + 1\right),$$

and $\Gamma \subset \{1, 2, \dots, J\}$ is an index set. At this point, note in particular that the latter means that not all marginal projections of $\mathbf{M}$ need to be assigned, as in the Wasserstein barycenter problem. It can be shown that the optimal solution to (1) is of the form $\mathbf{M} = \mathbf{K} \odot \mathbf{U}$, where $\odot$ denotes elementwise multiplication, $\mathbf{K} = \exp(-\mathbf{C}/\epsilon)$ and $\mathbf{U}$ can be

decomposed as

$$\mathbf{U} = u_1 \otimes u_2 \otimes \cdots \otimes u_J \tag{2}$$

with $u_j \in \mathbb{R}^n$ given by

$$u_j = \begin{cases} \exp(\lambda_j/\epsilon), & \text{if } j \in \Gamma \\ \mathbf{1}, & \text{else.} \end{cases}$$

Here $\lambda_j \in \mathbb{R}^n$ is the optimal dual variable corresponding to the constraint on the j-th marginal in the dual problem of (1). For details the reader is referred to, e.g., Elvander et al. (2020); Benamou et al. (2015).

The optimal $\mathbf{U}$ in (2) can be found by so-called Sinkhorn iterations, which are given by iteratively updating u_j according to

$$u_j \leftarrow u_j \odot \mu_j ./ P_j(\mathbf{K} \odot \mathbf{U}), \tag{3}$$

for all $j \in \Gamma$, where $./$ denotes elementwise division. In Benamou et al. (2015), this scheme was derived as Bregman projections, and in Elvander et al. (2020) as a block coordinate ascend in the dual. If an optimal solution to (1) exists, i.e., if the linear program is feasible, then the Sinkhorn iterations in (3) converge. The computational bottleneck of the Sinkhorn iterations (3) is computing the projections $P_j(\mathbf{M})$, for $j \in \Gamma$, which in general scales exponentially in J. In fact, even storing the tensor $\mathbf{M}$ is a challenge as it consists of n^J elements. However, in many cases of interest, structures in the cost tensors can be exploited to make the computation of the projections feasible, e.g., for computing Euler flows (see Benamou et al. (2015)) and in tracking and information fusion applications (see Elvander et al. (2020)).

2. MULTI-MARGINAL OPTIMAL TRANSPORT ON A TREE

In this section we generalize the methods for solving structured multi-marginal optimal transport problems in Elvander et al. (2020) to the setting where the cost tensor decouples according to a tree structure, that is, when the marginals of the optimal transport problem are associated with the nodes of a tree, and cost matrices are defined on its edges. Such structures appear in various applications of optimal transport. For instance, path trees are often used in tracking and interpolation applications, e.g., in Chen and Karlsson (2018); Solomon et al. (2015). Similarly, star trees describe barycenter problems, which occur for instance in information fusion applications (see, e.g., Cuturi and Doucet (2014); Elvander et al. (2019); Solomon et al. (2015)).

Definition 1. A graph $\mathcal{T} = (\mathcal{V}, \mathcal{E})$, with vertices $\mathcal{V}$ and edges $\mathcal{E}$, is a tree if it is acyclic and connected. The vertices with degree 1 are called leaves; the set of leaves is denoted $\mathcal{L}$. For a vertex $j \in \mathcal{V}$, the set of neighbours $\mathcal{N}_j$ is defined as the set of vertices, which have a common edge with j.

Let $\mathcal{T} = (\mathcal{V}, \mathcal{E})$ be a tree. Consider the entropy regularized multi-marginal optimal transport problem (1) where the marginals correspond to the nodes of the tree, i.e., $\mathcal{V} = \{1, 2, \ldots, J\}$. Assume that the cost tensor $\mathbf{C} \in \mathbb{R}_+^{n^J}$ decouples as

$$\mathbf{C}_{i_1,\ldots,i_J} = \sum_{(j_1,j_2)\in\mathcal{E}} C^{(j_1,j_2)}_{i_{j_1},i_{j_2}}, \tag{4}$$

where $C^{(j_1,j_2)} \in \mathbb{R}^{n\times n}$ is a cost matrix representing the cost of moving mass between marginals μ_{j_1} and μ_{j_2}, for $(j_1, j_2) \in \mathcal{E}$. Note that the cost on edge $(j_1, j_2) \in \mathcal{E}$ can be interchangeably expressed by $C^{(j_2,j_1)}$ without changing the cost tensor $\mathbf{C}$ in (4) by letting $C^{(j_2,j_1)} = (C^{(j_1,j_2)})^T$.

Given: Tree $\mathcal{T} = (\mathcal{V}, \mathcal{E})$ with leaves $\mathcal{L} = \{1, 2, \ldots, |\mathcal{L}|\}$.
Initial guess u_j, for $j \in \mathcal{L}$
for $(j_1, j_2) \in \mathcal{E}$ **do**
  Initialize $\alpha_{(j_1,j_2)}$ according to (5)
end for
Initialize $j \in \mathcal{L}$
while Sinkhorn not converged **do**
  $u_j \leftarrow u_j \odot \mu_j ./ \bigodot_{k\in\mathcal{N}_j} \alpha_{(j,k)}$
  for $(j_1, j_2) \in \mathcal{E}$ on the path from j to $(j + 1 \mod |\mathcal{L}|)$ **do**
    Update $\alpha_{(j_1,j_2)}$ according to (5)
  end for
  $j \leftarrow j + 1 \mod |\mathcal{L}|$
end while
return u_j for $j \in \mathcal{L}$

Algorithm 1. Sinkhorn method for the multi-marginal optimal transport problem on a tree.

The following theorem describes how to compute the projections of a tensor of the form $\mathbf{K} \odot \mathbf{U}$, where $\mathbf{U} = u_1 \otimes \cdots \otimes u_j$ and $\mathbf{K}$ decouples according to a tree, which appear in the Sinkhorn iterations (3) for optimal transport problems with tree-structured costs.

Theorem 1. Let $\mathbf{K} = \exp(-\mathbf{C}/\epsilon)$ with $\mathbf{C}$ as in (4) for the tree $\mathcal{T} = (\mathcal{V}, \mathcal{E})$, and let $\mathbf{U} = u_1 \otimes u_2 \otimes \cdots \otimes u_J$. Define $K^{(j_1,j_2)} = \exp(-C^{(j_1,j_2)}/\epsilon)$, for $(j_1, j_2) \in \mathcal{E}$. Then the projection on the j-th marginal of $\mathbf{K} \odot \mathbf{U}$ is of the form

$$P_j(\mathbf{K} \odot \mathbf{U}) = u_j \odot \bigodot_{k\in\mathcal{N}_j} \alpha_{(j,k)}.$$

The vectors $\alpha_{(j,k)}$, for all ordered tuples $(j, k) \in \mathcal{E}$, can be computed recursively starting in the leaves of the tree according to

$$\begin{aligned} \alpha_{(j,k)} &= K^{(j,k)} u_k && \text{for } k \in \mathcal{L} \\ \alpha_{(j,k)} &= K^{(j,k)} \Big(u_k \odot \bigodot_{\ell\in\mathcal{N}_k\setminus\{j\}} \alpha_{(k,\ell)} \Big) && \text{for } k \notin \mathcal{L}. \end{aligned} \tag{5}$$

The expressions for the projections in Theorem 1 can be used to solve a multi-marginal optimal transport problem on a tree $\mathcal{T} = (\mathcal{V}, \mathcal{E})$ by a Sinkhorn method as detailed in (3). Such a method is summarized in Algorithm 1, where we have also used the observation that in each iteration step some of the factors $\alpha_{(j_1,j_2)}$ do not change. More precisely, between two consecutive updates of u_{j_1} and u_{j_2} only the factors on all edges that lie on the path between nodes j_1 and j_2 are changed and thus need to be updated.

It should be noted that we restrict ourselves to the case where $\Gamma = \mathcal{L}$, since otherwise one can always formulate a multi-marginal optimal transport problem on a subtree (or a set of subtrees), where the marginals are known exactly on the set of leaves of the subtree, and which fully describes the solution to the original problem (see Haasler et al. (2021) for more details).

3. CONNECTIONS TO SCHRÖDINGER BRIDGES

Schrödinger (1931) studied the problem of determining the most likely evolution of a particle cloud observed at two

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

time instances, where the particle dynamics have deviated from the expected Brownian motion. This problem is tightly connected to the classical bi-marginal optimal transport problem, which has been extensively studied in Chen et al. (2016b,a); Léonard (2014). In a discrete setting, the Schrödinger bridge problem can be formulated by modeling the evolutions of a number of particles as a Markov chain (see Pavon and Ticozzi (2010); Georgiou and Pavon (2015)). In Haasler et al. (2019) a similar problem has been considered for hidden Markov chains. In this work, we extend the framework to Markov processes on arbitrary tree-structures, and show that its solution is equivalent to the solution of a certain entropy regularized multi-marginal optimal transport problem on the same tree.

To this end, given a tree $\mathcal{T} = (\mathcal{V}, \mathcal{E})$ we consider a rooted, directed tree $\mathcal{T}_r(\mathcal{V}, \mathcal{E}_r)$, rooted in a leaf $r \in \mathcal{L}$. The directions of the edges $\mathcal{E}_r$ are uniqely specificed by the condition that any node $j \in \mathcal{V}$ is reachable from the root r. Moreover, this introduces a partial ordering on $\mathcal{T}_r(\mathcal{V}, \mathcal{E}_r)$, i.e., $j_1 < j_2$ if j_1 is on the path from r to j_2.

Consider a cloud of N particles and assume that each particle evolves according to a Markov process. Denote the states of the Markov process by $X = \{X_1, X_2, \dots, X_n\}$ and let the transition probability matrix on edge $(j_1, j_2) \in \mathcal{E}_r$ be $A^{(j_1,j_2)} \in \mathbb{R}_+^{n\times n}$. Let the vector μ_j describe the particle distribution over the discrete state space X on node j, for $j = 1, \dots, J$. In analogy to the optimal transport framework we define the mass transport matrix $M^{(j_1,j_2)}$, where element $M_{k\ell}^{(j_1,j_2)}$ describes the number of particles transitioning from state k to state ℓ on edge (j_1, j_2). Given μ_{j_1} and $A_{(j_1,j_2)}$, the probability for the event that a given mass transfer matrix $M^{(j_1,j_2)}$ describes the underlying particle dynamics satisfies a large deviation principle with rate function $H(\cdot \,|\, \mathrm{diag}(\mu_{j_1})A^{(j_1,j_2)})$, i..e.,

$$\mathbb{P}_{\mu_{j_1},A^{(j_1,j_2)}}(M^{(j_1,j_2)}) \sim e^{-H\left(M^{(j_1,j_2)}|\mathrm{diag}(\mu_j)A^{(j_1,j_2)}\right)},$$

where $H(P \,|\, Q) := \sum_{i,j} \left(P_{i,j} \log\left(P_{ij}/Q_{ij}\right) - P_{ij} + Q_{ij}\right)$ is the normalized KL divergence between two matrices P and Q. Thus, the discrete Schrödinger bridge problem in Pavon and Ticozzi (2010) (see also Haasler et al. (2019)) can be naturally extended to the tree structure as

$$\begin{aligned} \underset{\substack{M^{(j_1,j_2)},\,(j_1,j_2)\in\mathcal{E}_r,\\ \mu_j,\,j\in\mathcal{V}\setminus\Gamma}}{\text{minimize}} \quad & \sum_{(j_1,j_2)\in\mathcal{E}_r} H\left(M^{(j_1,j_2)} \,|\, \mathrm{diag}(\mu_{j_1})A^{(j_1,j_2)}\right) \\ \text{subject to} \quad & M^{(j_1,j_2)}\mathbf{1} = \mu_{j_1},\ (M^{(j_1,j_2)})^T\mathbf{1} = \mu_{j_2}, \\ & \text{for} \ \ (j_1,j_2) \in \mathcal{E}_r. \end{aligned} \tag{6}$$

It can be shown that under certain conditions the solution to the generalized Schrödinger bridge problem (6) is equivalent to the solution of the entropy regularized multi-marginal optimal transport problem (1) on the same tree. In particular, if the cost matrices in (4) and the transition probabilities for problem (6) are chosen such that

$$C^{(j_1,j_2)} = -\epsilon \log(A^{(j_1,j_2)}), \ \text{for all } (j_1,j_2) \in \mathcal{E}_r, \tag{7}$$

then it holds for the optimizers of (1) and (6) that

$$P_{(j_1,j_2)}(\mathbf{M}) = M^{(j_1,j_2)}, \qquad \text{for } (j_1,j_2) \in \mathcal{E}_r,$$

where the pairwise projections are defined as

$$P_{j_1,j_2}(\mathbf{M}) = \sum_{i_1,\dots,i_J\setminus\{i_{j_1},i_{j_2}\}} \mathbf{M}_{i_1,\dots,i_J},$$

and consequently that $P_j(\mathbf{M}) = \mu_j$ for all $j \in \mathcal{V}$.

4. PAIRWISE REGULARIZED OPTIMAL TRANSPORT ON A TREE

Another natural way to define an optimal transport problem on the tree $\mathcal{T}$ is to minimize the sum of all bi-marginal transport costs on the edges of $\mathcal{T}$. In fact, barycenter problems are typically formulated in this pairwise manner, see, e.g., Cuturi and Doucet (2014); Elvander et al. (2019). Although, in the bi-marginal case the entropy regularized optimal transport problem is equivalent to the Schrödinger bridge, we show that this equivalence does not extend to the respective problems defined on trees.

Given the cost matrices $C^{(j_1,j_2)} \in \mathbb{R}_+^{n\times n}$ for $(j_1, j_2) \in \mathcal{E}$, the pairwise entropy regularized optimal transport problem on $\mathcal{T}$ is defined as

$$\underset{\mu_j,\,j\in\mathcal{V}\setminus\Gamma}{\text{minimize}} \quad \sum_{(j_1,j_2)\in\mathcal{E}} T_\epsilon^{(j_1,j_2)}(\mu_{j_1},\mu_{j_2}), \tag{8}$$

where

$$\begin{aligned} T_\epsilon(\mu_1,\mu_2) = \underset{M\in\mathbb{R}_+^{n\times n}}{\text{minimize}} \quad & \mathrm{trace}((C^{(j_1,j_2)})^T M) + \epsilon H(M) \\ \text{subject to} \quad & M\mathbf{1} = \mu_1, \quad M^T\mathbf{1} = \mu_2. \end{aligned}$$

We note that the objective function of the generalized Schrödinger bridge (6) can be written as

$$\sum_{(j_1,j_2)\in\mathcal{E}_r} H\left(M^{(j_1,j_2)} \,|\, A^{(j_1,j_2)}\right) - \sum_{j\in\mathcal{V}\setminus\mathcal{L}} (\deg(j)-1)H(\mu_j).$$

If relation (7) holds, the generalized Schrödinger bridge and entropy regularized multi-marginal optimal transport problem are equivalent, and can be written as

$$\underset{\mu_j,\,j\in\mathcal{V}\setminus\Gamma}{\text{minimize}} \sum_{(j_1,j_2)\in\mathcal{E}} T_\epsilon^{(j_1,j_2)}(\mu_{j_1},\mu_{j_2}) - \sum_{j\in\mathcal{V}\setminus\mathcal{L}} (\deg(j)-1)H(\mu_j).$$

Thus, the multi-marginal optimal transport problem penalizes not only the transport cost between the marginals, but in addition favors marginal distributions with high entropy. One can thus expect less smoothed out distributions when solving the multi-marginal optimal transport problem, which is desirable in many applications, such as the localization problems in Elvander et al. (2020) and computer vision applications (e.g., the ones in Solomon et al. (2015)). Note that this qualitative difference between the pairwise and multi-marginal formulation has been previously observed, yet not fully explained, for a barycenter optimal transport problem, i.e., a star graph in Elvander et al. (2020). Moreover, empirical study suggests that the multi-marginal problem is better conditioned compared to the pairwise problem, which allows for smaller values of the regularization parameter ϵ, while still yielding a numerically stable algorithm.

5. EXAMPLE

In this section we compare the solutions to the entropy regularized multi-marginal and pairwise optimal transport problems on the tree $\mathcal{T}$ illustrated in Figure 1(a). The marginals on the 15 nodes are all 50×50 pixel image, and the marginal images on the 8 leaves, colored in gray in Figure 1(a), are known. Each edge on the tree is associated with a cost function defined by the L_2-distance between any two pixels. Using this choice of cost function in the

(c) Solution using multi-marginal optimal transport, $\epsilon = 2 \cdot 10^{-3}$

(d) Solution using multi-marginal optimal transport, $\epsilon = 4 \cdot 10^{-4}$

Fig. 1. Estimated marginals of the pairwise (b) and multi-marginal (c,d) optimal transport solutions on the tree in (a).

corresponding optimal transport problems yields smooth translations of power for the intermediate marginals.

We solve the pairwise entropy regularized optimal transport problem (8) with regularization parameter $\epsilon = 2 \cdot 10^{-3}$ on $\mathcal{T}$. The solution can be seen in Figure 1(b). Compared to the pairwise optimal transport estimate, the solution to the entropy regularized multi-marginal optimal transport problem (1) on the same tree $\mathcal{T}$ and with the same regularization parameter ϵ is significantly sharper and less smoothed out, see Figure 1(c). For the pairwise optimal transport problem, the method diverges with a smaller regularization parameter, e.g., $\epsilon = 10^{-3}$. In contrast, for the multi-marginal formulation the regularization parameter can be decreased further, still yielding a numerically stable algorithm. We have found that the method is still stable for a regularization parameter of $\epsilon = 4 \cdot 10^{-4}$, which results in very clear estimates on the intermediate nodes.

Abstract: The splitting algorithms of monotone operator theory find zeros of sums of relations. This corresponds to solving series or parallel one-port electrical circuits, or the negative feedback interconnection of two subsystems. One-port circuits with series *and* parallel interconnections, or block diagrams with multiple forward and return paths, give rise to current-voltage relations consisting of nested sums *and inverses*. In this extended abstract, we present new splitting algorithms specially suited to these structures, for interconnections of monotone and anti-monotone relations.

Keywords: Scaled Relative Graph, Nyquist, loop shaping, robustness

1. INTRODUCTION

The mathematical property of *monotonicity* originated in the study of networks of nonlinear resistors (Duffin, 1946; Zarantonello, 1960; Dolph, 1961; Minty, 1960, 1961a,b). Monotonicity generalizes the concept of passivity from linear circuit theory; loosely speaking, an element is monotone if it is passive with respect to *any* possible reference trajectory. Following the influential paper of Rockafellar (1976), monotone operator theory has grown to become a pillar of large scale optimization theory (Bauschke and Combettes, 2011; Ryu and Yin, 2022; Parikh and Boyd, 2013; Bertsekas, 2011).

Central to this theory are the family of *splitting algorithms*. These algorithms find zeros of sums of monotone operators, and allow computation to be performed separately for each operator. Recent work by the authors has revisited the study of electrical networks using modern splitting algorithms (Chaffey and Sepulchre, 2021). The main idea is that finding a zero of the sum of two operators is equivalent to solving the port behavior of their parallel (or series) interconnection. In turn, this is equivalent to solving the behavior of the negative feedback interconnection of two elements. This observation motivates the development of splitting algorithms which match more general circuit architectures. In Section 4, we describe an algorithm which solves the behavior of arbitrary series/parallel one-port circuits.

While splitting methods require each circuit element to be monotone, similar ideas can be applied to *mixed monotone* circuits, consisting of port interconnections of monotone and anti-monotone elements. This significantly expands the possible types of circuit behavior, allowing, for example, relaxation oscillations (van der Pol, 1926) and neuronal excitability (FitzHugh, 1961). In (Das et al., 2021), the authors have adapted Difference of Convex Programming (Lipp and Boyd, 2016; Yuille and Rangarajan, 2003) to solve such behaviors. In Section 5, we describe a new splitting algorithm which matches the mixed feedback structure of oscillators such as the van der Pol and FitzHugh-Nagumo models.

While classical splitting methods deal only with sums, the algorithms we describe here deal with both sums and inverses - the two operations which constitute physical port interconnections. The algorithms described in this abstract form the basis for a more general class of splitting algorithms, which correspond to arbitrary interconnections of physical systems.

2. MONOTONE AND ANTI-MONOTONE RELATIONS

A Hilbert space $\mathcal{H}$ is a complete vector space equipped with an inner product, $\langle\cdot|\cdot\rangle : \mathcal{H}\times\mathcal{H}\to\mathbb{C}$, and an induced norm $\|x\| \coloneqq \sqrt{\langle x|x\rangle}$. In this abstract, we will treat general Hilbert spaces, although a common choice in practice is the space of square-summable, discrete time signals on $[0,T]$, denoted $l_{2,T}$.

An *operator* on $\mathcal{H}$, is a possibly multi-valued map $R:\mathcal{H}\to\mathcal{H}$. The identity operator, which maps $u\in\mathcal{X}$ to itself, is denoted by I. The domain of an operator R is denoted $\operatorname{dom} R$. The *graph*, or *relation*, of an operator, is the set $\{u,y \mid u\in\operatorname{dom} R, y\in R(u)\}\subseteq\mathcal{H}\times\mathcal{H}$. We use the notions of an operator and its relation interchangeably, and denote them in the same way.

The standard operations on functions can be extended to relations. Let R and S be relations on an arbitrary Hilbert space $\mathcal{H}$. Then:

$$S^{-1} = \{(y,u) \mid y\in S(u)\}$$
$$S+R = \{(x,y+z) \mid (x,y)\in S, (x,z)\in R\}$$
$$SR = \{(x,z) \mid \exists\, y \text{ s.t. } (x,y)\in R, (y,z)\in S\}.$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Note that S^{-1} always exists, but is not an inverse in the usual sense. In particular, in general $S^{-1}S \neq I$.

Definition 1. A relation $S \subseteq \mathcal{H} \times \mathcal{H}$ is called *monotone* if

$$\langle u_1 - u_2 | y_1 - y_2 \rangle \geq 0$$

for any $(u_1, y_1), (u_2, y_2) \in S$. A monotone relation is called *maximal* if it is not properly contained in any other monotone relation.

Definition 2. A relation $S : \mathcal{H} \to \mathcal{H}$ is *anti-monotone* if $-S$ is monotone.

3. SPLITTING TWO-ELEMENT CIRCUITS

There is a large body of literature on splitting algorithms, which solve problems of the form $0 \in M_1(u) + M_2(u)$, where M_1 and M_2 are maximal monotone relations. There is a direct analogy with electrical circuits: if M_1 and M_2 are resistances, their series interconnection is given by the relation $v = M_1(i) + M_2(i)$; if M_1 and M_2 are conductances, their parallel interconnection is given by $i = M_1(v) + M_2(v)$. Given a current, the corresponding voltage across a parallel interconnection can be found using a splitting algorithm, by solving $0 \in M_1(v) + M_2(v) - i$. Here, we briefly describe two splitting algorithms – the forward/backward splitting, and the Douglas-Rachford splitting. For the convergence properties of these algorithms, we refer the reader to (Giselsson and Moursi, 2019; Bauschke and Combettes, 2011; Ryu and Yin, 2022). Given an operator S and a scaling factor α, the α-resolvent of S is defined to be the operator

$$\operatorname{res}_{\alpha S} \coloneqq (I + \alpha S)^{-1}.$$

If S is maximal monotone, res_S is single-valued (Minty, 1961a).

3.1 Forward/backward splitting

The simplest splitting algorithm is the forward/backward splitting (Passty, 1979; Gabay, 1983; Tseng, 1988). Suppose M_1 and $\operatorname{res}_{\alpha M_2}$ are single-valued. Then:

$$\begin{aligned} & 0 \in M_1(x) + M_2(x) \\ \iff \quad & 0 \in x - \alpha M_1(x) - (x + \alpha M_2(x)) \\ \iff \quad & (I + \alpha M_2)x \ni (I - \alpha M_1)x \\ \iff \quad & x = \operatorname{res}_{\alpha M_2}(I - \alpha M_1)x. \end{aligned}$$

The fixed point iteration $x^{j+1} = \operatorname{res}_{\alpha M_2}(x^j - \alpha M_1(x^j))$ is the forward/backward splitting algorithm.

3.2 Douglas-Rachford splitting

The reflected resolvent, or Cayley operator, is the operator

$$R_{\alpha S} \coloneqq 2\operatorname{res}_{\alpha S} - I.$$

Given two operators M_1 and M_2, and a scaling factor α, the Douglas-Rachford algorithm (Douglas and Rachford, 1956; Lions and Mercier, 1979) is the iteration

$$\begin{aligned} z^{k+1} &= T(z^k), \\ x^k &= \operatorname{res}_{\alpha M_2}(z^k), \end{aligned}$$

where T is given by

$$T = \frac{1}{2}(I + R_{\alpha M_1} R_{\alpha M_2}). \tag{1}$$

4. SPLITTING N-ELEMENT CIRCUITS

If our circuit is composed of three elements, with one series interconnection and one parallel interconnection (Figure 1), it has the form $M = M_1 + (M_2 + M_3)^{-1}$. A naive approach to solving the behavior of this circuit is to use a splitting algorithm such as the forward/backward algorithm, with the resolvent step applied for M_1 and the forward step applied for $(M_2 + M_3)^{-1}$. Applying this forward step amounts to solving $v = (M_2 + M_3)^{-1}(i)$ for some u, which may be rewritten as $0 \in (M_2 + M_3)(v) - i$. This can be solved by again applying the forward/backward algorithm.

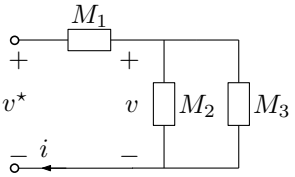

Fig. 1. Three elements with one series interconnection and one parallel interconnection.

This naive procedure has poor complexity: for every forward/backward step for $M_1 + (M_2 + M_3)^{-1}$, an *entire* fixed point iteration has to be computed for (an offset version of) $M_2 + M_3$. In (Chaffey and Sepulchre, 2021), we propose an alternative procedure for n-element circuits. Here, we sketch this procedure on the circuit of Figure 1. Rather than apply a forward step for the relation $(M_2 + M_3)^{-1}$, we simply apply a *single step* of the fixed point iteration needed to compute this forward step, using the forward/backward algorithm. Given $v^\star$, we want to solve $0 \in (M_1 + (M_2 + M_3)^{-1})(i) - v^\star$. Assume that M_3, $\operatorname{res}_{\alpha_1 M_2}$ and $\operatorname{res}_{\alpha_2 M_1}$ are single-valued. We then have:

$$v^\star \in v + M_1(i) \tag{2}$$

$$v \in (M_2 + M_3)^{-1}(i), \tag{3}$$

where v is the voltage over M_2, illustrated in Figure 1. Equation (2) gives

$$\begin{aligned} i + \alpha_2 M_1(i) &\ni i - \alpha_2 v + \alpha_2 v^\star \\ i &= (I + \alpha_2 M_1)^{-1}(i - \alpha_2 v + \alpha_2 v^\star) \\ i &= \operatorname{res}_{\alpha_2 M_1}(i - \alpha_2 v + \alpha_2 v^\star). \end{aligned}$$

Equation (3) gives

$$\begin{aligned} i &\in (M_2 + M_3)(v) \\ v + \alpha_1 M_2(v) &\ni v - \alpha_1 M_3(v) + \alpha_1 i \\ v &= (I + \alpha_1 M_2)^{-1}(v - \alpha_1 M_3(v) + \alpha_1 i) \\ v &= \operatorname{res}_{\alpha_1 M_2}(v - \alpha_1 M_3(v) + \alpha_1 i). \end{aligned}$$

This shows that a fixed point of the iteration

$$\begin{aligned} v^{k+1} &= \operatorname{res}_{\alpha_1 M_2}(v^k - \alpha_1 M_3(v^k) + \alpha_1 i^k) \\ i^{k+1} &= \operatorname{res}_{\alpha_2 M_1}(i^k - \alpha_2 v^{k+1} + \alpha_2 v^\star) \end{aligned}$$

is a solution to our original problem $0 \in (M_1 + (M_2 + M_3)^{-1})(i) - v^\star$.

5. SPLITTING THE DIFFERENCE

A mixture of positive and negative feedback is a ubiquitous mechanism, in both biology and engineering, for the generation of switches and oscillations (Sepulchre et al., 2019; Sepulchre and Stan, 2005; Stan et al., 2007; Stan and Sepulchre, 2007; Chua et al., 1987). Again adopting the

analogy of electrical circuits, such feedback systems can be thought of as the parallel interconnection of three elements (Figure 2) - the forward path and the negative feedback path, which we assume to be monotone, and the positive feedback path, which we assume to be anti-monotone. Such a structure encompasses systems such as the van der Pol and FitzHugh-Nagumo oscillators. For example, the van der Pol oscillator is given by $A_1(s) = (s^2+1)/s$, $A_2(v) = \mu v^3/3$ and $B(v) = \mu v$ (where s is the Laplace variable) (Das et al., 2021).

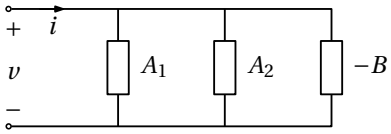

Fig. 2. A parallel mixed monotone circuit, which is a prototype structure for systems such as the van der Pol and FitzHugh-Nagumo oscillators.

Given the mixed monotone structure of Figure 2, we can find the steady state behavior of the system by solving a zero-finding problem: $0 \in A_1(v) + A_2(v) - B(v) - i$.

The authors have explored methods to solve these problems using an adaptation of Difference of Convex Programming in (Das et al., 2021). The method involves iterating the operator $(A_1 + A_2)^{-1}B$. Computing $(A_1 + A_2)^{-1}$ at every iteration is an expensive operation; in this section, we propose the *mixed monotone Douglas-Rachford algorithm* (Algorithm 7), which replaces $(A_1 + A_2)^{-1}$ with a single step of the Douglas-Rachford iteration needed to invert it.

For operators A_1 and A_2 and step size α, we define $T_\alpha(A_1, A_2)$ to be the Douglas-Rachford operator:

$$T_\alpha(A_1, A_2) = \frac{1}{2}(I + R_{\alpha A_1} R_{\alpha A_2}). \tag{4}$$

Recall that $R_{\alpha S}$ denotes the Cayley operator $2\mathrm{res}_{\alpha S} - I$.

Algorithm 1 Mixed-Monotone Douglas-Rachford

1: **Data:** Maximal monotone A_1, A_2. Monotone, single-valued B. Initial value x_1. Convergence tolerance $\varepsilon > 0$.
2: Define A_1^j by $x \mapsto A_1(x) - y_j$ for all j.
3: $j = 1$
4: **do**
5: Solve

$$x_{j+1} = \mathrm{res}_{\alpha A_2}(z_j)$$
$$y_{j+1} = B(x_{j+1})$$
$$z_{j+1} = T_\alpha(A_1^{j+1}, A_2 a)(z_j).$$

6: $j = j + 1$.
7: **while** $|x_{j+1} - x_j| > \varepsilon$

Note that a fixed point of this algorithm is a solution to $0 \in A_1(x) + A_2(x) - B(x)$: we know, by convergence of the Douglas-Rachford algorithm, that x is a solution to $0 \in A_1^j(x) + A_2(x)$, which is equal to $A_1(x) + A_2(x) - B(x)$ at a fixed point. (Chaffey, 2022, Thm. 4.1) gives a convergence condition for this algorithm. Figure 3 shows steady-state solutions to the van der Pol oscillator computed with Algorithm 7. For further details of the implementation, the reader is referred to (Chaffey, 2022, Example 4.3).

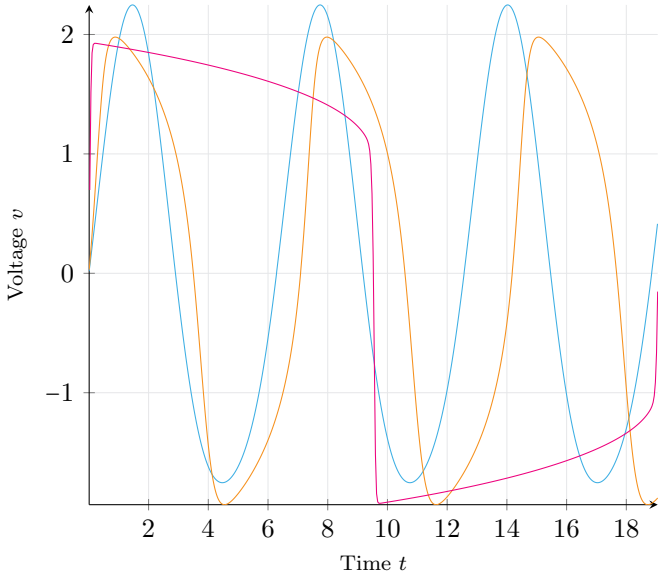

Fig. 3. Steady-state solutions to the van der Pol oscillator for $\mu = 0.0002$ (blue), 1.5 (orange) and 10 (red). Algorithmic parameters are a step size of $\alpha = 0.05$, convergence tolerance of $\varepsilon = 0.01$ and 5000 time steps.

Combining the SOS and SONC cones - A Hilbert's 1888 Theorem analogue and further separation results

Moritz Schick *

* *University of Konstanz, Konstanz, Germany (e-mail: moritz.schick@uni-konstanz.de).*

Abstract: Studying convex cones inside the cone of positive semidefinite (PSD) polynomials is an important field of research in real algebraic geometry and polynomial optimization. In this work, we combine two such well established cones, which are sums of squares (SOS) and sums of nonnegative circuit polynomials (SONC) and consider PSD polynomials, that decompose into an SOS and a SONC part. We call the resulting set the SOS+SONC cone. For this newly established cone, we prove two separation results. The first one is an analogue to Hilbert's 1888 Theorem for the SOS+SONC cone. The second one shows that whenever the SOS and SONC cones are proper subsets of the PSD cone, they are also proper subsets of the SOS+SONC cone.

Keywords: sums of squares, sums of nonnegative circuit polynomials, Hilbert's 1888 Theorem, polynomial optimization

1. INTRODUCTION

Minimizing a given real, multivariate polynomial $f \in \mathbb{R}[\mathbf{x}]$ is the central challenge of polynomial optimization. The importance of this topic can be seen in the variety of applications in different fields such as optimal control, mathematical finance and real-time decision making. It is well known that polynomial optimization can equivalently be viewed as the problem of deciding nonnegativity of real polynomials. This equivalence is of central meaning in real algebraic geometry since convex geometric tools can be used to obtain a deeper understanding of the set of nonnegative polynomials.

The relevance of a theoretical study of both problems is also stressed by the fact that both polynomial optimization and deciding nonnegativity of real polynomials are in general NP-hard even for low dimensional cases. Hence, one is often interested in solving easier problems instead, often involving trade offs between feasibility and preciseness of solutions. In this work we follow the real algebraic geometric approach of taking suitable inner approximations of the set of nonnegative polynomials.

A first inner approximation of the cone of nonnegative polynomials are *sums of squares (SOS)*, which have a long history in Mathematics and go back to Hilbert's seminal work in Hilbert (1888). The SOS approach has proven to be a powerful tool for solving a vast number of optimization problems, see see e.g. Lasserre (2009) for more details. However, it has its limitations especially in high degree and high number of variables cases.

A second approximation which has gained a lot of interest in recent years are *sums of nonnegative circuit (SONC) polynomials*, which were first introduced by Iliman and de Wolff (2016). The sparse structure of this class of polynomials allows to solve large problems, where the SOS approach has its difficulties. However, since the SONC approach is relatively new, it is only fully developed for special classes of polynomials, having e.g. simplex Newton polytopes. Indeed, there are different types of conic programming using SONC for polynomial optimization, see e.g. Wang and Magron (2020) and Dressler et al. (2020).

Dressler (2018) pointed out that if it would be possible to combine the two approaches and use the best of both worlds, one would get a new approximation which is at least as good as the single approaches themselves.

In terms of polynomial optimization, let $f \in \mathbb{R}[\mathbf{x}]$ and consider the global polynomial optimization problem $f^* = \inf_{x\in\mathbb{R}^n} f(x) = \sup\{\lambda \in \mathbb{R} : f - \lambda \geq 0 \text{ on } \mathbb{R}^n\}$. Let SOS and SONC denote the sets of SOS and SONC polynomials, respectively. Then, lower bounds on f^* can be achieved via $f_{\text{SOS}} := \sup\{\lambda \in \mathbb{R} : f - \lambda \in \text{SOS}\}$ and $f_{\text{SONC}} := \sup\{\lambda \in \mathbb{R} : f - \lambda \in \text{SONC}\}$. Taking the Minkowski sum $\text{SOS} + \text{SONC}$ leads to a third lower bound $f_{\text{SOS+SONC}} := f_{\text{SOS}+\text{SONC}} := \sup\{\lambda \in \mathbb{R} : f - \lambda \in \text{SOS} + \text{SONC}\}$ which satisfies $f_{\text{SOS}}, f_{\text{SONC}} \leq f_{\text{SOS+SONC}} \leq f^*$.

In this work, we fully characterize the numbers of variables and degrees of polynomials for which the above's inequalities are strict. Therefore, we formally introduce the cone of sums of squares and nonnegative polynomials (SOS+SONC) and present explicit examples of polynomials separating this cone from the SOS and SONC cones as well as the cone of positive semidefinite polynomials.

2. PRELIMINARIES

2.1 Notations

Let $\mathbb{N} := \{1, 2, 3, \ldots\}$ and $\mathbb{N}_0 := \mathbb{N} \cup \{0\}$ be the sets of positive and nonnegative integers, respectively and $[m] := \{1, \ldots, m\}$ $(m \in \mathbb{N})$. For $n \in \mathbb{N}$ let $\mathbb{R}[\mathbf{x}] := \mathbb{R}[\mathrm{x}_1, \ldots, \mathrm{x}_n]$

be the polynomial ring over $\mathbb{R}$ in n variables. The integer $n \in \mathbb{N}$ will be fixed throughout this work.

A polynomial $f \in \mathbb{R}[\mathbf{x}]$ with all monomials having the same degree $k \in \mathbb{N}$ is called *homogeneous* or a *form*. For $k \in \mathbb{N}$ we denote by $H_{n,k}$ the finite dimensional vector space of n-variate, homogeneous polynomials of degree k. For $f \in \mathbb{R}[\mathbf{x}]$, we write $\operatorname{supp}(f)$ for the *support* and $\operatorname{New}(f)$ for the *Newton polytope* of f, i.e. $\operatorname{New}(f) = \operatorname{conv}(\operatorname{supp}(f))$, where $\operatorname{conv}(S)$ is the *convex hull* of a set S. For an arbitrary polytope $\Delta \subseteq \mathbb{R}^n$, we denote its set of *vertices* by $V(\Delta)$. If $\Delta = \operatorname{New}(f)$ is the Newton polytope of a polynomial f, we also write $V(f) := V(\operatorname{New}(f))$. For $\alpha \in \mathbb{N}_0^n$ and $f \in \mathbb{R}[\mathbf{x}]$, we denote by f_α the coefficient of f corresponding to x^α, i.e. $f = \sum_{\alpha \in \mathbb{N}_0^n} f_\alpha \mathrm{x}^\alpha$ and $f_\alpha = 0$ if $\alpha \notin \operatorname{supp}(f)$.

2.2 Young's Inequality

The following Theorem is essential for proofs in Section 3.

Young's Inequality Let $1 < p, q < \infty$ be s.t. $1/p + 1/q = 1$. Further, let $a, b \in \mathbb{R}$ be arbitrary. Then $ab \leq \frac{|a|^p}{p} + \frac{|b|^q}{q}$. Further, for $a, b \geq 0$ equality holds if and only if $a^p = b^q$.

2.3 Positive Semidefinite (PSD) Polynomials

A polynomial $f \in \mathbb{R}[\mathbf{x}]$ is *positive semidefinite (PSD)* if $f(x) \geq 0$ for all $x \in \mathbb{R}^n$. Clearly, a PSD polynomial must have even degree. Therefore, an even integer $2d \in 2\mathbb{N}$ will be fixed throughout this work.

We denote by

$$P_{n,2d} := \{f \in H_{n,2d} : f \geq 0 \text{ on } \mathbb{R}^n\}$$

the set of PSD forms of degree $2d$. It is well known that $P_{n,2d}$ is a closed, convex cone in the vector space $H_{n,2d}$.

2.4 Sum of Squares (SOS) Polynomials

A polynomial $f \in \mathbb{R}[\mathbf{x}]$ is a *sum of squares (SOS)* if it admits a decomposition of the form $f = \sum_{i=1}^s f_i^2$ such that $s \in \mathbb{N}$, $f_i \in \mathbb{R}[\mathbf{x}]$ $(i \in [s])$. The set of SOS forms of degree $2d$ is denoted by

$$\Sigma_{n,2d} := \left\{ f = \sum_{i=1}^s f_i^2 : f_i \in \mathbb{R}[\mathbf{x}]_{\leq d}, s \in \mathbb{N} \right\}.$$

Similar as the PSD cone, $\Sigma_{n,2d}$ forms a closed, convex cone inside $P_{n,2d}$.

The following theorem characterizes precisely the cases of $(n, 2d)$ for which the PSD and SOS cones coincide. It goes back to Hilbert's work Hilbert (1888).

Hilbert 1888 It holds $\Sigma_{n,2d} = P_{n,2d}$ if and only if $n = 2$ or $2d = 2$ or $(n, 2d) = (3, 4)$.

2.5 Sums of Nonnegative Circuit (SONC) Polynomials

A polynomial $f = \sum_{i=1}^m c_i \underline{\mathrm{x}}^{\alpha(i)} + b\underline{\mathrm{x}}^\beta \in \mathbb{R}[\mathbf{x}]$ where $m \in \mathbb{N}$, $\alpha(1), \ldots, \alpha(m)$, $\beta \in \mathbb{N}_0^n$ and $c_1, \ldots, c_m, b \in \mathbb{R}$ is a *circuit polynomial* if it satisfies the following conditions:

(C1) The lattice points $\alpha(1), \ldots, \alpha(m)$ are even, i.e. $\alpha(1), \ldots, \alpha(m) \in (2\mathbb{N}_0)^n$ and affinely independent.
(C2) The coefficients c_i corresponding to the $\alpha(i)$ are positive, i.e. $c_i > 0$ for $i = 1, \ldots, m$.
(C3) The exponent β lies in the interior of the Newton polytope of f.

The monomials $c_i \mathrm{x}^{\alpha(i)}$ $(i = 1, \ldots, m)$ are called *vertex monomials*. In addition, if $b \neq 0$ the monomial $b\mathrm{x}^\beta$ is called *interior monomial*. The set of circuit polynomials supported on $A \subseteq \mathbb{N}_0^n$ is denoted by $\operatorname{Circ}_A \subseteq \mathbb{R}[\underline{\mathrm{x}}]$.

A polynomial $f \in \mathbb{R}[\mathbf{x}]$ is a *sum of nonnegative circuit polynomials (SONC)* if it admits a decomposition of the form $f = \sum_{i=1}^s f_i$ where $s \in \mathbb{N}$ and every f_i is a nonnegative circuit polynomial. We denote by

$$C_{n,2d} := \left\{ f = \sum_{i=1}^s f_i : f_i \in \operatorname{Circ}_{A_i} \cap P_{n,2d}, A_i \subseteq \mathbb{N}_0^n \right\}$$

the set of SONC polynomials of degree at most $2d$. Again, $C_{n,2d}$ is a closed, convex cone inside $P_{n,2d}$.

The following Theorem shows that $C_{n,2d}$ is an inner approximation of $P_{n,2d}$, which is independent of $\Sigma_{n,2d}$. It is a combination of results in (Iliman and de Wolff, 2016, Prop. 7.2) and (Dressler, 2018, Thm. 3.1.2)

Theorem The SONC cone $C_{n,2d}$ satisfies:

(1.) $C_{n,2d} \subseteq \Sigma_{n,2d}$ if and only if $n = 2$ or $2d = 2$ or $(n, 2d) = (3, 4)$.
(2.) $C_{2,2} = \Sigma_{2,2}$ and $\Sigma_{n,2} \not\subseteq C_{n,2}$ for all $n \geq 3$.
(3.) $\Sigma_{n,2d} \not\subseteq C_{n,2d}$ for all $(n, 2d)$ with $2d \geq 4$.

2.6 The combined cone SOS+SONC of sums of squares and nonnegative circuit polynomials

A polynomial $f \in \mathbb{R}[\mathbf{x}]$ is said to be a *sum of squares and nonnegative circuit polynomials (SOS+SONC)* if it has a decomposition of the form $f = g + h$ for some $f \in \Sigma_{n,2d}, g \in C_{n,2d}$. Further, we denote by

$$(\Sigma + C)_{n,2d} := \Sigma_{n,2d} + C_{n,2d}$$

the set of SOS+SONC forms in n variables of degree $2d$.

3. SEPARATING THE PSD CONE FROM THE SOS+SONC CONE - A SOS+SONC ANALOGUE TO HILBERT'S 1888 THEOREM

As in *Hilbert 1888* for the SOS case and the theorem of Section 2.5 for the SONC case, it is of interest to find separation results, which classify whenever a given inner approximation of the PSD cone is proper or not. Therefore, we show in Theorem 1 an analogue to *Hilbert 1888* for the SOS+SONC case. The following statement was already proven in a non constructive way in (Averkov, 2019, Corollary 2.17). As a contribution we present an alternative proof by constructing appropriate polynomials in the two basic cases $((n, 2d) \in \{(3, 6), (4, 4)\})$ and scaling them to higher dimensional and number of variables cases.

Theorem 1. It holds $(\Sigma + C)_{n,2d} = P_{n,2d}$ if and only if $n = 2$ or $2d = 2$ or $(n, 2d) = (3, 4)$.

As a first step, we show that it suffices to consider the two elementary cases of ternary sextics and quarternary quartics, i.e. $(n, 2d) \in \{(3, 6), (4, 4)\}$.

Lemma 2. If $(\Sigma+C)_{3,6} \subsetneq P_{3,6}$ and $(\Sigma+C)_{4,4} \subsetneq P_{4,4}$ then $(\Sigma_{n,k}+C)_{n,k} \subsetneq P_{n,k}$ for all $n \geq 3, k \geq 4$ and $(n,k) \neq (3,4)$ (k even).

Proof. We show equivalently: $P_{3,6}\backslash(\Sigma + C)_{3,6} \neq \emptyset$ and $P_{4,4}\backslash(\Sigma + C)_{4,4} \neq \emptyset$ imply $P_{n,k}\backslash(\Sigma + C)_{n,k} \neq \emptyset$ for all $n \geq 3, k \geq 4$ and $(n,k) \neq (3,4)$ where k is even.

Claim 1: $f \in P_{n,k}\backslash(\Sigma + C)_{n,k}$ implies for all $m \in \mathbb{N}$, $f \in P_{n+m,k}\backslash(\Sigma + C)_{n+m,k}$.

The case $m = 1$ can be seen easily, since SOS and SONC polynomials in $H_{n+1,k}$ stay SOS and SONC, respectively, after plugging in $\mathrm{x}_{n+1} = 0$. The general case follows inductively.

Claim 2: $f \in P_{n,k}\backslash(\Sigma + C)_{n,k}$ implies for all $\ell \in \mathbb{N}$ $\mathrm{x}_1^{2\ell} f \in P_{n,k+2\ell}\backslash(\Sigma + C)_{n,k+2\ell}$.

Consider $\ell = 1$ and let $f \in P_{n,k}\backslash(\Sigma + C)_{n,k}$ be arbitrary. Assume that $\mathrm{x}_1^2 f \in (\Sigma + C)_{n,k+2}$, i.e. there is a decomposition $\mathrm{x}_1^2 f = f_{\mathrm{SOS}} + f_{\mathrm{SONC}}$ with f_{SOS} and f_{SONC} being SOS and SONC polynomials in $H_{n,k+2}$, respectively. Since the left hand side vanishes at $\mathrm{x}_1 = 0$, the right hand side must vanish at $\mathrm{x}_1 = 0$ as well. Since $f_{\mathrm{SOS}}, f_{\mathrm{SONC}}$ are PSD, we obtain $f_{\mathrm{SOS}}(0, \mathrm{x}_2, \ldots, \mathrm{x}_n) = 0 = f_{\mathrm{SONC}}(0, \mathrm{x}_2, \ldots, \mathrm{x}_n)$. Hence $\mathrm{x}_1 \mid f_{\mathrm{SOS}}, f_{\mathrm{SONC}}$, i.e. $f_{\mathrm{SOS}} = \mathrm{x}_1 \cdot f_1, f_{\mathrm{SONC}} = \mathrm{x}_1 \cdot f_2$ for some $f_1, f_2 \in H_{n,k+1}$.

Write $f_{\mathrm{SOS}} = \sum_{i=1}^s g_i^2$, $f_{\mathrm{SONC}} = \sum_{j=1}^t h_j, s, t \in \mathbb{N}$ s.t. $g_i \in H_{n,k/2+1}$ and the h_j are nonnegative circuit polynomials. Similary as above, PSDness of g_i^2 and h_j yields $\mathrm{x}_1 \mid g_i^2, h_j$. For the SOS part, we immediately obtain $\mathrm{x}_1 \mid g_i$, i.e. $\mathrm{x}_1^2 \mid f_{\mathrm{SOS}}$. Remains to show $\mathrm{x}_1^2 \mid h_j$ for all j. However, this follows since all monomials of h_j must be divisible by x_1, all vertex monomials of x_1 are even lattice points and the only interior monomial is a convex combination of the vertex monomials. Hence we have $\mathrm{x}_1^2 \mid f_{\mathrm{SOS}}, f_{\mathrm{SONC}}$, which yields that $f = f_{\mathrm{SOS}}/\mathrm{x}_1^2 + f_{\mathrm{SONC}}/\mathrm{x}_1^2$ would be a SOS+SONC decomposition in $H_{n,k}$, a contradiction. This shows Claim 2 for $\ell = 1$. The general case follows inductively.

Combining Claim 1 and Claim 2 shows the Lemma.

Next, we cover the two elementary cases where $(n, 2d) \in \{(3,6),(4,4)\}$. Therefore, we show that the two Robinson forms from Robinson (1969) are indeed PSD but not SOS+SONC.

Lemma 3. It holds

$$\begin{aligned} R_1(\mathrm{x},\mathrm{y},\mathrm{z}) =& \mathrm{x}^6 + \mathrm{y}^6 + \mathrm{z}^6 - \left(\mathrm{x}^4\mathrm{y}^2 + \mathrm{x}^4\mathrm{z}^2 + \mathrm{y}^4\mathrm{x}^2 + \mathrm{y}^4\mathrm{z}^2\right. \\ &\left. + \mathrm{z}^4\mathrm{x}^2 + \mathrm{z}^4\mathrm{y}^2\right) + 3\mathrm{x}^2\mathrm{y}^2\mathrm{z}^2 \in P_{3,6}\backslash(\Sigma + C)_{3,6} \end{aligned}$$

and hence $P_{3,6} \neq (\Sigma + C)_{3,6}$.

Proof. Step 1: Assume that $R_1 \in (\Sigma + C)_{3,6}$ was SOS+SONC. Choose an SOS polynomial $f_{\mathrm{SOS}} \in \Sigma_{3,6}$ such that $R_1 - f_{\mathrm{SOS}} \in C_{3,6}$ is a SONC polynomial. Without loss of generality we can assume that $R_1 - f_{\mathrm{SOS}}$ decomposes into nonnegative circuit polynomials, which are not SOS. Since $R_1 = f_{\mathrm{SOS}} + (R_1 - f_{\mathrm{SOS}})$ is a decomposition into PSD polynomials, $\mathrm{New}(f_{\mathrm{SOS}})$, $\mathrm{New}(R_1 - f_{\mathrm{SOS}}) \subseteq \mathrm{New}(R_1)$ must hold (cf. (Reznick, 1978, Theorem 1)).

Step 2: By *Hilbert 1888*, we know that every PSD bivariate form is SOS, i.e. $P_{2,2d} = \Sigma_{2,2d}$ for all $d \in \mathbb{N}$. Now consider e.g. the monomial $m = \mathrm{x}^4\mathrm{y}^2$. Assume that the SONC part $R_1 - f_{\mathrm{SOS}}$ contains a nonnegative circuit polynomial h having m as interior monomial, i.e. $h_{(4,2,0)'} \lneq 0$. But then, since m is in the interior of $\mathrm{New}(h)$, the circuit polynomial h must clearly be bivariate, i.e. $h \in C_{2,6} \subseteq P_{2,6} = \Sigma_{2,6}$. This contradicts our assumption that no nonnegative circuit polynomial in $R_1 - f_{\mathrm{SOS}}$ is also SOS. Hence, m cannot be an interior monomial of any nonnegative circuit polynomials in the decomposition of $R_1 - f_{\mathrm{SOS}}$, which shows that $(R_1 - f_{\mathrm{SOS}})_{(4,2,0)'} \geq 0$ and equivalently $(f_{\mathrm{SOS}})_{(4,2,0)'} \leq -1$. Analogous argumentation shows

$$\left.\begin{matrix}(f_{\mathrm{SOS}})_{(4,2,0)'},\ (f_{\mathrm{SOS}})_{(4,0,2)'},\ (f_{\mathrm{SOS}})_{(2,4,0)'},\\ (f_{\mathrm{SOS}})_{(2,0,4)'},\ (f_{\mathrm{SOS}})_{(0,4,2)'},\ (f_{\mathrm{SOS}})_{(0,2,4)'}\end{matrix}\right\} \leq -1 \quad (1)$$

This yields in particular $\mathrm{x}^6, \mathrm{y}^6, \mathrm{z}^6 \in \mathrm{New}(f_{\mathrm{SOS}})$ and hence $\mathrm{New}(f_{\mathrm{SOS}}) = \mathrm{New}(R_1)$.

Step 3: Write $f_{\mathrm{SOS}} = \sum_{i=1}^s g_i^2$ s.t. $g_i \in H_{3,3}$, $s \in \mathbb{N}$. Since $\mathrm{New}(g_i) \subseteq \frac{1}{2}\mathrm{New}(f_{\mathrm{SOS}}) = \frac{1}{2}\mathrm{New}(R_1) = \mathrm{conv}(\mathrm{x}^3, \mathrm{y}^3, \mathrm{z}^3)$, all possible exponents of the g_i's are given by

$$\begin{aligned} &\alpha(1) = (3,0,0)',\ \alpha(2) = (2,1,0)',\ \alpha(3) = (2,0,1')),\\ &\alpha(4) = (1,2,0)',\ \alpha(5) = (1,1,1)',\ \alpha(6) = (1,0,2)',\\ &\alpha(7) = (0,3,0)',\ \alpha(8) = (0,2,1)',\ \alpha(9) = (0,1,2)^2,\\ &\alpha(10) = (0,0,3)' \end{aligned}$$

and we can write $g_i = \sum_{j=1}^{10} g_{ij}\mathrm{x}^{\alpha(j)}$ $(i = 1, \ldots, s)$, for some $g_{ij} \in \mathbb{R}$.

Step 4: By (1) and the decomposition of $f_{\mathrm{SOS}} = \sum_{i=1}^s g_i^2$, we know $-1 \geq (f_{\mathrm{SOS}})_{(4,2,0)'} = \sum_{i=1}^s g_{i,2}^2 + \sum_{i=1}^s 2g_{i,1}g_{i,4}$. Hence, using Young's inequality we obtain

$$\begin{aligned} -1 \geq (f_{\mathrm{SOS}})_{(4,2,0)'} &= \sum_{i=1}^s g_{i,2}^2 + \sum_{i=1}^s 2g_{i,1}g_{i,4} \\ &\geq \sum_{i=1}^s g_{i,2}^2 - \sum_{i=1}^s 2\,|g_{i,1}| \cdot |g_{i,4}| \\ &\geq \sum_{i=1}^s g_{i,2}^2 - \sum_{i=1}^s g_{i,1}^2 - \sum_{i=1}^s g_{i,4}^2 \\ &\geq -1 + \sum_{i=1}^s g_{i,2}^2 - \sum_{i=1}^s g_{i,4}^2, \end{aligned} \quad (2)$$

where we used that $(f_{\mathrm{SOS}})_{(6,0,0)'} = \sum_{i=1}^s g_{i,1}^2 \leq 1$ must hold. Rearranging (2) yields $\sum_{i=1}^s g_{i,2}^2 \leq \sum_{i=1}^s g_{i,4}^2$.

Analogous argumentation shows that e.g.

$$\begin{aligned} -1 \geq (f_{\mathrm{SOS}})_{(2,4,0)} &= \sum_{i=1}^s g_{i,4}^2 + \sum_{i=1}^s 2g_{i,7}g_{i,2} \\ &\geq \cdots \geq -1 + \sum_{i=1}^s g_{i,4}^2 - \sum_{i=1}^s g_{i,2}^2 \end{aligned}$$

and therefore $\sum_{i=1}^s g_{i,2}^2 \geq \sum_{i=1}^s g_{i,4}^2$. We finally obtain the equality $\sum_{i=1}^s g_{i,2}^2 = \sum_{i=1}^s g_{i,4}^2$. Hence, equality must hold everywhere in (2), which shows:

(III) $(f_{\mathrm{SOS}})'_{(6,0,0)} = \sum_{i=1}^s g_{i,1}^2 = -1$.
(IV) By Young's Inequality: $g_{i,1} \neq 0$ if and only if $g_{i,4} \neq 0$ and in this case $|g_{i,1}| = |g_{i,4}|$ $(i \in [s])$.
(V) $\mathrm{sign}(g_{i,1}) = -\mathrm{sign}(g_{i,4})$ $(i \in [s])$.
(VI) $(f_{\mathrm{SOS}})_{(4,2,0)'} = -1$.

Clearly, similar observations as in (III)-(V) can be made for all pairs $(g_{i,r}, g_{i,s})$ s.t. $(r,s) \in \{(1,4),(1,6),(7,2),(7,9),(10,3),(10,8)\}$. In addition, as in (VI), we obtain for the other coefficients as in (1):

$$(f_{\text{SOS}})_{(4,2,0)'} = (f_{\text{SOS}})_{(4,0,2)'} = \ldots = -1. \tag{3}$$

Step 5: By (3), we have

$$(R_1 - f_{\text{SOS}})_{(4,2,0)'} = (R_1 - f_{\text{SOS}})_{(4,0,2)'} = \ldots = 0.$$

Furthermore, (III) for all possible coefficients leads to

$$\begin{aligned}&(R_1 - f_{\text{SOS}})_{(6,0,0)'} = (R_1 - f_{\text{SOS}})_{(0,6,0)'}\\ =&(R_1 - f_{\text{SOS}})_{(0,0,6)'} = 0.\end{aligned}$$

To sum up, we now have x^6, y^6, z^6, $\mathrm{x}^4\mathrm{y}^2$, $\mathrm{x}^4\mathrm{z}^2, \mathrm{x}^2\mathrm{y}^4$, $\mathrm{x}^2\mathrm{z}^4$, $\mathrm{y}^4\mathrm{z}^2, \mathrm{y}^2\mathrm{z}^4 \notin \operatorname{supp}(R_1 - f_{\text{SOS}})$. However, the form $R_1 - f_{\text{SOS}}$ is SONC and in particular PSD. Hence all vertices in $V(R_1 - f_{\text{SOS}})$ are even. Since $\operatorname{New}(R_1 - f_{\text{SOS}}) \subseteq \operatorname{New}(R_1)$, the only possible lattice point left is $\mathrm{x}^2\mathrm{y}^2\mathrm{z}^2$. Hence, $\operatorname{New}(R_1 - f_{\text{SOS}}) \subseteq \operatorname{conv}(\mathrm{x}^2\mathrm{y}^2\mathrm{z}^2) = \{\mathrm{x}^2\mathrm{y}^2\mathrm{z}^2\}$ must hold and $R_1 - f_{\text{SOS}}$ would be SOS, which is a contradiction.

For the quarternary quartics case, we can argue similarly.

Lemma 4. It holds $P_{4,4} \neq (\Sigma + C)_{4,4}$. More precisely, we have

$$\begin{aligned}R_2(\mathrm{x},\mathrm{y},\mathrm{z},\mathrm{w}) = &\,\mathrm{x}^2(\mathrm{x}-\mathrm{w})^2 + \mathrm{y}^2(\mathrm{y}-\mathrm{w})^2 + \mathrm{z}^2(\mathrm{z}-\mathrm{w})^2\\ &+ 2\mathrm{xyz}(\mathrm{x}+\mathrm{y}+\mathrm{z}-2\mathrm{w}) \in P_{4,4}\backslash(\Sigma + C)_{4,4}.\end{aligned}$$

Proof. The proof follows an analogous argumentation as in Lemma 3. By *Hilbert 1888*, we can without loss of generality choose $f_{\text{SOS}} \in \Sigma_{4,4}$ s.t. $R_2 - f_{\text{SOS}} \in C_{4,4}$ is SONC and does not contain any nonnegative circuit polynomial in three variables in its decomposition. It can be deduced that $\operatorname{New}(f_{\text{SOS}}) = \operatorname{New}(R_2)$ must hold.

Further, using Young's inequality for the coefficients of $\mathrm{x}^3\mathrm{w}$, $\mathrm{y}^3\mathrm{w}$, $\mathrm{z}^3\mathrm{w}$ it can be seen that

$$\mathrm{x}^4,\ \mathrm{x}^2\mathrm{w}^2,\ \mathrm{y}^4,\ \mathrm{y}^2\mathrm{w}^2,\ \mathrm{z}^4,\ \mathrm{z}^2\mathrm{w}^2 \notin \operatorname{supp}(R_2 - f_{\text{SOS}}).$$

Hence, the only even exponents in $\operatorname{supp}(R_2)$ left as possible lattice points for $R_2 - f_{\text{SOS}}$ are $\mathrm{x}^2\mathrm{y}^2$, $\mathrm{x}^2\mathrm{z}^2$, $\mathrm{y}^2\mathrm{z}^2$. However, this means that $R_2 - f_{\text{SOS}}$ is a PSD form in three variables of degree four, which is SOS by *Hilbert 1888*. Hence, R_2 is SOS as well, which is a contradiction. For this reason, R_2 cannot be SOS+SONC.

We are now able to prove Theorem 1.

Proof. [Theorem 1.] "$\Leftarrow$" is clear by *Hilbert 1888*.

"$\Rightarrow$": The Robinson polynomials from Lemma 3 and Lemma 4 are examples of polynomials in $P_{3,6}\backslash(\Sigma + C)_{3,6}$ and $P_{4,4}\backslash(\Sigma + C)_{4,4}$, respectively. Hence, the claim follows directly from Lemma 2.

4. SEPARATING THE SOS+SONC CONE FROM THE SOS AND SONC CONE

In this section, we present a theorem which shows that the SOS+SONC cone is a proper cone extension of both the SOS and the SONC cones for all $(n,2d) \geq (3,4), (n,2d) \neq (3,4)$. This shows that for all nontrivial $(n,2d)$, the SOS+SONC cone is a better inner approximation of the PSD cone than the single SOS and SONC cones.

Theorem 5. For all $(n,2d) \geq (3,4), (n,2d) \neq (3,4)$ it holds

$$(\Sigma + C)_{n,2d} \not\subseteq (\Sigma_{n,2d} \cup C_{n,2d})\,.$$

Proof. Similarly as in Lemma 2 one can show that it suffices to consider the cases $(n,2d) \in \{(3,6),(4,4)\}$. Hence, the claim follows by constructing explicit examples for the two elementary cases. Indeed, we have e.g.

$$\begin{aligned}f_1 =&\,\mathrm{x}^4\mathrm{y}^2 + \mathrm{x}^2\mathrm{y}^4 + \mathrm{z}^6 - 3\mathrm{x}^2\mathrm{y}^2\mathrm{z}^2\\ &+ {}^1\!/_2 \cdot (\mathrm{z}^3 + 2\mathrm{xyz} + \mathrm{x}^2\mathrm{y})^2 \in (\Sigma + C)_{3,6}\backslash(\Sigma \cup C)_{3,6},\\ f_2 =&\,\mathrm{x}^2\mathrm{y}^2 + \mathrm{x}^2\mathrm{z}^2 + \mathrm{y}^2\mathrm{z}^2 + \mathrm{w}^4 - 4\mathrm{wxyz}\\ &+ (\mathrm{xy} + \mathrm{xz} + \mathrm{yz})^2 + \mathrm{w}^4 \in (\Sigma + C)_{4,4}\backslash(\Sigma \cup C)_{4,4}.\end{aligned}$$

5. CONCLUSION

Combining Theorem 1 and Theorem 5 we have shown that for all non Hilbert cases $(n,2d) \geq (3,4)$, $(n,2d) \neq (3,4)$, it holds $(\Sigma_{n,2d} \cup C_{n,2d}) \subsetneq (\Sigma + C)_{n,2d} \subsetneq P_{n,2d}$.

We presented explicit examples R_1, R_2 and f_1, f_2 showing the inequalities for the two basic cases and demonstrated how two scale them to arbitrary cases. In terms of polynomial optimization, this shows that for all mentioned cases of n and $2d$, there are PSD polynomial which can be handled by the SOS+SONC cone but neither the SOS nor the SONC cone themselves. On the other hand, there are polynomials which are not classifiable as being PSD by SOS+SONC. It remains to find an efficient way to actually decide membership to the combined SOS+SONC cone.

Compatible snapshot-based model reduction of a nonlinear port-Hamiltonian PDE on networks ⋆

Björn Liljegren-Sailer * **Nicole Marheineke** *

* *Trier University, 54286 Trier, Germany (e-mail: {bjoern.sailer, marheineke}@uni-trier.de).*

Abstract: This contribution is on the construction of structure-preserving, online-efficient reduced models for a class of nonlinear partial differential equations on networks, which inherit a port-Hamiltonian structure. The flow problem finds broad application, e.g., in the context of gas distribution networks. We propose a snapshot-based reduction approach that consists of a mixed variational Galerkin approximation combined with quadrature-type complexity reduction. Its main feature is that certain compatibility conditions are assured during the training phase, which make our approach structure-preserving. The resulting reduced models are locally mass conservative and inherit an energy-bound and port-Hamiltonian structure. We demonstrate the applicability and good stability properties of our approach using the example of the Euler equations on networks.

Keywords: port-Hamiltonian systems; structure-preserving scheme; systems on graphs; model reduction; Legendre transformation; network systems; Euler equations.

1. INTRODUCTION

Structure-preserving approximation is an active research area. By preserving or mimicking relevant geometric structures such as, e.g., conservation laws, dissipative relations, or symplecticities, unphysical solution behavior and numerical instabilities can be avoided in many cases. The model problem in this contribution describes nonlinear flows on networks and has a port-Hamiltonian structure. It finds, e.g., application in the context of gas network systems or electric transmission lines. The network is assumed to be described by a directed graph. Each edge ω of the graph can be identified with an interval. Given a strictly convex smooth function $h : \mathbb{R}^2 \to \mathbb{R}$ and a non-negative function $\tilde{r} : \mathbb{R}^2 \to \mathbb{R}$, the edgewise states $\underline{\mathbf{z}}^\omega = [z_1^\omega; z_2^\omega] : [0,T] \times \omega \to \mathbb{R}^2$ are governed by

$$\begin{aligned} \partial_t z_1^\omega(t,x) &= -\partial_x \nabla_2 h(\underline{\mathbf{z}}^\omega(t,x)), \\ \partial_t z_2^\omega(t,x) &= -\partial_x \nabla_1 h(\underline{\mathbf{z}}^\omega(t,x)) \\ &\quad - \tilde{r}(\underline{\mathbf{z}}^\omega(t,x)) \nabla_2 h(\underline{\mathbf{z}}^\omega(t,x)), \end{aligned} \tag{1}$$

whereby $\nabla_i h(\underline{\mathbf{z}}^\omega(t,x)) = \partial_{z_i} h([z_1; z_2])_{|[z_1;z_2]=\underline{\mathbf{z}}^\omega(t,x)}$ for $i = 1, 2$. The expressions $\mathcal{M}(\underline{\mathbf{z}}) = \sum_{\omega\in\mathcal{E}} \int_\omega z_1^\omega dx$ and $\tilde{\mathcal{H}}(\underline{\mathbf{z}}) = \sum_{\omega\in\mathcal{E}} \int_\omega h(\underline{\mathbf{z}}^\omega) dx$, with $\mathcal{E}$ the set of all edges, represent the total mass and the Hamiltonian of the system. Fundamental properties of the hyperbolic model problem are that, under appropriate coupling conditions on the edgewise equations, conservation of mass and dissipation of the Hamiltonian (energy dissipation) hold up to the exchange with the boundary. Moreover, the convective terms can be related to a certain skew symmetric geometric structure.

Following the approach by Liljegren-Sailer and Marheineke (2021), we aim for a structure-preserving approximation procedure for the flow problem on network, which can be used for the discretization by finite elements, as well as the subsequent snapshot-based model reduction. The model reduction consists in general of a projection-based step and an additional complexity reduction of the nonlinearities employing a quadrature-based approach in our case. In this brief, we summarize and rephrase the results from Liljegren-Sailer and Marheineke (2021) in the abstract port-Hamiltonian setting.

For ease of presentation, we consider the case of a single edge in the remaining sections, i.e., without loss of generality the spatial domain $\Omega = [0, \ell]$ with $\ell > 0$. For the generalization to the network case and the choice of coupling-conditions, we refer to Liljegren-Sailer and Marheineke (2020).

2. AN EXEMPLARY HIERARCHY OF MODELS

Flow models of different complexity are covered by the problem (1), e.g., the following hierarchy used for the modeling of gas distribution networks, cf., Mindt et al. (2019).

- *Isothermal Euler equations:* The equations for density ρ and velocity v for $x \in \Omega$ and $t \geq 0$ read

$$\begin{aligned} \partial_t \rho &= -\partial_x(\rho v) \\ \partial_t(\rho v) &= -\partial_x(\rho v^2 + \hat{p}(\rho)) - c_f \frac{|\rho v|}{\rho} \rho v \end{aligned}$$

⋆ The support of the German Federal Ministry of Education and Research (BMBF) via the project *EiFer* is acknowledged. Moreover, we thank for the support of the DFG research training group 2126 on algorithmic optimization.

with pressure $p(\rho) = RT\frac{\rho}{1-RT\alpha\rho}$ (constants $RT > 0$, $\alpha < 0$). To rewrite the system as in (1), we define $\underline{\mathbf{z}} = [\rho; v]$, $\tilde{r}(\underline{\mathbf{z}}) = c_f\frac{|v|}{\rho}$ and

$$h(\underline{\mathbf{z}}) = \rho\frac{v^2}{2} + RT\rho\log\left(\rho_{sc}\frac{1-RT\alpha\rho}{\rho}\right).$$

- *Simplified isothermal Euler equations:* These equations result from the isothermal Euler equations by neglecting the term $\partial_x(\rho v^2)$. Reformulation (1) is obtained for $m = \rho v$, $\tilde{r}(\underline{\mathbf{z}}) = c_f\frac{|m|}{\rho}$ and

$$h(\underline{\mathbf{z}}) = \frac{1}{2}m^2 + \frac{-1}{RT\alpha^2}\left(\log\left(1-RT\alpha\rho\right) + RT\alpha\rho\right).$$

- *Damped wave equation:* A damped wave equation is obtained for

$$h(\underline{\mathbf{z}}) = 1/2(z_1^2+z_2^2), \quad \tilde{r}(\underline{\mathbf{z}}) > 0 \quad \text{for all } \underline{\mathbf{z}}.$$

The system is linear, when $\tilde{r}$ is chosen to be constant.

Note that in contrast to the isothermal Euler equations, the simplified version inherits a Hamiltonian density which is separable into $h(\underline{\mathbf{z}}) = h_1(z_1) + h_2(z_2)$ with quadratic h_2. For the damped wave equation, the Hamiltonian density is a fully quadratic function and $\underline{\mathbf{z}} = \nabla_{\underline{\mathbf{z}}}h(\underline{\mathbf{z}})$.

3. VARIATIONAL PRINCIPLE

Let the domain $\mathbb{S} = \mathbb{S}_1 \times \mathbb{S}_2 \subset \mathbb{R}^2$ of the Hamiltonian density h be open and convex. Then the so-called partial Legendre transformation g for $\quad = [a_1; a_2]$ is given by

$$g(\ ) = \sup_{z_2 \in \{\bar{z}_2 : [a_1;\bar{z}_2]\in\mathbb{S}\}} a_2 \cdot z_2 - h([a_1; z_2]).$$

It inherits the smoothness and strict convexity w.r.t. the second argument from h, cf., Rockafellar and Wets (1998). A certain variable transformation is induced by the Legendre transformation: Let for $\mathbf{z} \in \mathbb{S}$, $\quad = [z_1; \nabla_2 h(\mathbf{z})]$. Then it follows $\nabla_1 h(\mathbf{z}) = -\nabla_1 g(\ )$ and $z_2 = \nabla_2 g(\ )$, i.e., $a_2 \mapsto \nabla_2 g([z_1; a_2])$ is the inverse function of $z_2 \mapsto \nabla_2 h([z_1; z_2])$.

Thus, when $\underline{\mathbf{z}}(t,x) = [z_1(t,x); z_2(t,x)]$ is a smooth function, for which (1) holds for $t \geq 0$ and $x \in \Omega$, the function $_(t,x) = [a_1(t,x); a_2(t,x)] = [z_1(t,x); \nabla_2 h(\underline{\mathbf{z}}(t,x))]$ fulfills

$$\begin{aligned} \partial_t a_1(t,x) &= -\partial_x \nabla_2 a_2(t,x)), \\ \partial_t \nabla_2 g(a_2(t,x)) &= \partial_x \nabla_1 g(_(t,x)) - r(_(t,x))a_2(t,x) \end{aligned} \tag{2}$$

for a non-negative mapping r. The system can be closed by, e.g., the initial conditions $_(0,x) = _0(x)$ and boundary-conditions $-[\nabla_1 g(_(t,0); \nabla_1 g(_(t,\ell))] = \quad (t)$, $t \geq 0$ for given $_0 : \Omega \to \mathbb{R}^2$ and $\quad : [0,T] \to \mathbb{R}^2$.

Let the function spaces $\mathcal{L}^2(\Omega)$ and $\mathcal{H}^1(\Omega)$ denote the Sobolev space of square integrable functions on Ω and the Sobolev space with additionally square integrable weak derivatives, respectively. The $\mathcal{L}^2$-scalar product is written as $\langle\cdot,\cdot\rangle$ and the boundary terms for $b \in \mathbb{H}^1(\Omega)$ are denoted as $b[0]$ and $b[\ell]$. Accordingly, we define the boundary operator $\mathbf{T} : \mathbb{H}^1(\Omega) \to \mathbb{R}^2$ as $\mathbf{T}b = -[b[0]; b[\ell]]$. For any $_ \in \mathcal{C}^1([0,T], \mathcal{C}^1(\Omega) \times \mathcal{C}^1(\Omega))$ fulfilling (2) the variational principle

$$\begin{aligned} \langle \partial_t a_1(t), b_1\rangle &= -\langle \partial_x \nabla_2 a_2(t)), b_1\rangle \\ \langle \partial_t \nabla_2 g(a_2(t)), b_2\rangle &= -\langle \nabla_1 g(_(t)), \partial_x b_2\rangle \\ &\quad - \langle r(_(t))a_2(t), b_2\rangle + \quad (t)\cdot\mathbf{T}b_2. \end{aligned}$$

for $b_1 \in \mathcal{L}^2(\Omega)$, $b_2 \in \mathcal{H}^1(\Omega)$ holds, as one shows by multiplying (2) with the test functions b_1, b_2 and using integration by parts in the second equation. Note that here the solution is interpreted as a function in time with values in a function space.

4. APPROXIMATION ANSATZ

As we showed in Liljegren-Sailer and Marheineke (2020), a class of structure-preserving approximations is obtained by Galerkin approximation with compatible spaces that can be supplemented by a quadrature-type complexity reduction. The latter allows for sparse approximations of the nonlinearities and is required for reduced models to be online-efficient.

Assumption 1. (Compatibility of spaces). Let $\mathcal{V} = \mathcal{Q} \times \mathcal{W} \subset \mathcal{L}^2(\Omega) \times \mathcal{H}^1(\Omega)$ be a finite dimensional subspace fulfilling the compatibility conditions

A1) $\mathcal{Q} = \{\xi : \text{It exists } \zeta \in \mathcal{W} \text{ with } \partial_x\zeta = \xi\}$,
A2) $\{b_2 \in \mathcal{H}^1(\Omega) : \partial_x b_2 = 0\} \subset \mathcal{W}$.

Assumption 2. (Compatibility of scalar product). Let the bilinear form $\langle\cdot,\cdot\rangle_* : \mathcal{L}^2(\Omega) \times \mathcal{L}^2(\Omega) \to \mathbb{R}$ be such that the following holds:

A1) For a constant $\tilde{C} \geq 1$ and $||b||_* = \sqrt{\langle b, b\rangle_*}$, it holds $\tilde{C}^{-1}||b||_* \leq ||b|| \leq \tilde{C}||b||_*$ for all $b \in \mathcal{Q} \cup \mathcal{W}$.
A2) For any $f \in \mathcal{C}(\Omega)$ with $f \geq 0$ it holds $\langle f, 1\rangle_* \geq 0$.

The posed assumption assures that $\langle\cdot,\cdot\rangle_*$ is a scalar product on $\mathcal{Q}$ and $\mathcal{W}$. Note that the $\mathcal{L}^2$-product is particularly one possible choice, which results in a model without complexity reduction.

For approximation spaces and bilinear products as in the assumptions, our abstract approximation ansatz reads as follows: Given $_0 \in \mathcal{Q} \times \mathcal{W}$ and $\quad : [0,T] \to \mathbb{R}^2$, find $_ = [a_1; a_2] \in \mathcal{C}^1([0,T]; \mathcal{Q} \times \mathcal{W})$ with $_(0) = _0$, and

$$\begin{aligned} \langle \partial_t a_1(t), b_1\rangle &= -\langle \partial_x \nabla_2 a_2(t)), b_1\rangle \\ \langle \partial_t \nabla_2 g(a_2(t)), b_2\rangle_* &= -\langle \nabla_1 g(_(t)), \partial_x b_2\rangle_* \\ &\quad - \langle r(_(t))a_2(t), b_2\rangle_* + \quad (t)\cdot\mathbf{T}b_2. \end{aligned}$$

for $b_1 \in \mathcal{Q}$, $b_2 \in \mathcal{W}$.

The proposed approximations can be shown to be of port-Hamiltonian form with the Hamiltonian defined as $\mathcal{H}_*(_(t)) = \langle \nabla_2 g(_(t))a_2(t) - g(_(t)), 1\rangle_*$. Moreover, they inherit energy dissipation and mass conservation up to the exchange with the boundary,

$$\begin{aligned} \frac{d}{dt}\mathcal{H}_*(_(t)) &= -\langle r(_(t)), a_2(t)^2\rangle_* + \quad (t)\cdot\mathbf{T}a_2(t) \\ &\leq \quad (t)\cdot\mathbf{T}a_2(t) \\ \frac{d}{dt}\int_\Omega a_1(t)dx &= a_2(t)[0] + a_2(t)[\ell]. \end{aligned}$$

5. APPLICATION

The presented approximation framework can be realized by mixed finite elements but also can be used for the construction of online-efficient reduced models. The numerical results in this section focus on the reduction steps, i.e., the model order- and complexity-reduction. We showcase the improved performance when regarding the compatibility conditions as opposed to using standard (non-compatible) methods. We refer to Liljegren-Sailer and Marheineke

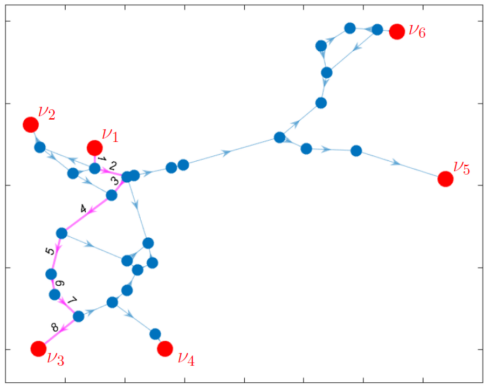

Fig. 1. Topology of network with boundary nodes ν_i, $i = 1, ..., 6$ (red circles).

(2021) for the algorithmic treatment of the compatibility conditions, the complete set of parameters and more numerical results. The test case employs the isothermal Euler equations in a regime relevant for gas distribution networks and the topology visualized in Fig. 1. As starting point for all reduction methods, a mixed finite element discretization with a system dimension of $N = 10\,156$ is used.

We simulate the high dimensional system using the boundary conditions for $t \in [0, 5t_\star]$ (reference values marked by stars, e.g., time $t_\star = 1[h]$),

$$\rho(t,\nu_1) = (65 + u(t/t_\star))\,\rho_\star, \qquad \rho(t,\nu_2) = (50 + u(t/t_\star))\,\rho_\star,$$
$$\rho(t,\nu_4) = (60 - u(t/t_\star))\,\rho_\star, \qquad \rho(t,\nu_5) = 60\,\rho_\star,$$
$$\rho(t,\nu_6) = 45\,\rho_\star, \qquad Am(t,\nu_3) = -100\,(Am)_\star,$$

at the six boundary nodes ν_i, $i = 1, ..., 6$ with the input profile $u = u_A$ (training case) and $u = u_B$ (testing case),

$$u_A(t) = 6\exp\left(-\frac{3}{2}t\right) + 4\cos\left(\frac{\pi}{2}t\right) + \frac{3}{2}\sin(10\pi\,t)$$

$$u_B(t) = 8t^3\exp(-t) - 4\,(t-2)\,f(3t).$$

with $f(t) = 1 - |(t \bmod 2) - 1|$. As initial condition the respective stationary solution for $t = 0$ is chosen. Reduced models without and with complexity reduction are obtained using snapshots from the training case. The fidelity of the resulting models are compared in Fig. 2 and Fig. 3 for varying dimensions of in the model order- and complexity-reduction. As is observed, our proposed schemes clearly outperform the non-structure-preserving conventional reduced models in the test case.

Abstract: This extended abstract proposes a passivity-based approach using bearing and velocity information for an angle-based formation control with a class of underlying triangulated Laman graphs. The controller is designed using virtual couplings on the relative measurements related to the edges. The different embedding of the graph is mapped by the measurement Jacobian, which is calculated by the time-evolution of the measurement. Furthermore, to avoid unavailable distance measurements in the control law, an estimator is designed based on the port-Hamiltonian theory using bearing and velocity measurements. The stability analysis of the closed-loop system is provided and simulations are performed to illustrate the effectiveness of the approach.

1. INTRODUCTION

Over the last three decades, formation control has attracted extensive interest due to its potential applications in many domains. Recently, the passivity-based port-Hamiltonian (pH) approach has been used for the design of formation controllers, such as Vos et al. (2014), Stacey and Mahony (2015), Xu and Liang (2018). This approach not only allows for complex and heterogenous agent dynamics but also enables the flexibility and scalability of the network.

In terms of the sensing capability, using partial information of the positions of agents requires fewer onboard sensors, which reduces the cost of hardware and introduces fewer measurement errors. Much research has been reported on this topic in recent years, such as Anderson et al. (2008), Cao et al. (2011) for distance measurement, Zhao et al. (2019), Trinh et al. (2018) for bearing measurement, and Chen et al. (2020), Jing et al. (2019) for angle measurement. In this extended abstract, we study the case where the sensing capability of the agents is based on bearing and relative velocity measurements, and angles constrain the interaction topology of agents. Remarkably, angle-based constraints are expressed by less information of the agents compared with position-, distance- and bearing-based approaches. Therefore, it is invariant to more group motions, such as translation, rotation, scaling and reflection, which means the agents can perform these maneuvers while satisfying angle-based constraints.

We consider a particular class of undirected, triangulated Laman graphs $\mathcal{G}_N(\mathcal{V}_N, \mathcal{E})$ introduced in Chen et al. (2017), where the interaction topology is determined only by angles. According to Jing et al. (2019), if a triangulated Laman framework $(\mathcal{G}_N, q)$ is strongly nondegenerate, then it is globally angle rigid. Therefore, the only realization of the framework with the underlying graph $\mathcal{G}_N$ is guaranteed. Since the topology of any formation shape constrained by angles can be designed as an underlying triangulated Laman graph, our proposed controller is not restrictive on formation shape.

In this work, we adopt a passivity-based approach, where the control objectives are achieved by virtual couplings where the virtual springs determine the formation by shaping the potential energy function of the network, while the virtual dampers shape the transient response by injecting damping. Customarily, controllers resulting from passivity-based approaches require the agents to have complete information of the relative positions even if the sensing capability and the interaction topology of the agents are both only angles. To solve this problem, we extend the passive adaptive compensator proposed for bearing formation control in Stacey and Mahony (2015) to estimate the unavailable distance information by using relative velocity.

Examples of recent literature on the angle-based formation problem are Basiri et al. (2010) and Chen et al. (2020), where an intuitive control law is proposed using only local bearing information while proving stability via linearization. However, a suitable Lyapunov function is not given for stability analysis and only single integrator models are considered. In Jing et al. (2019), a gradient-like control law is proposed for a single integrator model using bearing and distance information. Although only bearing and distance measurement are used to achieve the formation stabilization, when considering the trajectory tracking for complex dynamics, the velocity measurement is also needed. In contrast to the mentioned reference, our approach can achieve the trajectory tracking for complex dynamics without distance measurement.

The contributions of our approach are summarized as follows:

(i) Existing research only considers the single integrator case. In this work, we propose a control law and and estimator based on virtual couplings and pH theory for a double integrator model. Due to the pH framework, this approach is not only applicable to angle information but also for other measurements, such as displacement, bearing, and

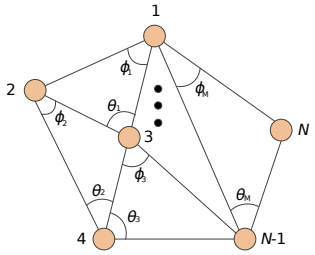

Fig. 1. Triangulated Laman graph with M triangles

distance. Therefore, our approach gives a general framework for the heterogeneous information of a multi-agent system.

(ii) We use less information to achieve more formation maneuvers. We not only consider the formation stabilization but also several maneuvers, such as velocity tracking, scale and orientation control. In particular, compared with displacement-based, distance-based, bearing-based formation, the angle-based formation can achieve more maneuvers while satisfying the constraints. Moreover, since a pH-based distance estimator is designed using bearing and velocity measurements, our approach achieves these maneuvers without using distance measurement.

The rest of the abstract is structured as follows: the problem formulation is introduced in Section 2, the control architecture is developed in Section 3, and the formation maneuvering design is provided in Section 4.

2. PROBLEM FORMULATION

Consider a group of N agents. The dynamics of the agents are given by double integrators on $\mathbb{R}^2$, which are expressed in pH form as

$$\begin{pmatrix}\dot{q}_n\\ \dot{p}_n\end{pmatrix} = \begin{pmatrix}0 & I_2\\ -I_2 & 0\end{pmatrix}\begin{pmatrix}\frac{\partial H_n}{\partial q_n}(p_n)\\ \frac{\partial H_n}{\partial p_n}(p_n)\end{pmatrix} + \begin{pmatrix}0\\ I_2\end{pmatrix}U_n, \tag{1}$$

$$H_n(p_n) = \frac{1}{2m_n}p_n^T p_n,\ \ Y_n = \frac{\partial H_n}{\partial p_n}(p_n),\ \ n \in \{1,2,...,N\}$$

where $q_n = (q_{x_n}, q_{y_n}) \in \mathbb{R}^2$, $p_n = (p_{x_n}, p_{y_n}) \in \mathbb{R}^2$, and m_n denote the position, momentum, and mass of agent n, respectively; $U_n = (U_{x_n}, U_{y_n}) \in \mathbb{R}^2$ and $Y_n = (Y_{x_n}, Y_{y_n}) \in \mathbb{R}^2$ denote the input and output, respectively; and $H_n : \mathbb{R}^2 \to \mathbb{R}$ represents the Hamiltonian of agent n.

We assume that each agent has access to bearing and relative velocity information. For relative velocity information, each agent is either able to estimate and communicate its own velocity or measure the relative velocity directly. We consider that the group of agents is connected by an underlying triangulated Laman graph $\mathcal{G}_N(\mathcal{V}_N, \mathcal{E})$ with M triangles as shown in Fig.1. We refer the reader to Chen et al. (2017) for specific definitions. Note that the graph considered in this work is undirected and the angle rigidity is ensured by Lemma 1, Jing et al. (2019).

Lemma 1. A triangulated Laman framework $(\mathcal{G}_N, q)$ is strongly nondegenerate, i.e., the three edges of each triangle are not collinear, only if $(\mathcal{G}_N, q)$ is globally angle rigid.

Note that the framework is composed of the graph $\mathcal{G}_N$ and the realization q, where *angle rigid* means that the formation shape is uniquely determined up to translations, scalings, and rotations. For more details about angle rigid, see Chen et al. (2020) and Jing et al. (2019). In particular, a triangulated Laman graph is constructed from a line graph with two nodes, every new adding node is connected by two existing nodes which are also connected. As shown in Fig. 1, the formation shape is determined by the marked angles. Since every triangulated Laman graph can be decomposed into several triangular graphs, we first design the controller for a specific triangular graph and then extend it to a general triangulated Laman graph.

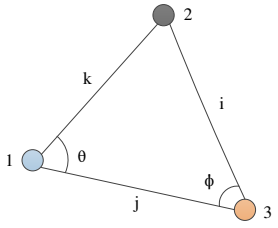

Fig. 2. Triangular formation

3. FORMATION STABILIZATION

3.1 Controller for triangular formation

Consider the triangular case shown in Fig.2, where $1,2,3$ are agents and i,j,k are the the edges. Angle 1 and 2 are the angles to be controlled. Then, the relative position, distance, and bearing of the edge k are defined as

$$z_k = q_1 - q_2, \quad r_k = ||z_k||, \quad s_k = \frac{z_k}{||z_k||},$$

respectively. Since the cosine function is monotone in the domain of the inner angle, i.e., $[0,\pi]$, we use the cosine of the angle to represent the angle measurement, which can be calculated via bearing measurement. In particular, for the angles θ and ϕ, we have

$$\cos\theta = s_k^T s_j, \quad \cos\phi = s_i^T s_j.$$

Now we consider the controller of agent 1. Since the moving of agent 1 affects both θ and ϕ, the controller of the agent 1 consist of two parts. One is to satisfy the constraint of the angle θ, the other is to satisfy the constraint of the angle ϕ. The control aim is to design a controller to ensure the cosine of θ , given by $(s_k^T s_j)$, to converge to the desired value $(s_k^T s_j)^*$. Hence, we define the error as

$$\widetilde{(s_k^T s_j)} := (s_k^T s_j) - (s_k^T s_j)^*. \tag{2}$$

It is necessary to assign a new potential energy related to the angle to ensure that the system converges to the desired point, i.e., the error converges to zero. To this end, we propose the following Hamiltonian function

$$H_{\theta 1} = \frac{1}{2}c_{\theta 1}\widetilde{(s_k^T s_j)}^2, \tag{3}$$

where $c_{\theta 1} > 0$ is a constant. Hence, the corresponding controller with spring and damping term can be derived as

$$\dot{\widetilde{(s_k^T s_j)}} = \omega_{\theta 1}, \quad \gamma_{\theta 1} = \frac{\partial H_{\theta 1}}{\partial \widetilde{(s_k^T s_j)}} + d_{\theta 1}\omega_{\theta 1}, \tag{4}$$

where $\omega_{\theta 1}$ denotes the input of the controller, $d_{\theta 1} > 0$ is a positive constant. Note that $\gamma_{\theta 1}$ is the resulting virtual force in the space of angle measurements. According to the pH theory van der Schaft and Jeltsema (2014), we define the force and

velocity as effort and flow, respectively. Thus, the power of the port can be derived as

$$< \gamma_{\theta 1} | \frac{\mathrm{d}(s_k^T s_j)}{\mathrm{d}t} >= \gamma_{\theta 1}^T \frac{\mathrm{d}(s_k^T s_j)}{\mathrm{d}t}. \tag{5}$$

Note that we only consider the relation between the agent 1 and the angle θ. To transform the power from angle measurement space to $\mathbb{R}^2$, we compute

$$\begin{aligned} < \gamma_{\theta 1} | \frac{\mathrm{d}(s_k^T s_j)}{\mathrm{d}t} > &=< \gamma_{\theta 1} | L_{\theta 1} \dot{q}_1 > \\ &=< -L_{s_k}^T s_j \gamma_{\theta 1} | \dot{q}_1 > + < -L_{s_j}^T s_k \gamma_{\theta 1} | \dot{q}_1 >, \end{aligned} \tag{6}$$

where $L_{s_k} = \frac{1}{r_k}(I_2 - s_k s_k{}^T) \in \mathbb{R}^{2\times 2}$ and $L_{s_j} = \frac{1}{r_j}(I_2 - s_j s_j{}^T) \in \mathbb{R}^{2\times 2}$. The effort of the port in (6) relies on the distance information which is not measurable. In order to avoid distance measurement, we use the relative velocity measurement to estimate the unknown distance Duindam et al. (2009).

Note that the estimated distance is used, the distance term in the angle Jacobian also needs to be replaced, accordingly. Therefore, the estimated angle Jacobian is given by

$$\begin{aligned} \hat{L}_{\theta 1} &= s_j^T \hat{L}_{\theta s_k} + s_k^T \hat{L}_{\theta s_j} \\ &= s_j^T \frac{1}{\hat{r}_{\theta k}}(I_2 - s_k s_k{}^T) + s_k^T \frac{1}{\hat{r}_{\theta j}}(I_2 - s_j s_j{}^T), \end{aligned} \tag{7}$$

where $\hat{r}_{\theta k}$ is the estimate of the edge k using the measurement of the angle θ, and $\hat{r}_{\theta j}$ is the estimate of the edge j using the measurement of the angle θ. Correspondingly, $\hat{L}_{\theta s_k}, \hat{L}_{\theta s_j}$ are the estimated bearing Jacobians using the measurement of θ. However, if $\hat{L}_{\theta 1}$ is used to replace $L_{\theta 1}$ in the right-hand side of (6), the equation is not satisfied because the effort $\gamma_{\theta 1}$ corresponds to the real flow (i.e., the time derivative of $s_k^T s_j$) in the angle space. This causes a discrepancy in the power through the virtual coupling due to the error between the estimated distance and the real unknown distance.

Define the distance errors

$$\bar{r}_{\theta k} := \hat{r}_{\theta k} - r_k, \quad \bar{r}_{\theta j} := \hat{r}_{\theta j} - r_j.$$

Then, the estimated effort in $\mathbb{R}^2$ is

$$-(\hat{L}_{\theta s_k}^T s_j + \hat{L}_{\theta s_j}^T s_k)\gamma_{\theta 1} = -L_{s_k}^T s_j \alpha_{\theta k} - L_{s_j}^T s_k \alpha_{\theta j}, \tag{8}$$

where $\alpha_{\theta k} := \frac{r_k}{\hat{r}_{\theta k}}\gamma_{\theta 1}$ is the estimated effort related to $\hat{r}_{\theta k}$ and $\alpha_{\theta j} := \frac{r_j}{\hat{r}_{\theta j}}\gamma_{\theta 1}$ is the estimated effort related to $\hat{r}_{\theta j}$. Furthermore, considering the ports in different spaces, we have

$$\begin{aligned} < \hat{L}_{\theta 1}^T \gamma_{\theta 1} | \dot{q}_1 > &=< -L_{s_k}^T s_j \alpha_{\theta k} - L_{s_j}^T s_k \alpha_{\theta j} | \dot{q}_1 > \\ &=< \alpha_{\theta k} | \frac{\mathrm{d}(s_k^T s_j)}{\mathrm{d}t} > + < \alpha_{\theta j} | \frac{\mathrm{d}(s_k^T s_j)}{\mathrm{d}t} > . \end{aligned} \tag{9}$$

Comparing (6) with (9), the discrepancy between the real effort and the estimated effort can be derived as

$$\begin{aligned} \beta_{\theta k} &= \alpha_{\theta k} - \gamma_{\theta 1} = -\frac{\bar{r}_k}{\hat{r}_{\theta k}}\gamma_{\theta 1}, \\ \beta_{\theta j} &= \alpha_{\theta j} - \gamma_{\theta 1} = -\frac{\bar{r}_j}{\hat{r}_{\theta j}}\gamma_{\theta 1}. \end{aligned} \tag{10}$$

Hence, the power of the ports, with $\beta_{\theta k}$, $\beta_{\theta j}$ as the efforts, are

$$< \beta_{\theta k} | - s_j^T L_{s_k} \dot{q}_1 >, \quad < \beta_{\theta j} | - s_k^T L_{s_j} \dot{q}_1 > . \tag{11}$$

To account for the power associated with the ports in distance space, we define the corresponding Hamiltonian as

$$H_{\theta k} := \frac{1}{2} c_{\theta k} \bar{r}_{\theta k}^2, \quad H_{\theta j} := \frac{1}{2} c_{\theta j} \bar{r}_{\theta j}^2, \tag{12}$$

where $c_{\theta k}, c_{\theta j} > 0$ are constants. Then, the power of the ports in distance space are given by

$$\begin{aligned} < \frac{\partial H_{\theta k}}{\partial \bar{r}_{\theta k}} | \dot{\bar{r}}_{\theta k} > &=< c_{\theta k} \bar{r}_{\theta k} | \dot{\bar{r}}_{\theta k} >, \\ < \frac{\partial H_{\theta j}}{\partial \bar{r}_{\theta j}} | \dot{\bar{r}}_{\theta j} > &=< c_{\theta j} \bar{r}_{\theta j} | \dot{\bar{r}}_{\theta j} > . \end{aligned} \tag{13}$$

Since energy is coordinate free, the power in angle space and distance space are the same. Therefore, comparing (11) and (13), we have

$$\begin{aligned} < \beta_{\theta k} | - s_j^T L_{s_k} \dot{q}_1 > &= < c_{\theta k} \bar{r}_{\theta k} | \dot{\bar{r}}_{\theta k} > \\ \Rightarrow \qquad \dot{\bar{r}}_{\theta k} &= -\frac{\gamma_{\theta 1}^T}{c_{\theta k} \hat{r}_{\theta k}}(-s_j^T L_{s_k} \dot{q}_1). \end{aligned} \tag{14}$$

Furthermore, the dynamics of the estimators are given by

$$\dot{\hat{r}}_{\theta k} = \dot{r}_k + \dot{\bar{r}}_{\theta k} = s_k^T \dot{z}_k - \frac{\gamma_{\theta 1}^T}{c_{\theta k} \hat{r}_{\theta k}}(-s_j^T L_{s_k} \dot{q}_1). \tag{15}$$

Similarly,

$$\dot{\hat{r}}_{\theta j} = \dot{r}_j + \dot{\bar{r}}_{\theta j} = s_j^T \dot{z}_j - \frac{\gamma_{\theta 1}^T}{c_{\theta j} \hat{r}_{\theta j}}(-s_k^T L_{s_j} \dot{q}_1). \tag{16}$$

Note that we only require the relative velocity and bearing measurement in the above estimators, while the information of distance measurement is not used.

The control law of the agent 1 for the angle θ is given by

$$\begin{aligned} U_{\theta 1} =& [\frac{1}{\hat{r}_{\theta k}}(I_2 - s_k s_k{}^T)^T s_j + \frac{1}{\hat{r}_{\theta j}}(I_2 - s_j s_j{}^T)^T s_k] \\ & \times [c_{\theta 1}\widetilde{(s_k^T s_j)} + d_{\theta 1}\widetilde{\dot{(s_k^T s_j)}}]. \end{aligned} \tag{17}$$

Now, we design the controller of the agent 1 to control the angle ϕ. To this end, define the corresponding Hamiltonian as

$$H_{\phi 1} := \frac{1}{2} c_{\phi 1} \widetilde{(s_i^T s_j)}^2, \tag{18}$$

where $c_{\phi 1} > 0$ is a constant. The controller with spring and damping term is given by

$$\widetilde{\dot{(s_i^T s_j)}} = \omega_{\phi 1}, \quad \gamma_{\phi 1} = \frac{\partial H_{\phi 1}}{\partial \widetilde{(s_i^T s_j)}} + d_{\phi 1}\omega_{\phi 1}, \tag{19}$$

where $\omega_{\phi 1}$ denotes the input of the controller and $d_{\phi 1} > 0$ is a constant. Considering the ports in different spaces, we have that

$$\begin{aligned} < \alpha_{\phi 1} | (-s_i^T L_{s_j} \dot{q}_1) > &=< \hat{L}_{\phi 1}^T \gamma_{\phi 1} | \dot{q}_1 >, \\ \hat{L}_{\phi 1} = s_i^T \hat{L}_{\phi s_k} &= s_i^T \frac{1}{\hat{r}_{\phi k 1}}(I_2 - s_k s_k{}^T), \end{aligned} \tag{20}$$

where $\hat{L}_{\phi 1}$ is the estimated angle Jacobian mapping from position of the agent 1 to the angle ϕ; $\hat{L}_{\phi s_k}$ is the estimated bearing Jacobian using the measurement of the angle ϕ; and $\hat{r}_{\phi k 1}$ is the estimated distance of the edge k by the agent 1 using the measurement of the angle ϕ. Furthermore, taking the same steps as for θ, we have the following estimator

$$\dot{\hat{r}}_{\phi k 1} = \dot{r}_k + \dot{\bar{r}}_{\phi k 1} = s_k^T \dot{z}_k - \frac{\gamma_{\phi 1}^T}{c_{\phi k} \hat{r}_{\phi k 1}}(-s_i^T L_{s_j} \dot{q}_1), \tag{21}$$

where $c_{\phi k} > 0$ is a constant. Correspondingly, the control law of the agent 1 for the angle ϕ is given by

$$U_{\phi 1} = \frac{1}{\hat{r}_{\phi k 1}}(I_2 - s_k s_k{}^T)^T s_i [c_{\phi 1}\widetilde{(s_i^T s_j)} + d_{\phi 1}\widetilde{\dot{(s_i^T s_j)}}]. \tag{22}$$

Since the design process for agents 2 and 3 is similar to the process for agent 1, we omit the details.

3.2 Extension to triangulated Laman graph

Assume that the topology is designed as a class of a triangulated Laman graph $\mathcal{G}_N(\mathcal{V}_N, \mathcal{E})$ with M triangles as shown in Fig.1. In each triangle, the control law is designed as in Section 3.1. To satisfy all the angle constraints, the general control law for the whole group is sum of the control laws derived from all related triangles. Therefore, the control law for each agent is the sum of all the corresponding control laws introduced by the triangles the agent forms. Moreover, the corresponding Hamiltonian and control law are given as follows

$$\begin{aligned} H =& \frac{1}{2}(m_1\dot{q}_1^T\dot{q}_1 + m_2\dot{q}_2^T\dot{q}_2 + ... + m_N\dot{q}_N^T\dot{q}_N) \\ & \frac{1}{2}(c_{\theta_1}\widetilde{\cos\theta_1}^2 + c_{\phi_1}\widetilde{\cos\phi_1}^2 + c_{\theta_2}\widetilde{\cos\theta_2}^2 + c_{\phi_2}\widetilde{\cos\phi_2}^2 \\ & + ... + c_{\theta_M}\widetilde{\cos\theta_M}^2 + c_{\phi_M}\widetilde{\cos\phi_M}^2) \\ & + \frac{1}{2}\sum_{\varepsilon\in\mathcal{E}} c_\varepsilon \bar{r}_\varepsilon^2, \end{aligned} \tag{23}$$

$$\begin{aligned} U =& \sum_{m=1}^{M}\sum_{n\in\mathcal{N}_m}(U_{\theta_m n} + U_{\phi_m n}) \\ =& \sum_{m=1}^{M}\sum_{n\in\mathcal{N}_m}(\hat{L}_{\theta_m n}(c_{\theta_m n}\widetilde{\cos\theta_n} + d_{\theta_m n}\frac{\mathrm{d}(\cos\theta_\mathrm{m})}{\mathrm{d}t}) \\ & + \hat{L}_{\phi_m n}(c_{\phi_m n}\widetilde{\cos\phi_m} + d_{\phi_m n}\frac{\mathrm{d}(\cos\phi_\mathrm{m})}{\mathrm{d}t})), \end{aligned} \tag{24}$$

where $\mathcal{N}_m$ is the index set of agents forming the triangle m. To ensure the stability of the closed-loop system, we first give the following conjecture.

Conjecture 1. If any three agents $n \in \mathcal{N}_m$ forming the triangle m are neither coincident nor collinear at $t_0 \in \mathbb{R}_{\geq 0}$. Then, the matrix $[\hat{L}_{\theta_m n} \quad \hat{L}_{\phi_m n}]$ for the triangle m is full column rank for any $t \geq t_0$.

The main result for formation stabilization is given by the following theorem.

Theorem 1. Consider a triangulated Laman graph $\mathcal{G}_n(\mathcal{V}_n, \mathcal{E})$ with with m triangles. Under Conjecture 1 and the proposed control law (24), the group of agents converges to the desired formation constrained by the angles.

4. FORMATION MANEUVERING

To complete a certain task, such as a group of agents move an object together along a desired trajectory, formation stabilization is not enough, it is necessary to maneuver the whole formation. In this regard, we design controllers for scale and direction control, and velocity tracking, respectively.

For scale and orientation control, without loss of generality, we choose the edge k, connecting the reference agents 1 and 2, as the reference edge. Assume the coordinates of the mentioned agents are aligned and the desired displacement with prespecified scale and orientation can be described as $z_k^* = q_1^* - q_2^*$. Then, the corresponding Hamiltonian is given by

$$H_k = \frac{1}{2}||z_k - z_k^*||^2. \tag{25}$$

Then, the control law is

$$u_1 = -\frac{\partial H_k}{\partial q_1} - d_z\dot{z}_k, \quad u_2 = -\frac{\partial H_k}{\partial q_2} + d_z\dot{z}_k, \tag{26}$$

where $d_z \in \mathbb{R}^{+2\times 1}$ is a constant matrix.

For velocity tracking, we use the leader-follower strategy and consider reference agents as the leaders, which know the desired velocity v^*. Hence, the corresponding Hamiltonian is

$$H_i^v = \frac{1}{2m_i}(p_i - p^*)^T(p_i - p^*) - p_i^T v^*,$$

where p^* is the desired momentum. Furthermore, the control law is

$$U_i = -d_r v^* - d_v(v_i - v^*), \tag{27}$$

where $d_v \geq \varepsilon I_2 > 0$.

The main result of this work is given by the following theorem.

Theorem 2. Consider a group of agents modeled as in (1) and connected by a triangulated Laman graph $\mathcal{G}_n(\mathcal{V}_n, \mathcal{E})$ with M triangles. Under Conjecture 1, the desired formation shape is achieved by the control law proposed in (24), while the desired scale and orientation are achieved by the control law (26), and the velocity tracking is achieved by the control law (27).

Abstract: The synthesis of bandpass microwave filters is based on the use of equivalent circuit models made of coupled resonators. These couplings are usually supposed to be independent of the frequency. We present in this paper a circuit model including possibly frequency varying couplings. After presenting some of its properties we consider the associated synthesis problem and show how techniques such as Groebner basis computation and Schur analysis based extraction techniques can be used to solve the latter exhaustively.

Keywords: Filter synthesis, Circuit synthesis, Structured realization, Microwave filters

1. INTRODUCTION

Microwave filters are usually synthesized using equivalent circuit models. For band-pass filters circuits made of electromagnetically coupled resonators are considered. The synthesis of such circuits when starting from a prescribed scattering response, has been studied extensively Cameron (1999); Cameron et al. (2007b, 2002); Amari (2000). In particular, the relation between the coupling topology of the circuit, that is the way each circuit is coupled to the others, and its associated class of realizable transfer functions is now well understood Amari (1999); Seyfert and Bila (2007). It was shown that for a given coupling topology several circuits with different circuital values, might realize the same response. When the considered coupling topology has the so-called non-redundant property the set of equivalent circuits is finite and approaches based on the use of Gröbner basis Cameron et al. (2005, 2007a) and continuation techniques have been developed to solve this structured realisation problem exhaustively (see software Seyfert (2005)).

In waveguide filters, the electromagnetic couplings between resonators that are realised via irises or coupling windows are usually supposed frequency independent and modelled by an idealised electrical component called inverter. When the relative functioning frequency band of the filter is increased, or the thickness of the coupling irises widened, the frequency independence of the coupling elements no longer holds and might lead to substantial modelling errors. When the frequency dependency is modelled as linear, it was recently advocated that the coupling slope, when controllable, could serve as an extra design parameter Amari et al. (2010); He et al. (2019); Szydlowski et al. (2013).

In this work we will detail the underlying electrical synthesis problem and characterize, for a given coupling topology including certain frequency dependent elements, the set of scattering responses that can be achieved. Eventually the problem of determining all electrical circuits with a given coupling structure that realise a specified response will be shown equivalent to a multivariate algebraic problem. When the latter is zero dimensional we will show how a combination of Schur analysis based methods and Groebner basis techniques from computer algebra allows for an effective and exhaustive solution of the electrical synthesis problem.

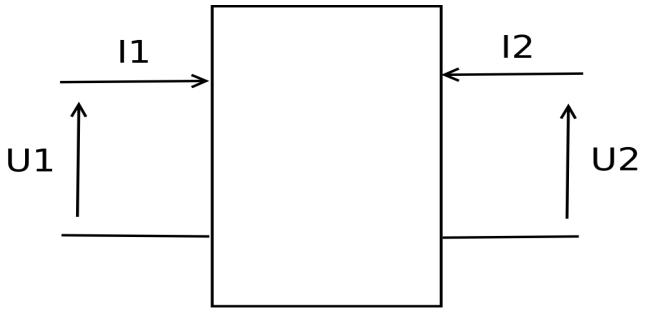

Fig. 1. Coupling structure: the inverter

2. ELECTRICAL MODEL

2.1 Frequency dependent couplings

The classical coupling element used to model small apertures in microwave filter design is the two port admittance inverter, see Figure 1. It is entirely characterised by its coupling coefficient K, and its admittance matrix is defined by following input output relation between voltages and currents at its ports:

$$\begin{cases} I_1 = jKU_2 \\ I_2 = jKU_1 \end{cases} \tag{1}$$

where we use the physicist's notation for the complex number $j^2 = -1$. The inverter is an idealised coupling element, which is introduced to model the effect of a small

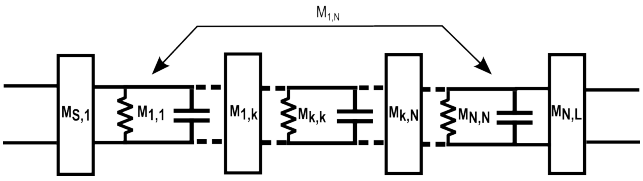

Fig. 2. Low pass equivalent circuit

aperture between coupling cavities. This complex valued electrical elements are used within low-pass equivalent circuits of filters that model, within a normalized pass-band $\omega = [-1, 1]$ the scattering behavior of the filter by means of coupled resonators, see Figure 2. If $S^h(s = j\omega)$ is the scattering matrix of the microwave filter and S^c the one of its low-pass equivalent, then

$$S^h(s) \approx S^c(as + b), \forall s \in j[-1, 1],$$

where the coefficient a, b are chosen such the frequency interval $[-1, 1]$ is mapped linearly to the actual high-frequency passband of the filter $[\omega_1, \omega_1]$. For short the low-pass equivalent circuit is a circuit with complex elements that furnishes a good approximation of a real system, i.e. the filter, within its functioning band.

As announced we introduce now a frequency variant inverter for which the admittance parameters writes,

$$\begin{cases} I_1 = j|G|\omega U_1 + j(K + G\omega)U_2 \\ I_2 = j(K + G\omega)U_1 + j|G|\omega U_2. \end{cases} \quad (2)$$

It is easily verified that the admittance matrix of the introduced frequency dependent inverter is positive real and loss-less and of McMillan degree one. The sign of the off diagonal frequency variant component G is used to model alternatively inductive or (locally) capacitiv coupling effects.

3. GENERAL LOW-PASS EQUIVALENT MODEL

We now consider low-pass circuits as represented on Fig.2, where the couplings $M_{i,j}$ between circuits can be either frequency independent, that is as described by equation (1), or frequency dependent in accordance with equation (2). The input and output couplings $M_{S,k}$ and $M_{k,L}$ are supposed frequency independent. Kirchhoff's law yields following state space equations in descriptor form for this kind of low-pass circuits,

$$\begin{cases} E\dot{V} = -jF.V + BU_{in} \\ I_{out} = B^t V \end{cases} \quad (3)$$

where E is a $n \times n$ positive definite matrix and F a symmetric matrix of same size, while B is $n \times 2$. The 2×1 voltage vector U_{in} represents the voltages at both ports of the circuit, while I_{out} represents the currents at the same locations. Eventually the state vector V is defined as $V = jU$ where $U(k)$ is the voltage in resonator k. There is of course a direct link between the electrical components of the circuit and the elements of matrix (E, F, B). If the circuit i is coupled to the circuit j in a frequency dependent manner described by the obviously defined parameters $K_{i,j}, G_{i,j}$ we have

$$E_{i,j} = E_{j,i} = G_{i,j},\ F_{i,j} = F_{j,i} = K_{i,j}.$$

If they are coupled in a frequency independent way we obviously have $E_{i,j} = 0$ and $F_{i,j} = F_{j,i} = K_{i,j}$. Eventually if they aren't coupled at all $E_{i,j} = F_{i,j} = 0$. As for the diagonal terms we have,

$$E_{i,i} = C_i + \sum_{k \neq i} |G_{k,i}|,\ F_{i,i} = M_{i,i}$$

where C_i is the capacitance of the i^{th} resonator, and $M_{i,i}$ a susceptance that allows to tune its resonant frequency. The first column of B is equal to the $M'_{S,k}s$, that is $B(k, 1) = M_{S,k}$ and the second to the $M'_{L,k}s$ that is $B(k, 2) = M_{L,k}$.

We will call circuital a realisation (E, F, B) corresponding to system (3), with E and F symmetric and E invertible.

Proposition 1. We sum up some elementary properties of these realisations. We call admittance the transfer function of a circuital realisation.

- Let (E, F, B) be a circuital realisation, E, F, B all real and E positive definite, then its admittance
$$Y = B(sE + jF)^{-1}B^t = -jB(\omega E + F)^{-1}B^t$$
is a 2×2 strictly proper, reciprocal, loss-less positive real transfer function.
- If Y is a 2×2 strictly proper, reciprocal, loss-less positive real transfer function there exists a circuital realisation (E, F, B) to it, where $E = Id$ and (F, B) are real.
- Suppose (E, F, B) and (E', F', B') are two minimal circuital realizations (possibly with complex entries) of McMillan degree n with same admittance matrix then there exists a non-singular $n \times n$ matrix P such that,
$$E' = P^t EP,\ F' = P^t FP,\ B' = P^t B.$$

4. COUPLING GRAPH AND TRANSMISSION ZEROS

The scattering matrix S of a circuit is defined as the Cayley transform of its admittance matrix,

$$S = (I - Y)(I + Y)^{-1}.$$

When Y is positive real and loss-less S is a 2×2 inner matrix. The transmission zeros are defined as the zeros of the rational function $S_{1,2}S_{2,1}$ that lie in the closed left-half plan with the convention that zeros occurring on the imaginary axis are counted with half their multiplicity (see Carlin and Civalleri (1997)). Using the Belevitch form of 2×2 inner matrices it is easily seen that their number k cannot exceed the McMillan degree n of S. If k is not maximal we say that $n - k$ transmission zeros are at infinity. The synthesis of microwave filters usually starts with the determination of an "optimal" scattering responses, passing maximally the signal in the pass-band(s) while rejecting it with a prescribed rejection level in the stop bands. The computation of such responses is done by solving quasi-convex Zolotarev problems involving the filtering function $S_{1,2}/S_{1,1}$ of the scattering matrix Lunot et al. (2008). For these problems the number of available transmission zeros is crucial, as their presence allow to obtain very selective responses with steep slopes in the transition regions between pass and stop bands. We give here a result relating the maximal number of transmission zeros a circuit can achieve to the network structure of its coupling scheme.

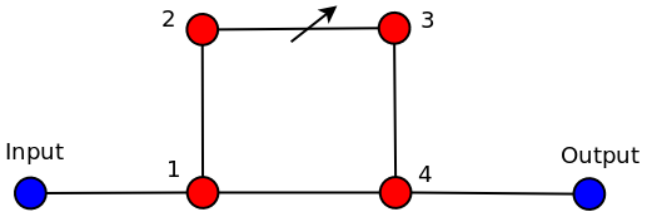

Fig. 3. Coupling graph corresponding to a four resonators filter with a "quadruplet" coupling structure. The frequency varying coupling is noted by an extra diagonal ascending arrow between resonator 2 and 3.

Proposition 2. **Shortest path rule**: To every coupled resonator circuit, we associate a coupling graph defined as described: every resonator is represented by a node, and two additional separate nodes are drawn to symbolize the input and output. Edges of length one are drawn between the input (resp. output) node and a resonator k if the corresponding $B(k,1)$ (resp. $B(k,2)$) coupling elements is present in the circuit. Edges of length one are drawn between resonators nodes k and l if a non frequency dependent coupling $F(k,l)$ (and $E(k,l)=0$) is available. Eventually an edge of length zero is drawn between resonator k and l if a frequency dependent couplings $E(k,l)$ (and $F(k,l)\neq 0$) is available in the circuit. Consider a circuit with n resonators. Let l be the length of the shortest path in the coupling graph between input and output, then the scattering matrix of this circuit can maximally possess $n+1-l$ transmission zeros.

Figure (3) represents such a coupling graph for a quadruplet structure. The shortest path between input and output is here 3, which indicates by the preceding proposition that this coupling structure can accommodate maximally $4+1-3=2$ transmission zeros. If an additional frequency varying coupling were to be placed between resonator 1 and 2 the shortest path would have a length of 2 indicating that maximally 3 transmission zeros can be produced by such a structure. Eventually note that quadruplet with independently adjustable transmission zeros are usually by means of a frequency independent cross-coupling $F(1,3)$ which is complicate to realize in practice and necessitate the placement of a wire probe between resonator 1 and 3. The use of a frequency dependent coupling that can be realized with thickened coupling irises appears here to offer an interesting alternative option for the hardware implementation of the filter.

5. CANONICAL FORM

We now come to some canonical realization of these circuits.

Proposition 3. Suppose Y is a strictly proper admittance matrix, reciprocal, positive real and loss-less of McMillan degree n. Suppose in addition that $Y_{1,1}$ and $Y_{2,2}$ are different from zeros. Let

$$Y=\sum_{k=1}^{\infty}\frac{G_k}{s^k}$$

be the formal development of Y at infinity where the $G_k's$ are the Markov parameters. The matrix Y admits a real valued circuital realization (Id,F,B) where,

- B has only three non vanishing element $B(1,1)$, $B(n,1)$, $B(n,2)$.
- The only possibly non-vanishing elements in F are its diagonal, sub and sur-diagonal, as well as it last line and last column
- If the first Markov parameter is diagonal, i.e the anti-diagonal terms of G_1 are zero, then $B(n,1)=0$. If further k first Markov parameters are diagonal $(1<k\leq n-1)$ then $F(1\dots k-1,n)=F(n,1\dots k-1)=0$
- Let S be the scattering matrix associated to Y then if S has k finite transmission zeros then the first $n-k-1$ Markov parameters of Y are diagonal.

6. SYNTHESIS OF STRUCTURED REALIZATIONS

In order to tackle the problem of synthesizing a scattering matrix with a circuit with a prescribed coupling topology we first give an algebraic meaning to the word coupling topology. A topology σ is a set of formal structured matrices (E,F,B) populated with their specific non zero elements. The parameter set X of a coupling topology is the set of formal variables representing the variable entries of E,F,B. For example the parameter set X associated to the coupling topology shown on Figure (3) is

$$X=\{B(1,1),B(2,4),F(1,1),F(2,2),F(3,3), \quad (4)$$
$$F(4,4),F(1,2),F(2,3),F(3,4),F(1,4),E(2,3)\} \quad (5)$$

while the diagonal of E is here considered as equal to the identity matrix which corresponds to a classical normalisation.

We suppose that formally (as a polynomial in $\mathbb{C}[X]$) $\det(E)\neq 0$, that is the set of singular $E's$ form a strict sub-variety $\mathcal{W}$ of $\mathbb{C}^r$, where r is the cardinality of X. To every coupling topology σ we will associate a realization map,

$$\begin{aligned}\pi_\sigma:\ \mathbb{C}^r\setminus\ \mathcal{W} &\mapsto \left(\mathbb{C}^{2\times 2}\right)^{2n-1}\\ x &\mapsto \left(B^t(x)E^{-1}(x)B(x),\, B^t(x)E^{-1}(x)F(x)E^{-1}B(x)\right. \quad (6)\\ &\quad \left.\dots\, B^t(x)(E^{-1}F)^{2n-1}(x)E^{-1}(x)B(x)\right).\end{aligned}$$

Adapting the algebraic framework detailed in Seyfert (2019) we obtain following results.

Definition 1. For a topology $\sigma=(E,F,B,X)$ with $r=card(X)$ we define $\mathcal{V}(\sigma)=\overline{\pi_\sigma(\mathbb{C}^r)}$ to be its admissible set. It is equivalent, up to the closure operation, to the set of all possible admittances the topology can generate, when its parameters range over $\mathbb{C}^r\setminus\mathcal{W}$.

Definition 2. Let $\sigma=(B,E,F,X)$ be a topology. As a polynomial map, π_σ has a Jacobian matrix. On an non-empty open Zariski set of $\mathbb{C}[X]$ this Jacobian has constant rank, which is often called its generic rank. We will say that a topology is non-redundant, if the Jacobian of its realisation map is generically full rank, that is of rank $r=card(X)$.

Solving our coupling matrix synthesis problem is about inverting π_σ on $\mathcal{V}(\sigma)$. We have following properties,

Proposition 4. Let $\sigma=(B,E,F,X)$ be a coupling topology, with $r=card(X)$. We have,

- $\mathcal{V}(\sigma)$ is an irreducible algebraic variety.
- If σ is non-redundant, then the dimension of $\mathcal{V}(\sigma)$ as an algebraic variety is r.

- If σ is non-redundant there exists an integer $\Theta(\sigma)$ such that all fibers of π_σ are generically of cardinality $\Theta(\sigma)$. More precisely there exists a non-empty Zariski set $\mathcal{U}$ open in $\mathcal{V}(\sigma)$ such that $\forall y \in U$, $card(\pi_\sigma^{-1}(y)) = \Theta(\sigma)$. U is dense in $\mathcal{V}(\sigma)$ in both topologies (Zariski and euclidean). We call $\Theta(\sigma)$ the order of the topology σ.
- If σ_1 and σ_2 are two non-redundant topologies with parameter sets of the same cardinality, and if $\mathcal{V}(\sigma_1) \subset \mathcal{V}(\sigma_2)$ then $\mathcal{V}(\sigma_1) = \mathcal{V}(\sigma_2)$
- If σ_1 and σ_2 are coupling topologies, and $\mathcal{V}(\sigma_1) \cap \mathcal{V}(\sigma_2) \neq \mathcal{V}(\sigma_1)$, then generically, on a non-empty Zariski open set $\mathcal{U}$ of $\mathcal{V}(\sigma_1)$, we have

$$\forall y \in \mathcal{U},\ \pi_{\sigma_2}^{-1}(y) = \emptyset.$$

In the talk we will detail how to solve a typical synthesis problem. Starting from a synthesized "optimal" frequency response S with a given number of transmission zeros, a canonical form (E_0, F_0, B_0) is computed. Considering a non-redundant coupling topology σ with same admissible set as the computed canonical form (specialized to the particular number of considered transmission zeros) we set up an algebraic system of multivariate polynomial equations based on the item of proposition (1) in order to find all equivalent realizations with topology σ similar (with same transfer function) to (E_0, F_0, B_0). The system is solved using Gröbner basis. For large systems we will show that for particular coupling topologies a divide and conquer strategy can be designed in order to split the original structured realisation problem in several smaller ones. This strategy uses Schur analysis to decompose the function to be realised as a sequence of chained responses of lower degree than the initial one. Details about these procedures can be found in Zhang et al. (2021a,b).

Abstract: We present a data-driven predictive control scheme for the stabilization of unknown LTI systems subject to process disturbances. The scheme uses Willems' lemma for the prediction of future system trajectories and can be set up using only a priori measured input-output data of the disturbed system and an upper bound on its order. The main contribution is the introduction of a novel constraint tightening, which purely based on data guarantees closed-loop constraint satisfaction and recursive feasibility, even in the presence of process disturbances. Furthermore, a pre-stabilizing controller can be integrated into the scheme which ensures applicability for unstable systems.

Keywords: Model predictive control, data-driven control, robust control

1. INTRODUCTION

Recent research has focused on the idea of establishing predictive control schemes without explicit model knowledge using only a priori measured data sequences (Yang and Li, 2015; Coulson et al., 2019, 2021; Berberich et al., 2021). To this end, the above publications employ Willems' lemma (Willems et al., 2005) for the data-based prediction of future system trajectories.

One of the major strengths of model predictive control (MPC) is its capability of including state and input constraints into the optimal control problem, and therefore, guaranteeing the satisfaction of these constraints in closed-loop operation. In the data-driven setting –based on Willems' lemma– these closed-loop guarantees were so far only achieved in Berberich et al. (2020a) by the introduction of a proper constraint tightening which can be parametrized using only measured data. However, the aforementioned publication only considers additive output measurement noise, whereas process disturbances, acting directly on the states, were barely considered in the data-driven MPC literature so far.

While process disturbances are considered in Huang et al. (2021) and Umenberger (2021), knowledge of a priori measured disturbances is assumed in both publications which could be a rather restrictive assumption depending on the application. Moreover, no closed-loop guarantees were derived in both publications. Recently, a scheme guaranteeing closed-loop stability and recursive feasibility in the presence of process disturbances was introduced in Liu et al. (2021), which, however, lacks of guarantees for closed-loop constraint satisfaction.

The predictive control scheme introduced in the following closes this gap by extending the constraint tightening from Berberich et al. (2020a) to the case with process disturbances. As a key advantage, the proposed approach allows for the inclusion of a pre-stabilizing feedback, which enables the usage of the proposed scheme even in the case of unstable systems. Furthermore, a suitable input constraint tightening is introduced in order to guarantee closed-loop input constraint satisfaction while using the pre-stabilizing controller.

In this extended abstract, after introducing the problem setup in Section 2, we present the proposed data-based MPC scheme and state its main properties (closed-loop constraint satisfaction and practical exponential stability) in Section 3. More details on the results presented, as well as the associated proofs, can be found in Klöppelt et al. (2022).

Notation: We denote the set of continuous, strictly increasing functions $\alpha : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ with $\alpha(0) = 0$ by $\mathcal{K}$ and the subset of unbounded functions in $\mathcal{K}$ as $\mathcal{K}_\infty$.

For a sequence $\{z_k\}_{k=0}^{N-1}$ we define the Hankel matrix of depth L as

$$H_L(z) = \begin{bmatrix} z_0 & z_1 & \cdots & z_{N-L} \\ z_1 & z_2 & \cdots & z_{N-L+1} \\ \vdots & \vdots & \ddots & \vdots \\ z_{L-1} & z_L & \cdots & z_{N-1} \end{bmatrix},$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

and the stacked window from time instant a to b as

$$z_{[a,b]} = \begin{bmatrix} z_a^\top & \cdots & z_b^\top \end{bmatrix}^\top.$$

2. PROBLEM SETUP

We consider the discrete-time LTI system

$$x_{k+1} = Ax_k + Bu_k + w_k \tag{1}$$

with the state $x_k \in \mathbb{R}^n$, the input $u_k \in \mathbb{R}^m$, and the process disturbance $w_k \in \mathbb{R}^n$, where the pair (A, B) is controllable. We assume that the state, input, and disturbance are subject to constraints in the form of hypercubes, i.e., the input constraint set is given by

$$\mathbb{U} = \{u \in \mathbb{R}^m \mid \|u\|_\infty \leq u_{\max}\}, \tag{2}$$

for some $u_{\max} > 0$, and analogously for the state and disturbance constraint sets $\mathbb{X}$ and $\mathbb{W}$. The control goal is to stabilize the origin in the presence of the bounded disturbance $w_k \in \mathbb{W}$ for all $k \geq 0$, while satisfying the input and state constraints $x_k \in \mathbb{X}$ and $u_k \in \mathbb{U}$ for all $k \geq 0$. We assume that the system matrices A and B are unknown, but that the system order n, as well as the constraints $u_{\max}$, $x_{\max}$, $w_{\max}$ are known. Hence, for controller design, only the latter shall be used together with measured input and state sequences. Note that the following results also hold if only an upper bound on the system order is known.

To this end, we a priori apply a persistently exciting (PE) input sequence to the system and measure the resulting state sequence, where a PE sequence is defined as follows.

Definition 1. A sequence $\{u_k\}_{k=0}^{N-1}$, with $u_k \in \mathbb{R}^m$, is persistently exciting of order L if $\operatorname{rank}(H_L(u)) = mL$.

Using the input-state data sequences we make use of Willems' fundamental lemma. This result states that in the absence of disturbances (i.e., if $w_k = 0$ for all $k \geq 0$) all system trajectories can be parametrized by the linear combination of time shifts of a priori measured system trajectories.

Lemma 1. (Willems et al. (2005)). Suppose the data sequence $\{u_k, \hat{x}_k\}_{k=0}^{N-1}$ is a trajectory of the system

$$\hat{x}_{k+1} = A\hat{x}_k + Bu_k \tag{3}$$

and u is PE of order $L + n$. Then, $\{\bar{u}_k, \bar{x}_k\}_{k=0}^{L-1}$ is a trajectory of system (3) if and only if there exists $\alpha \in \mathbb{R}^{N-L+1}$ such that

$$\begin{bmatrix} H_L(u) \\ H_L(\hat{x}) \end{bmatrix} \alpha = \begin{bmatrix} \bar{u} \\ \bar{x} \end{bmatrix}.$$

In the next section, we set up an MPC scheme which uses Lemma 1 for the prediction of future trajectories, and moreover, guarantees closed-loop constraint satisfaction.

3. DATA-DRIVEN PREDICTIVE CONTROL SCHEME

First, we assume that we have access to a state feedback matrix K such that all eigenvalues of $A_K = A + BK$ lie strictly inside the unit disc. In case of a stable system, this feedback can be set to zero. In case of an unstable system, such a control law can be computed purely from data, e.g., following the approaches in Berberich et al. (2020b); Van Waarde et al. (2020). We use this feedback matrix to pre-stabilize the system by using the input parametrization

$$u_k = Kx_k + \nu_k \tag{4}$$

as it is common, for example, in tube-based MPC (Chisci et al., 2001).

To make use of Lemma 1 for the prediction of state sequences, we consider the input ν_k of the pre-stabilized system

$$x_{k+1} = A_K x_k + B\nu_k + w_k, \tag{5}$$

apply the PE input sequence $\{\nu_k^d\}_{k=0}^{N-1}$ of length N to system (5), and measure the resulting state sequence $\{x_k^d\}_{k=0}^{N}$, where the superscript "d" is used to denote the fact that this is a priori collected data.

Assumption 1. The input sequence $\{\nu_k^d\}_{k=0}^{N-1}$ is persistently exciting of order $L + n$.

Assumption 1 can be easily enforced in practice by choosing a rich enough input sequence to generate the data. It is not restrictive in the sense that the set of signals which are not PE has measure zero.

With these a priori generated data sequences,we are now in the position to set up the optimal control problem (OCP) at time t with the prediction horizon L

$$J_L^*(x_t) = \min_{\substack{\alpha(t),\sigma(t),\\ \bar{u}(t),\bar{x}(t)}} J_L\left(\bar{u}(t), \bar{x}(t), \alpha(t), \sigma(t)\right), \tag{6a}$$

$$\text{s.t.} \begin{bmatrix} \bar{u}(t) \\ \bar{x}(t) + \sigma(t) \end{bmatrix} = \begin{bmatrix} H_L(\nu^d) \\ H_{L+1}(x^d) \end{bmatrix} \alpha(t), \tag{6b}$$

$$\bar{x}_0(t) = x_t, \tag{6c}$$

$$\bar{x}_L(t) = 0, \tag{6d}$$

$$f_k^x\left(\bar{u}(t), \bar{x}(t), \alpha(t), \sigma(t)\right) \leq x_{\max}, \tag{6e}$$

$$f_k^u\left(\bar{u}(t), \bar{x}(t), \alpha(t), \sigma(t)\right) \leq u_{\max}, \tag{6f}$$

$$\forall k = 0, \ldots, L-1, \tag{6g}$$

where (6b) is used as prediction for future state sequences $\bar{x}(t)$ (compare Lemma 1), (6c) and (6d) are the initial and terminal condition of the OCP. The terminal equality constraint is used to prove exponential stability in Theorem 1, similar to standard (model-based) MPC (Rawlings et al., 2017). Further, (6e) and (6f) are suitable tightened constraints ensuring recursive feasibility and closed-loop constraint satisfaction.

We use the cost function

$$\begin{aligned} J_L\left(\bar{u}(t), \bar{x}(t), \alpha(t), \sigma(t)\right) = &\sum_{k=0}^{L-1} \left(\|\bar{u}_k(t)\|_R^2 + \|\bar{x}_k(t)\|_Q^2 \right) \\ &+ \lambda_\alpha w_{\max} \|\alpha(t)\|_2^2 \\ &+ \frac{\lambda_\sigma}{w_{\max}} \|\sigma(t)\|_2^2, \end{aligned} \tag{7}$$

with quadratic regularization on $\alpha(t)$, and $\sigma(t)$ (compare Berberich et al. (2021)). Using the slack variable σ (first introduced in Coulson et al. (2019)) is common in data-driven predictive control, in order to ensure feasibility of (6b) even in the presence of disturbances. The state and input constraint functions are given by

$$\begin{aligned} f_k^x\left(\bar{u}(t), \bar{x}(t), \alpha(t), \sigma(t)\right) = &\|\bar{x}_k(t)\|_\infty + a_{u,k} \|\bar{u}(t)\|_1 + a_{c,k} \\ &+ a_{\alpha,k} \|\alpha(t)\|_1 + a_{\sigma,k} \|\sigma_k(t)\|_\infty \end{aligned} \tag{8}$$

$$f_k^u\left(\bar{u}(t),\bar{x}(t),\alpha(t),\sigma(t)\right) = \left\|\bar{u}_k(t)\right\|_\infty + b_{u,k}\left\|\bar{u}(t)\right\|_1 + b_{c,k} + b_{\alpha,k}\left\|\alpha(t)\right\|_1 + b_{\sigma,k}\left\|\sigma_k(t)\right\|_\infty + \left\|K\bar{x}_k(t)\right\|_\infty. \tag{9}$$

In the following, we describe how the various constants appearing in (8), (9) are defined. This is done in a similar fashion as in Berberich et al. (2020a), but suitably extended in order to be able to account for process disturbances and the additional pre-stabilizing feedback in (4). In particular, a suitable input constraint tightening resulting in (6f) and (9) was not present in Berberich et al. (2020a). First, define the constants

$$c_{\alpha,k} \coloneqq \rho_{A,k}\bar{d}_{N-L} + \bar{d}_{N-L+k}, \tag{10}$$

$$c_{\sigma,k} \coloneqq \rho_{A,k} + 1, \tag{11}$$

for $k = 0,\dots,L-1$, where $\rho_{A,k} \geq \left\|A_K^k\right\|_\infty$ and $\bar{d}_k \geq \left\|d_k\right\|_\infty$, with

$$d_k \coloneqq \sum_{i=0}^{k-1} A_K^{k-1-i} w_i. \tag{12}$$

Moreover, note that $\rho_{A,k}$ and $\bar{d}_k$ can be computed based on the available input-state data and the disturbance bound $w_{\max}$, following the approach of Wildhagen et al. (2022, Section IV.B). Furthermore, we consider a controllability constant Γ, which also can be computed from data (Berberich et al., 2020a, Section V.A), and the constant $c_{pe} = \left\|H_{u\hat{x}}^\dagger\right\|_1$, with

$$H_{u\hat{x}} = \begin{bmatrix} H_L\left(\nu^d\right) \\ H_1\left(\hat{x}^d_{[0,N-L]}\right) \end{bmatrix}, \tag{13}$$

where $\hat{x}^d_{[0,N-L]}$ denotes the a priori measured state sequence without process disturbances. We approximate $c_{pe} \approx \left\|H_{ux}^\dagger\right\|_1$, where H_{ux} is analogous to (13) but contains disturbances in the measured state sequence. However, the error between the real value and the approximation of c_{pe} is small for sufficiently small disturbance levels $w_{\max}$, as was confirmed by numerical simulations.

Using these system constants, as well as $\bar{K} = \left\|K\right\|_\infty$, we can now define the coefficients of the state constraint tightening (8) as

$$a_{u,k} = 0,\ a_{\alpha,k} = c_{\alpha,k},\ a_{\sigma,k} = c_{\sigma,k},\ a_{c,k} = \bar{d}_k, \tag{14}$$

for $k = 0,\dots,n-1$, and

$$\begin{aligned} a_{u,k+n} &= a_{u,k} + a_{\alpha,k}c_{pe} + a_{\sigma,k}c_{pe}\bar{d}_n, \\ a_{\alpha,k+n} &= a_{u,k+n}\Gamma c_{\alpha,L-1} + c_{\alpha,k+n}, \\ a_{\sigma,k+n} &= a_{u,k+n}\Gamma c_{\sigma,L-1} + c_{\sigma,k+n}, \\ a_{c,k+n} &= \bar{d}_n + a_{c,k} + a_{\alpha,k}\left(nx_{\max} + n\bar{d}_n\right) \\ &\quad + a_{\sigma,k}\left(\bar{d}_{N-1}c_{pe}\left(nx_{\max} + n\bar{d}_n\right) + \bar{d}_n\right). \end{aligned} \tag{15}$$

for $k = 0,\dots,L-n-1$. Further, we define the coefficients for the input constraint tightening (9) as

$$b_{u,k} = 0, b_{\alpha,k} = \bar{K}c_{\alpha,k}, b_{\sigma,k} = \bar{K}c_{\sigma,k}, b_{c,k} = \bar{K}\bar{d}_k, \tag{16}$$

for $k = 0,\dots,n-1$, and

$$\begin{aligned} b_{u,k+n} &= b_{u,k} + b_{\alpha,k}c_{pe} + b_{\sigma,k}c_{pe}\bar{d}_n, \\ b_{\alpha,k+n} &= b_{u,k+n}\Gamma c_{\alpha,L-1} + \bar{K}c_{\alpha,k+n}, \\ b_{\sigma,k+n} &= b_{u,k+n}\Gamma c_{\sigma,L-1} + \bar{K}c_{\sigma,k+n}, \\ b_{c,k+n} &= \bar{K}\bar{d}_n b_{c,k} + b_{\alpha,k}\left(nx_{\max} + n\bar{d}_n\right) \\ &\quad + a_{\sigma,k}\left(\bar{d}_{N-1}c_{pe}\left(nx_{\max} + n\bar{d}_n\right) + \bar{d}_n\right), \end{aligned} \tag{17}$$

for $k = 0,\dots,L-n-1$. At this point it becomes clear why in case of an unstable system a pre-stabilizing controller (4) should be included into the control scheme, as in case of eigenvalues of A lying on or outside the unit disc the constants $\rho_{A,k}$ and $\bar{d}_k$ would (exponentially) diverge. Thus, the coefficients (14)-(17) would diverge as well, resulting in an infeasible OCP (6) due to (6e), (6f) even for small prediction horizons L.

The strictly convex OCP (6) is now solved in an n-step receding horizon manner, i.e., it is solved at time t with the measured state x_t, the first n optimal inputs $\bar{u}^*_{[0,n-1]}(t)$ are applied to system (1) via the input parametrization (4), i.e., $u_{t+k} = Kx_{t+k} + \bar{u}^*_k(t)$ for $k = 0,\dots,n-1$. This procedure is then repeated at time $t + jn$ for all $j \in \mathbb{N}$. Next, we state that for all states inside the region of attraction, i.e., with $J_L^*(x_t) \leq V_{\mathrm{ROA}}$, a sufficiently small disturbance bound $w_{\max}$ can be found such that the MPC scheme results in recursive feasibility, practical exponential stability, and closed-loop constraint satisfaction, i.e., $x_t \in \mathbb{X}$ and $u_t \in \mathbb{U}$ for all $t \geq 0$.

Theorem 1. Suppose that Assumption 1 holds. Then, for any $V_{\mathrm{ROA}} > 0$, there exist $\underline{\lambda}_\alpha$, $\overline{\lambda}_\alpha$, $\underline{\lambda}_\sigma$, $\overline{\lambda}_\sigma > 0$ such that for all λ_α, λ_σ satisfying

$$\underline{\lambda}_\alpha \leq \lambda_\alpha \leq \overline{\lambda}_\alpha, \quad \underline{\lambda}_\sigma \leq \lambda_\sigma \leq \overline{\lambda}_\sigma, \tag{18}$$

there exist $\bar{w}$, $\bar{c}_{pe} > 0$ as well as a function $\beta \in \mathcal{K}_\infty$, such that for all $w_{\max}$ and c_{pe} satisfying

$$w_{\max} \leq \min\left\{\bar{w},\ \frac{\bar{c}_{pe}}{c_{pe}}\right\}, \tag{19}$$

the following holds for the closed-loop of the n-step MPC scheme:

(i) If $J_L^*(x_t) \leq V_{\mathrm{ROA}}$ for some $t \geq 0$, then OCP (6) is feasible at time $t + n$.
(ii) For any initial condition satisfying $J_T^*(x_0) \leq V_{\mathrm{ROA}}$ it holds that $x_t \in \mathbb{X}$ and $u_t \in \mathbb{U}$ for all $t \geq 0$, and $J_L^*(x_t)$ converges exponentially to $J_L^*(x_t) \leq \beta(\bar{w})$.

Note that (ii) only shows exponential convergence of x_t to a neighborhood of $x = 0$, however, it is possible to establish a suitable lower as well as an upper bound on $J_L^*(x_t)$ (Berberich et al., 2021, Lemma 1), thus, resulting in practical exponential stability. The proof of this theorem as well as extensions to the case of output feedback can be found in Klöppelt et al. (2022). For a detailed discussion on the parameters λ_α, λ_σ, and c_{pe} we refer to Berberich et al. (2021).

4. CONCLUSION

In this extended abstract, we introduced a data-driven predictive control scheme, capable of stabilizing the origin even in the presence of process disturbances. To this end, we proposed a state constraint tightening which can be constructed using only system constants that can be estimated purely from data. The presented MPC scheme includes a pre-stabilizing controller and an associated input constraint tightening such that it can also cope with unstable systems. The introduced predictive controller guarantees closed-loop recursive feasibility, practical exponential stability, and constraint satisfaction.

On Cameron-Liebler sets of k-spaces in finite projective spaces (Part I)

Jan De Beule *

* *Vrije Universiteit Brussel, Pleinlaan 2, B–1050 Brussel (e-mail: Jan.De.Beule@vub.be).*

Abstract: Cameron-Liebler sets of lines in a finite 3-dimensional space $\mathrm{PG}(3,q)$ originate from the study by Cameron and Liebler in 1982 of groups of collineations with equally many orbits on the points and the lines of $\mathrm{PG}(3,q)$. These objects have some interesting equivalent characterizations, and are examples of Boolean functions of degree one and completely regular codes. In this talk, we focus on these objects from a geometric perspective, and report on several existence and non-existence results, including a recent so-called modular equality for the parameter of Cameron-Liebler sets of k-spaces in finite n-dimensional projective spaces.

Keywords: low degree Boolean functions, completely regular codes, irreducible groups, Cameron-Liebler sets, extremal sets, strongly regular graphs.

1. INTRODUCTION

Let $q = p^h$ be a prime power, and denote the finite field of order q as $\mathrm{GF}(q)$. The d-dimensional projective space over $\mathrm{GF}(q)$ is the geometry consisting of all i-dimensional subspaces of the $d+1$-dimensional vector space $V(d+1,q)$ over $\mathrm{GF}(q)$, $1 \leq i \leq d$, and is denoted by $\mathrm{PG}(d,q)$. The fundamental theorem of projective geometry states that all isomorphisms of $\mathrm{PG}(d,q)$ are induced by the semi-linear maps of the underlying vector space. The group of isomorphisms of $\mathrm{PG}(d,q)$ is also called the group of collineations. Note that we call the i-dimensional subspaces of $V(d+1,q)$, $1 \leq i \leq d$, the points, lines, planes, etc. of $\mathrm{PG}(d,q)$.

In Cameron and Liebler (1982), irreducible collineation groups of $\mathrm{PG}(d,q)$, having equally many point orbits as line orbits are studied. There are several ways to characterize the line orbits of such a collineation group. One way is geometric, using spreads of the projective space. A *k-spread of* $\mathrm{PG}(d,q)$ is a set of k-dimensional projective subspaces partitioning the point set of $\mathrm{PG}(d,q)$. It is well known that a k-spread of $\mathrm{PG}(d,q)$ exists if and only if $k+1 \mid d+1$. Hence e.g. $\mathrm{PG}(d,q)$ has line spreads if and only if $2 \mid d+1$. In Cameron and Liebler (1982), it is shown that the line orbits have constant intersection with any spread, i.e. there exists a natural number x such that for any line orbit O, $|O \cap S| = x$ for any line spread S of $\mathrm{PG}(d,q)$. Such a line set O will be called a *Cameron-Liebler line class (CLLC) with parameter x.*

It was conjectured in Cameron and Liebler (1982) that such a group is line transitive or fixes a hyperplane and acts transitively on the lines of the hyperplanes, or, dually, fixes a point and acts transitively on the lines through the fixed point. Clearly, the set of lines through a fixed point p meets every spread in exactly one line. Dually, the set of lines in a fixed plane π meets every spread in exactly one line. Both line sets are CLLCs with parameter 1. They are called *trivial*. If $p \notin \pi$, the union of the set of lines through p and the set of lines in π meets every spread in exactly 2 lines. Also this example is called a trivial CLLC. Note that from the intersection property with spreads, it follows that the complement of a CLLC with parameter x in the line set, is a CLLC with parameter q^2+1-x. The complement of a trivial CLLC will also be called a trivial CLLC. The conjecture of Cameron and Liebler was disproven by Drudge (1998) and by Bruen and Drudge (1999). More precisely, in Bruen and Drudge (1999), the authors constructed a CLLC in $\mathrm{PG}(3,q)$ with parameter $x = \frac{q^2+1}{2}$ for odd q. Since the work of Bruen and Drudge, a lot of research has been done with as main objective either to construct new non-trivial CLLCs, or to show that CLLCs do not exist for particular values of the parameter x.

Now we switch to the world of low degree Boolean functions. The following theorem is well known.

Theorem 1. (Nisan and Szegedy (1994)). A Boolean degree d function on the hypercube depends on at most $d2^{d-1}$ coordinates.

In the last years, comparable results for low degree Boolean functions on different domains have been obtained. Let $J(n,k)$ denote the Johnson graph, i.e. the graph with vertex set all k-subsets of $\{1,\ldots,n\}$, two vertices being adjacent if and only if the corresponding sets meet in exactly $k-1$ elements. The following theorem is from Filmus (2016) and Meyerowitz (1992).

Theorem 2. Let $n-k, k \geq 2$. A Boolean degree 1 function on the Johnson graph $J(n,k)$ depends on at most one coordinate.

From this perspective, it is natural to consider the q-analogue of the Johnson graph as domain. This is the Grassmann graph $J_q(n,k)$, the graph with vertex set all k-dimensional subspaces of the vector space $V(n,q)$, and two vertices being adjacent if and only if their corresponding subspaces meet in a $(k-1)$-dimensional subspace of $V(n,q)$.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

The original conjecture of Cameron and Liebler is translated in the language of Boolean degree one functions on $J_q(n,k)$ as follows.

Conjecture 3. (Cameron, Liebler (1982)). Let $n \geq 4$ and $k = 2$. If f is a Boolean degree 1 function on the Grassmann graph $J_q(n,k)$, then f depends on at most one point and one hyperplane.

Now we switch the viewpoint to coding theory. Let $n \geq 1$ and A be a set of q symbols. The Hamming graph $H(n,q)$ is the graph with vertex set the set of words of length n over A and two vertices being adjacent if and only if their Hamming distance is 1. The Hamming graph $H(n,2)$ is the hypercube. Clearly, a q-ary code of length n can be considered as a subset of the vertex set of $H(n,q)$. So it is quite natural to translate properties of the code C into graph theoretical properties. Conversely, it is natural to define codes as substructures in graphs different from the Hamming graph as well, replacing the Hamming distance by the graph distance. Let C be a code in a regular graph Γ with vertex set V. We follow the definition found in e.g. Neumaier (1992). Let x be any vertex of Γ, then $d(x,C) = \min\{d(x,y)|y \in C\}$. The covering radius $\rho = \max\{d(x,C)|x \in \Gamma\}$, it is the minimal integer ρ such that the spheres of radius ρ around the codewords of C cover the vertices of Γ. For a code C, minimum distance $d(C)$ and covering radius $\rho(C)$ are related by $d(C) \leq 2\rho(C)+1$. The code C is called *perfect* in case of equality, which is equivalent with the property that the spheres with radius $\rho(C)$ around the codewords partition the vertex set V.

Completely regular codes have been introduced in Delsarte (1973) as a generalization of perfect codes. Assume that C is a code in a distance regular graph. Let $C_i = \{x \in \Gamma | d(x,C) = i\}$, then $C_i \neq \emptyset \iff 0 \leq i \leq \rho(C)$, and $C_0 = C$. The sets C_i partition the vertex set of Γ. The code C is called *completely regular* if every vertex $x \in C_i$ has a constant number of neighbors a_i, b_i, respectively c_i in C_{i-1}, C_i, respectively C_{i+1}. This is equivalent with the partition of the vertex set of Γ into the components C_i being equitable.

As it is natural to move from the hypercube to the Grassmann graph as domain for low degree Boolean functions, it is equally natural to consider completely regular codes in the Grassmann graph, and it is well known that completely regular codes of covering radius 1 are equivalent to Cameron-Liebler line classes, see e.g. Filmus and Ihringer (2019).

In this talk, we will briefly overview the different points of view on CLLCs. Then we discuss the current state of the art on the existence of non-trivial CLLCs in $\mathrm{PG}(3,q)$, overview the non-existence results for CLLCs with a given particular parameter x, discuss the generalization of CLLCs to Cameron-Liebler sets of k-subspaces of the projective and affine space, and present a recent modular equality on the parameter of these generalizations.

2. KNOWN EXAMPLES AND A MODULAR EQUALITY FOR CAMERON-LIEBLER LINE CLASSES

The geometrical characterization of CLLCs, i.e. such an object has constant intersection with any spread of $\mathrm{PG}(3,q)$, is useful to generalize the notion of these objects to higher dimension if spreads exist. For d-dimensional projective spaces, this is only possible if $2 \mid d+1$. However, this restriction does not occur when dealing with affine spaces.

Recall that a d-dimensional affine space over the finite field $\mathrm{GF}(q)$ is the geometry consisting of all cosets of i-dimensional subspaces of the vector space $V(d,q)$, $0 \leq i \leq d-1$. This geometry is denoted by $\mathrm{AG}(d,q)$. It is well known that spreads of k-dimensional subspaces always exist in an affine space, it is sufficient to consider the set of k-spaces in one parallel class. A *Cameron-Liebler line set in* $\mathrm{AG}(3,q)$ is a set of lines meeting any line spread in a constant number. This is not just a straightforward generalization, as it can be shown that this definition is one of the similar characterizations possible in an affine context.

Now we are ready to overview known results for CLLCs in three dimensions.

Non-trivial examples of Cameron-Liebler line classes are rare. The first example of an infinite family was given in Bruen and Drudge (1999) (q odd, $x = \frac{q^2+1}{2}$). More recently, examples with parameter $x = \frac{q^2-1}{2}$ have been discovered in Rodgers (2013) and are described as an infinite family De Beule et al. (2016); Feng et al. (2015). These examples require $q \equiv 5$ or $9 \bmod 12$. Examples with parameter $x = \frac{(q+1)^2}{3}$ from Rodgers (2013) for $q \equiv 2 \bmod 3$ are described as an infinite family in Feng et al. (2021). Non-isomorphic derivations of some of these examples with parameter $x = \frac{q^2-1}{2}$ are found in Cossidente and Pavese (2019a) ($q > 7$ odd), and in Cossidente and Pavese (2019b) ($q \equiv 1 \bmod 4$, $q \geq 9$). Note that for some of these examples, there exists a plane of $\mathrm{PG}(3,q)$ not containing any line, and hence such examples live in $\mathrm{AG}(3,q)$. Hence, by (D'haeseleer et al., 2020, Theorem 3.8), these examples are also examples of non-trivial Cameron-Liebler line classes in $\mathrm{AG}(3,q)$. As mentioned in the introduction, non-existence results are of great interest as well, and one of the most consequential non-existence conditions is the following theorem.

Theorem 4. (Gavrilyuk and Metsch, 2014, Theorem 1.1) Suppose that L is a Cameron-Liebler line class with parameter x of $\mathrm{PG}(3,q)$. Then for every plane and every point of $\mathrm{PG}(3,q)$,

$$\binom{x}{2} + m(m-x) \equiv 0 \bmod (q+1), \tag{1}$$

where m is the number of lines of L in the plane, respectively through the point.

As a corollary of Theorem 4, the following theorem is given in D'haeseleer et al. (2020)

Theorem 5. Suppose that L is a Cameron-Liebler line class in $\mathrm{AG}(3,q)$ with parameter x. Then

$$x(x-1) \equiv 0 \bmod 2(q+1)\,. \tag{2}$$

3. A MODULAR EQUALITY FOR CAMERON-LIEBLER SETS OF K-SPACES

The main results we present in the talk, is the generalization of Theorem 4, respectively 5, to Cameron-Liebler

line classes in projective spaces, respectively affine spaces of dimension $n \geq 3$ odd. This is joint work with Jonathan Mannaert.

Recall the Gaussian binomial coefficient, for $a \leq b$ natural numbers,

$$\begin{bmatrix} b \\ a \end{bmatrix}_q = \frac{(q^b-1)\dots(q^{b-a+1}-1)}{(q^a-1)\dots(q-1)}$$

which represents the number of $(a-1)$-dimensional projective spaces in a projective space of dimension $b-1$.

For the sake of completeness, we mention one alternative definition of Cameron-Liebler sets of lines in $\mathrm{PG}(d,q)$ that avoids the use of line spreads, which do not exist if d is even. A *Cameron-Liebler set of lines in* $\mathrm{PG}(d,q)$ is a set L of lines of which the characteristic vector χ_L is a linear combination of characteristic vectors of the point-line pencils in $\mathrm{PG}(d,q)$. In case $d=3$, then the number

$$x = \frac{|L|}{\begin{bmatrix} d \\ 1 \end{bmatrix}_q}$$

coincides with the parameter of L as defined in Section 1. Therefore we use this number as definition of the *parameter of a Cameron-Liebler set of lines in* $\mathrm{PG}(d,q)$ for $d \geq 3$. The parameter will be an integer if and only if d is odd.

The following lemma originates from Drudge (1998). It turns out to be essential to prove the desired generalization of Theorem 4. A short proof can e.g. be found in De Beule et al. (2022).

Lemma 6. Let L be a Cameron-Liebler set of lines in $\mathrm{PG}(d,q)$, $d \geq 3$, and let π be any i-dimensional projective subspace of $\mathrm{PG}(d,q)$, $i \geq 2$. Then the set of lines of L contained in π is a Cameron-Liebler set of lines in π, with parameter x_π.

Secondly, a series of combinatorial lemmas are needed. These are the following.

Lemma 7. (De Beule et al., 2022, Theorem 5.1 for $k=1$ and $t=3$) Suppose that $\mathcal{L}$ is a non-empty Cameron-Liebler line class in $\mathrm{PG}(n,q)$, $n \geq 4$ even, with parameter x. Then

$$x = 1 + \frac{C}{\begin{bmatrix} n-2 \\ 1 \end{bmatrix}_q},$$

for some $C \in \mathbb{N}$.

Lemma 8. (Blokhuis et al., 2019, Theorem 2.9) Suppose that $\mathcal{L}$ is a Cameron- Liebler line class with parameter x in $\mathrm{PG}(n,q)$, with $n \geq 3$. If ℓ is an arbitrary line in $\mathrm{PG}(n,q)$ then there are in total $q^2\frac{q^{n-2}-1}{q-1}(x-\chi(\ell))$ lines of $\mathcal{L}$ skew to ℓ. Here $\chi(\ell)$ equals one if $\ell \in \mathcal{L}$ or zero otherwise.

Lemma 9. (Segre, 1961, Section 170) The number of j-spaces disjoint to a fixed m-space in $\mathrm{PG}(n,q)$ is equal to $q^{(m+1)(j+1)} \begin{bmatrix} n-m \\ j+1 \end{bmatrix}_q$.

The arguments to prove the following theorem, are of combinatorial nature. The above Lemmas 6, 7, 8, and 9 enable a series of arguments that relate the parameter of a Cameron-Liebler set of lines to the parameter of the induced Cameron-Liebler line class in different 3-dimensional projective spaces, the latter for which we can use Theorem 4. The main result for the projective case is the following theorem.

Theorem 10. (De Beule and Mannaert (2022)). Let L be a Cameron-Liebler line class with parameter x in $\mathrm{PG}(n,q)$, with $n \geq 7$ odd. Then for any point p,

$$x(x-1) + 2\overline{m}(\overline{m}-x) \equiv 0 \mod (q+1),$$

where $\overline{m}$ is the number of lines of L through p.

Lemma 6 can be reformulated for Cameron-Liebler line sets in affine spaces, see e.g. De Beule et al. (2022).

Lemma 11. Suppose that $\mathcal{L}$ is a Cameron-Liebler set of lines in $\mathrm{AG}(n,q)$, $n >$. Then for every i-dimensional subspace π, with $i > 1$ the set of lines of L in π is a Cameron-Liebler line set in π, with parameter x_π.

The generalization of Theorem 5 now becomes

Theorem 12. (De Beule and Mannaert (2022)). Let L be a Cameron-Liebler line class in $\mathrm{AG}(n,q)$, $n \geq 3$ odd, with parameter x, then

$$x(x-1) \equiv 0 \mod 2(q+1).$$

We will illustrate how both Theorem 10 and 12 can be used to reduce the admitted parameters for given n and q.

(e-mail: ramikatz@mail.tau.ac.il,emilia@tauex.tau.ac.il)

Abstract: We study global finite-dimensional observer-based stabilization of a 1D heat equation with a known globally Lipschitz semilinearity in the state variable. We consider Neumann actuation and point measurement. Using dynamic extension and modal decomposition we derive nonlinear ODEs for the modes of the state. We then design a finite-dimensional nonlinear Luenberger observer, which takes into account the known semilinearity. The proposed controller is based on this observer. Our Lypunov H^1-stability analysis leads to LMIs, which are feasible for a large enough observer dimension and small enough Lipschitz constant.

Keywords: Distributed parameter systems, nonlinear systems, observer-based control, Lyapunov method.

1. INTRODUCTION

Observer-based control of parabolic PDEs is a challenging problem with numerous applications, including chemical reactors, flame propagation and viscous flow (Christofides [2001]). Output-feedback controllers for PDEs have been constructed by the modal decomposition approach (Curtain [1982], Lasiecka and Triggiani [2000], Orlov et al. [2004]), the backstepping method (Krstic and Smyshlyaev [2008]) and the spatial decomposition approach (Fridman and Blighovsky [2012], Kang and Fridman [2020]). Constructive finite-dimensional observer-based design for linear 1D parabolic PDEs was introduced in (Katz and Fridman [2020, 2021a]), via modal decomposition. The challenging problem of efficient finite-dimensional observer-based design for semilinear parabolic PDEs remained open.

State-feedback control of some semilinear PDEs was studied in (Vazquez and Krstic [2008]) using backstepping, in (Karafyllis and Krstic [2019]) using small-gain theorem and in (Karafyllis [2021]) via control Lyapunov functions. Recently, modal-decomposition-based state-feedback was proposed in (Katz and Fridman [2021b]) for global stabilization of heat equation and in (Katz and Fridman [2021a]) for regional stabilization of Kuramoto-Sivashinsky equation. Finite-dimensional control based on linear observers was proposed in (Wu et al. [2016]) for semilinear parabolic PDEs via modal decomposition. Linear observers should have high gains required to dominate the nonlinearity, which leads to small delays that preserve the stability (Lei and Khalil [2016], Najafi and Ekramian [2021]).

For semilinear parabolic PDEs, efficient finite-dimensional observer-based controller design remained an open challenging problems that we address in the present paper. We consider global stabilization of a semilinear heat equation under Neumann actuation and point measurement. The semilinarity is assumed to be globally Lipschitz in the state. Using dynamic extension and modal decomposition we derive nonlinear ODEs for the modes of the state. We then design a finite-dimensional *nonlinear* Luenberger observer, which takes into account the known semilinearity. The proposed controller is based on the nonlinear finite-dimensional observer. The challenge in the Lyapunov-based analysis is due to the coupling between the finite-dimensional and infinite-dimensional parts of the closed-loop system, introduced by both the semilinearity and the estimation error. Our H^1-stability analysis leads to LMIs, which are feasible for a large enough observer dimension and small enough Lipschitz constant. The results in this manuscript have been recently extended to finite-dimensional observer-based stabilization of a semilinear heat in the presence of large input delay in (Katz and Fridman [2022]).

Preliminaries: $L^2(0,1)$ is the space of Lebesgue measurable and square integrable functions $f:[0,1]\to\mathbb{R}$ with the inner product $\langle f,g\rangle := \int_0^1 f(x)g(x)dx$ and induced norm $\|f\|^2 := \langle f,f\rangle$. $H^k(0,1)$ is the Sobolev space of functions $f:[0,1]\to\mathbb{R}$ having k square integrable weak derivatives, with the norm $\|f\|_{H^k}^2 := \sum_{j=0}^k \left\|f^{(j)}\right\|^2$. The Euclidean norm on $\mathbb{R}^n$ is denoted by $|\cdot|$. For $P\in\mathbb{R}^{n\times n}$, $P>0$ means that P is symmetric and positive definite. The subdiagonal elements of a symmetric matrix will be denoted by $*$.

Consider the Sturm-Liouville eigenvalue problem

$$\phi''+\lambda\phi=0,\quad x\in(0,1) \tag{1.1}$$

with boundary conditions

$$\phi'(0)=\phi'(1)=0. \tag{1.2}$$

⋆ Supported by Israel Science Foundation (grant no. 673/19) and by C. and H. Manderman Chair at Tel Aviv University

This problem induces a sequence of eigenvalues with corresponding eigenfunctions. The normalized eigenfunctions form a complete orthonormal system in $L^2(0,1)$. The eigenvalues and corresponding eigenfunctions are given by

$$\begin{aligned}&\phi_0(x)\equiv 1,\ \phi_n(x)=\sqrt{2}\cos\left(\sqrt{\lambda_n}x\right),\\&\lambda_n=n^2\pi^2,\ n\in\mathbb{Z}_+.\end{aligned}\tag{1.3}$$

The following lemmas will be used:

Lemma 1.1. (Katz and Fridman [2020]) Let $h\overset{L^2}{=}\sum_{n=0}^{\infty}h_n\phi_n$. Then $h\in H^2(0,1)$ with $h'(0)=h'(1)=0$ if and only if $\sum_{n=1}^{\infty}\lambda_n^2h_n^2<\infty$. Moreover, $\|h'\|^2=\sum_{n=1}^{\infty}\lambda_nh_n^2$.

Lemma 1.2. (Sobolev's inequality, Kang and Fridman [2019]) Let $h\in H^1(0,1)$. Then, for all $\Gamma>0$, $max_{x\in[0,1]}|h(x)|^2\le(1+\Gamma)\|h\|^2+\Gamma^{-1}\|h'\|^2$.

2. FINITE-DIMENSIONAL OBSERVER-BASED CONTROL OF A SEMILINEAR HEAT EQUATION

We consider stabilization of the semilinear 1D heat equation

$$z_t(x,t)=z_{xx}(x,t)+g\left(t,x,z(x,t)\right),\ t\ge 0\tag{2.1}$$

where $x\in[0,1]$ and $z(x,t)\in\mathbb{R}$. We consider Neumann actuation

$$z_x(0,t)=0,\quad z_x(1,t)=u(t)\tag{2.2}$$

where $u(t)$ is a control input to be designed. We further assume point measurement given by

$$y(t)=z(x_*,t),\quad x_*\in[0,1].\tag{2.3}$$

Note that $x_*=0$ or $x_*=1$ correspond to boundary measurements. Here $g:\mathbb{R}^3\to\mathbb{R}$ is a locally Lipschitz function which satisfies $g(t,x,0)\equiv 0$ and

$$\sup_{z_1\ne z_2}\frac{|g(t,x,z_1)-g(t,x,z_2)|}{|z_1-z_2|}\le\sigma,\ \forall\,(t,x)\in\mathbb{R}^2\tag{2.4}$$

for some $\sigma>0$, independent of $(t,x)\in\mathbb{R}^2$.

Let $\psi(x)=-\frac{2}{\pi}\cos\left(\frac{\pi}{2}x\right)$ and note that it satisfies

$$\begin{aligned}&\psi''(x)=-\mu\psi(x),\quad \mu=\frac{\pi^2}{4},\\&\psi'(0)=0,\ \psi'(1)=1,\ \|\psi\|^2=\frac{2}{\pi^2}.\end{aligned}\tag{2.5}$$

Forthermore,

$$\langle\psi,\phi_0\rangle=\frac{4}{\pi^2},\ \langle\psi,\phi_n\rangle=\frac{\sqrt{2}(-1)^n}{\lambda_n-\mu},\ n\ge 1.\tag{2.6}$$

Similar to (Karafyllis [2021]), we introduce

$$w(x,t)=z(x,t)-\psi(x)u(t).\tag{2.7}$$

We define further the new control input $v(t)$ that satisfies the following relations:

$$\dot u(t)=-\mu u(t)+v(t),\quad u(0)=0,\quad t\ge 0.$$

Then we obtain the equivalent ODE-PDE system

$$\begin{aligned}&\dot u(t)=-\mu u(t)+v(t),\quad t\ge 0,\\&w_t(x,t)=w_{xx}(x,t)+g\left(t,x,w(x,t)+\psi(x)u(t)\right)\\&\qquad\quad -\psi(x)v(t),\\&w_x(0,t)=w_x(1,t)=0\end{aligned}\tag{2.8}$$

with measurement

$$y(t)=w(x_*,t)+\psi(x_*)u(t).\tag{2.9}$$

We will treat further $u(t)$ as an additional state variable.

We present the solution to (2.8) as

$$w(x,t)=\sum_{n=0}^{\infty}w_n(t)\phi_n(x),\ w_n(t)=\langle w(\cdot,t),\phi_n\rangle,\tag{2.10}$$

with $\{\phi_n\}_{n=0}^{\infty}$ defined in (1.3). By differentiating under the integral sign, integrating by parts and using (1.1) and (1.2) we obtain for $t\ge 0$

$$\begin{aligned}&\dot w_n(t)=-\lambda_nw_n(t)+g_n(t)+b_nv(t),\\&w_n(0)=\langle w(\cdot,0),\phi_n\rangle,\end{aligned}\tag{2.11}$$

where

$$\begin{aligned}&g_n(t)=\langle g\left(t,\cdot,w(\cdot,t)+\psi(\cdot)u(t)\right),\phi_n\rangle,\\&b_0\overset{(2.6)}{=}\frac{4}{\pi^2},\quad b_n\overset{(2.6)}{=}\frac{(-1)^{n+1}4\sqrt{2}}{\pi^2\left(4n^2-1\right)},\ n\ge 1.\end{aligned}\tag{2.12}$$

Note that given $N\in\mathbb{Z}_+$, (2.12) and the integral test for series convergence imply

$$\begin{aligned}&\sum_{n=N+1}^{\infty}\lambda_nb_n^2=\frac{32}{\pi^2}\sum_{n=N+1}^{\infty}\frac{n^2}{(4n^2-1)^2}\le\frac{2\xi_{N+1}}{\pi^2},\\&\xi_{N+1}=\left(1+\frac{1}{4(N+1)^2-1}\right)^2\frac{1}{N}.\end{aligned}\tag{2.13}$$

Let $\delta>0$ be a desired decay rate and let $N_0\in\mathbb{Z}_+$ satisfy

$$-\lambda_n+\sigma<-\delta,\quad n>N_0.\tag{2.14}$$

N_0 is the number of modes in our controller, whereas $N\in\mathbb{Z}_+$, $N\ge N_0$ is the observer dimension. We construct a finite-dimensional observer of the form

$$\hat w(x,t)=\sum_{n=0}^{N}\hat w_n(t)\phi_n(x)\tag{2.15}$$

where $\{\hat w_n(t)\}_{n=0}^{N}$ satisfy the *nonlinear* ODEs

$$\begin{aligned}&\dot{\hat w}_n(t)=-\lambda_n\hat w_n(t)+\hat g_n(t)+b_nv(t)\\&-l_n\left[\hat w(x_*,t)+\psi(x_*)u(t)-y(t)\right],\ 0\le n\le N\end{aligned}\tag{2.16}$$

with scalar observer gains $\{l_n\}_{n=0}^{N}$ and

$$\hat g_n(t)=\langle g\left(t,\cdot,\hat w(\cdot,t)+\psi(\cdot)u(t)\right),\phi_n\rangle,\ 0\le n\le N.\tag{2.17}$$

In particular, we approximate the projections of the semilinearity $g(t,x,w(x,t)+\psi(x)u(t))$ onto $\{\phi_n\}_{n=0}^{N}$ by the projections of $g(t,x,\hat w(x,t)+\psi(x)u(t))$ onto $\{\phi_n\}_{n=0}^{N}$.

Assumption 1: The point $x_*\in[0,1]$ satisfies

$$c_n=\phi_n(x_*)\ne 0,\quad 0\le n\le N_0.\tag{2.18}$$

Note that Assumption 1 holds for the particular case of boundary measurements $x_*=0$ or $x_*=1$.

Denote

$$\begin{aligned}&\tilde A_0=\mathrm{diag}\left\{-\mu,A_0\right\},\quad \tilde B_0=\mathrm{col}\left\{1,B_0\right\}\\&A_0=\mathrm{diag}\left\{-\lambda_n\right\}_{n=0}^{N_0},\quad B_0=\mathrm{col}\left\{b_n\right\}_{n=0}^{N_0}\\&C_0=[c_0,\ldots,c_{N_0}],\quad C_1=[c_{N_0+1},\ldots,c_N],\end{aligned}\tag{2.19}$$

Under Assumption 1, the pair (A_0,C_0) is observable by the Hautus lemma. Let $L_0=\{l_n\}_{n=0}^{N_0}\in\mathbb{R}^{N_0+1}$ satisfy the Lyapunov inequality

$$P_{\mathrm{o}}(A_0-L_0C_0)+(A_0-L_0C_0)^TP_{\mathrm{o}}<-2\delta P_{\mathrm{o}}\tag{2.20}$$

with $0<P_{\mathrm{o}}\in\mathbb{R}^{(N_0+1)\times(N_0+1)}$. We further choose the remaining gains as $l_n=0,\ N_0+1\le n\le N$.

Similarly, by the Hautus lemma, the pair $(\tilde A_0,\tilde B_0)$ is controllable. Let $K_0\in\mathbb{R}^{1\times(N_0+2)}$ satisfy

$$P_{\mathrm{c}}(\tilde A_0-\tilde B_0K_0)+(\tilde A_0-\tilde B_0K_0)^TP_{\mathrm{c}}<-2\delta P_{\mathrm{c}},\tag{2.21}$$

with $0 < P_{\mathrm{c}} \in \mathbb{R}^{(N_0+2)\times(N_0+2)}$. We propose the controller

$$v(t) = -K_0\hat{w}^{N_0}(t),\ \hat{w}^{N_0}(t) = \mathrm{col}\left\{u(t), \hat{w}_n(t)\right\}_{n=0}^{N_0} \tag{2.22}$$

which is based on the finite-dimensional observer (2.15).

For well-posedness of the closed-loop system (2.7), (2.16) subject to the control law (2.22), consider the operator $\mathcal{A} : \mathcal{D}(\mathcal{A}) \to L^2(0,1)$, $\mathcal{A} = -\partial_{xx}$ with $\mathcal{D}(\mathcal{A}) = \left\{h \in H^2(0,1) \mid h'(0) = h'(1) = 0\right\}$. Let $\theta > 0$ and $\mathcal{A}_\theta = \mathcal{A} + \theta I$. $-\mathcal{A}_\theta$ generates an analytic semigroup on $L^2(0,1)$. Moreover, there exists a unique positive root $\mathcal{A}_\theta^{\frac{1}{2}}$ with $\mathcal{D}\left(\mathcal{A}_\theta^{\frac{1}{2}}\right) = H^1(0,1)$. Let $\mathcal{H} = L^2(0,1)\times\mathbb{R}^{N+2}$ be a Hilbert space with the norm $\|\cdot\|_{\mathcal{H}}^2 := \|\cdot\|^2 + |\cdot|^2$. Introducing

$$\begin{aligned}&\xi(t) = \mathrm{col}\left\{\xi_1(t), \xi_2(t)\right\},\ \xi_1(t) = w(\cdot,t),\ \xi_2(t) = \hat{w}^N(t),\\ &\hat{w}^N(t) = \mathrm{col}\left\{u(t), \hat{w}_0(t), \dots, \hat{w}_N(t)\right\}\end{aligned} \tag{2.23}$$

the closed-loop system can be presented as

$$\begin{aligned}&\frac{d\xi}{dt}(t) + \mathrm{diag}\left\{\mathcal{A}_\theta, \mathcal{B}\right\}\xi(t) = \begin{bmatrix} f_1(\xi) \\ f_2(\xi)\end{bmatrix},\\ &\mathcal{D}(\mathcal{B}) = \mathbb{R}^{N+2},\ \mathcal{B}a = \begin{bmatrix} -\tilde{A}_0 + \tilde{B}_0K_0 + \tilde{L}_0[0\ C_0] & \tilde{L}_0C_1 \\ B_1K_0 & -A_1\end{bmatrix} a\\ &f_1(t,\xi) = \theta w(\cdot,t) + g\left(t,\cdot,w(\cdot,t) + \psi(\cdot)u(t)\right)\\ &\qquad +\psi(\cdot)K_0\hat{w}^{N_0}(t),\\ &f_2(t,\xi) = \mathrm{col}\left\{\hat{G}^{N_0}(t) + \tilde{L}_0 w(x_*,t), \hat{G}^{N-N_0}(t)\right\},\\ &\hat{G}^{N_0}(t) = \mathrm{col}\left\{0, \hat{g}_n(t)\right\}_{n=0}^{N_0},\\ &\hat{G}^{N-N_0}(t) = \mathrm{col}\left\{\hat{g}_n(t)\right\}_{n=N_0+1}^{N},\ \tilde{L}_0 = \mathrm{col}\left\{0, l_n\right\}_{n=0}^{N_0},\\ &A_1 = \mathrm{diag}\left\{-\lambda_n\right\}_{n=N_0+1}^{N},\ B_1 = \mathrm{col}\left\{b_n\right\}_{n=N_0+1}^{N}.\end{aligned} \tag{2.24}$$

It can be shown that given $w(\cdot,0) \in H^1(0,1)$, the system (2.24) has a unique classical solution satisfying $\xi \in C\left([0,\infty);\mathcal{H}\right) \cap C^1\left((0,\infty);\mathcal{H}\right)$ and such that $\xi(t) \in \mathcal{D}\left(\mathrm{diag}\left\{\mathcal{A}_\theta, \mathcal{B}\right\}\right) = \mathcal{D}(\mathcal{A}) \times \mathbb{R}^{N+2}\ \ \forall t > 0$. Details are omitted due to space constraints (see (Katz and Fridman [2022])).

Introduce the estimation error $e_n(t) = w_n(t) - \hat{w}_n(t)$, $0 \le n \le N_0$. Using the estimation error and $\{c_n\}_{n=0}^N$ in (2.19), the innovation term in (2.16) can be presented as

$$\begin{aligned}&\hat{w}(x_*,t) + \psi(x_*)u(t) - y(t) = \hat{w}(x_*,t) - w(x_*,t)\\ &= -\sum_{n=0}^{N} c_n e_n(t) - \zeta(t),\ \zeta(t) = w(0,t) - \sum_{n=0}^{N} w_n(t)\phi_n.\end{aligned} \tag{2.25}$$

Let $\Gamma > 0$. By Lemmas 1.1 and 1.2 we have

$$\zeta^2(t) \le \sum_{n=N+1}^{\infty} \kappa_n w_n^2(t),\ \kappa_n = 1 + \Gamma + \Gamma^{-1}\lambda_n. \tag{2.26}$$

Taking into account (2.11), (2.16), (2.19) and (2.25), the estimation error satisfies the following ODEs

$$\begin{aligned}&\dot{e}_n(t) = -\lambda_n e_n(t) + h_n(t)\\ &\qquad -l_n\sum_{n=0}^{N} c_n e_n(t) - l_n\zeta(t),\ 0 \le n \le N_0,\\ &\dot{e}_n(t) = -\lambda_n e_n(t) + h_n(t),\ N_0 + 1 \le n \le N.\end{aligned} \tag{2.27}$$

where we define

$$h_n(t) = g_n(t) - \hat{g}_n(t), \quad n \ge 0. \tag{2.28}$$

Recall (2.19) and denote

$$\begin{aligned}&\hat{w}^{N-N_0}(t) = \mathrm{col}\left\{\hat{w}_n(t)\right\}_{n=N_0+1}^{N},\ e^{N_0}(t) = \mathrm{col}\left\{e_n(t)\right\}_{n=0}^{N_0},\\ &e^{N-N_0}(t) = \mathrm{col}\left\{e_n(t)\right\}_{n=N_0+1}^{N},\ H^{N_0}(t) = \mathrm{col}\left\{h_n(t)\right\}_{n=0}^{N_0},\\ &H^{N-N_0}(t) = \mathrm{col}\left\{h_n(t)\right\}_{n=N_0+1}^{N},\ L_\zeta = \mathrm{col}\left\{\tilde{L}_0, -L_0, 0, 0\right\},\\ &X(t) = \mathrm{col}\left\{\hat{w}^{N_0}(t), e^{N_0}(t), \hat{w}^{N-N_0}(t), e^{N-N_0}(t)\right\},\\ &\hat{G}(t) = \mathrm{col}\left\{\hat{G}^{N_0}(t), 0, \hat{G}^{N-N_0}(t), 0\right\},\ K_X = [K_0, 0, 0, 0],\\ &H(t) = \mathrm{col}\left\{0, H^{N_0}(t), 0, H^{N-N_0}(t)\right\}.\end{aligned} \tag{2.29}$$

Using (2.11), (2.16) - (2.19), (2.22), (2.25), (2.27) and (2.29), the closed-loop system for $t \ge 0$ is presented as

$$\begin{aligned}&\dot{X}(t) = F_X X(t) + L_\zeta\zeta(t) + \hat{G}(t) + H(t),\\ &\dot{w}_n(t) = -\lambda_n w_n(t) + \hat{g}_n(t) + h_n(t)\\ &\qquad -b_n K_X X(t),\ n > N,\\ &F_X = \begin{bmatrix} \tilde{A}_0 - \tilde{B}_0K_0 & \tilde{L}_0C_0 & 0 & \tilde{L}_0C_1 \\ 0 & A_0 - L_0C_0 & 0 & -L_0C_1 \\ -B_1K_0 & 0 & A_1 & 0 \\ 0 & 0 & 0 & A_1\end{bmatrix}.\end{aligned} \tag{2.30}$$

For H^1-stability analysis of the closed-loop system (2.30) we consider the Lyapunov function

$$V(t) = X^T(t)P_X X(t) + \sum_{n=N+1}^{\infty} \lambda_n w_n^2(t) \tag{2.31}$$

where $0 < P_X \in \mathbb{R}^{(2N+3)\times(2N+3)}$. Differentiating $V(t)$ along the solution to the closed-loop system (2.30) we have

$$\begin{aligned}&\dot{V} + 2\delta V = 2X^T(t)\left[P_X F_X + F_X^T P_X + 2\delta P_X\right]X(t)\\ &+2X^T(t)P_X L_\zeta\zeta(t) + 2X^T(t)P_X\hat{G}(t) + 2X^T(t)P_X H(t)\\ &+2\sum_{n=N+1}^{\infty}\left(-\lambda_n^2 + \delta\lambda_n\right)w_n^2(t)\\ &+2\sum_{n=N+1}^{\infty}\lambda_n w_n(t)\left[\hat{g}_n(t) + h_n(t) - b_N K_X X(t)\right].\end{aligned} \tag{2.32}$$

Let $\alpha_1 > 0$, we compensate the series with $\{\hat{g}_n(t)\}_{n=N+1}^{\infty}$ by using the Young inequality

$$\begin{aligned}&2\sum_{n=N+1}^{\infty}\lambda_n w_n(t)\hat{g}_n(t) \le \frac{1}{\alpha_1}\sum_{n=N+1}^{\infty}\lambda_n^2 w_n^2(t)\\ &-\alpha_1\left|\hat{G}(t)\right|^2 + \alpha_1\sum_{n=0}^{\infty}\hat{g}_n^2(t),\\ &\alpha_1\sum_{n=0}^{\infty}\hat{g}_n^2(t) \overset{(2.4)}{\le} 2\alpha_1\sigma^2 X^T(t)\Xi_X X(t)\\ &\Xi_X \overset{(2.5)}{=} \mathrm{diag}\left\{\frac{2}{\pi^2}, I_{N_0+1}, 0, I_{N-N_0}, 0\right\}.\end{aligned} \tag{2.33}$$

Similarly, introducing $\alpha_2 > 0$ we have

$$\begin{aligned}&2\sum_{n=N+1}^{\infty}\lambda_n w_n(t)h_n(t) \le \frac{1}{\alpha_2}\sum_{n=N+1}^{\infty}\lambda_n^2 w_n^2(t)\\ &-\alpha_2\left|H(t)\right|^2 + \alpha_2\sigma^2 X^T(t)\Xi_E X(t) + \alpha_2\sigma^2\sum_{n=N+1}^{\infty} w_n^2(t),\\ &\Xi_E = \mathrm{diag}\left\{0, I_{N_0}, 0, I_{N-N_0}\right\} \in \mathbb{R}^{(2N+3)\times(2N+3)}.\end{aligned} \tag{2.34}$$

We bound the last term in (2.32) by using Young's inequality with some $\alpha_3 > 0$:

$$2\sum_{n=N+1}^{\infty}\lambda_n w_n(t)\left(-b_n K_X X(t)\right)\overset{(2.13)}{\leq}\frac{1}{\alpha_3}\sum_{n=N+1}^{\infty}\lambda_n w_n^2(t)+\frac{2\alpha_3\xi_{N+1}}{\pi^2}\left|K_X X(t)\right|^2. \tag{2.35}$$

Let $\rho_n=\kappa_n^{-1}\left(-\lambda_n^2+\delta\lambda_n+\frac{\lambda_n}{2\alpha_3}+\frac{\lambda_n^2}{2\alpha_2}+\frac{\lambda_n^2}{2\alpha_2}+\frac{\alpha_2\sigma^2}{2}\right)$ for $n\geq N$. Assuming that $\rho_{N+1}<0$, it can be seen that ρ_n is monotonically decreasing. The latter follows from monotonicity of λ_n. Then

$$\sum_{n=N+1}^{\infty}\left(-\lambda_n^2+\delta\lambda_n+\frac{\lambda_n}{2\alpha_3}+\frac{\lambda_n^2}{2\alpha_1}+\frac{\lambda_n^2}{2\alpha_2}+\frac{\alpha_2\sigma^2}{2}\right)w_n^2(t)=\sum_{n=N+1}^{\infty}\rho_n\kappa_n w_n^2(t)\overset{(2.26)}{\leq}\rho_{N+1}\zeta^2(t). \tag{2.36}$$

Let $\eta(t)=\operatorname{col}\left\{X(t),\zeta(t),\hat{G}(t),H(t)\right\}$. From (2.32)-(2.36) we have $\dot{V}+2\delta V\leq\eta^T(t)\Psi_0\eta(t)\leq 0$, provided

$$\Psi_0=\left[\begin{array}{cc|cc}\psi_0 & P_X L_\zeta & P_X & P_X\\ * & 2\rho_{N+1} & 0 & 0\\ \hline * & & \multicolumn{2}{c}{\operatorname{diag}\{-\alpha_1 I,-\alpha_2 I\}}\end{array}\right]<0,\ \psi_0=P_X F_X$$
$$F_X^T P_X+2\delta P_X+\frac{2\alpha_3\xi_{N+1}}{\pi^2}K_X^T K_X+2\alpha_1\sigma^2\Xi_X+\alpha_2\sigma^2\Xi_E \tag{2.37}$$

Summarizing, we arrive at

Theorem 2.1. Consider the system (2.8) with point measurement (2.9) and control law (2.22). Assume that $g(t,x,z)$ is a locally Lipschitz function satisfying $g(t,x,0)\equiv 0$ and (2.4) for a given $\sigma>0$. Let $\delta>0$, $N_0\in\mathbb{N}$ satisfy (2.14) and $N\in\mathbb{N}$ satisfy $N_0\leq N$. Let L_0 and K_0 be obtained using (2.20) and (2.21), respectively. Given $\Gamma>0$, let there exist $0<P\in\mathbb{R}^{(2N+3)\times(2N+3)}$ and scalars $\alpha_1,\alpha_2,\alpha_3>0$ such that (2.37) holds. Then, given $w(\cdot,0)\in H^1(0,1)$, the classical solution $u(t),w(x,t)$ of (2.8) subject to the control law (2.22) and the observer $\hat{w}(x,t)$ defined by (2.15)-(2.17), satisfy $u^2(t)+\|w(\cdot,t)\|_{H^1}^2+\|\hat{w}(\cdot,t)\|_{H^1}^2\leq De^{-2\delta t}\|w(\cdot,0)\|_{H^1}^2$ for $t\geq 0$ and some $D\geq 1$. Moreover, (2.37) is always feasible for N large enough and $\sigma>0$ small enough.

3. CONCLUSIONS

We studied global boundary stabilization of a semilinear heat equation under point measurement. Taking into accound the known globally Lipschitz semilinearity, we suggested a finite-dimensional nonlinear observer-based controller. Our H^1-stability analysis leads to LMIs, which are feasible for a large enough observer dimension and small enough Lipschitz constant. Our method can be extended to other semilinear PDEs. Numerical examples can be found in the recent paper (Katz and Fridman [2022]), which extends the results presented here to systems with large input delays.

Abstract: We consider deterministic mean field games in which the agents control their acceleration and are constrained to remain in a region of $\mathbb{R}^n$. We study relaxed equilibria in the Lagrangian setting; they are described by a probability measure on trajectories. The main results of the paper concern the existence of relaxed equilibria under suitable assumptions. The fact that the optimal trajectories of the related optimal control problem solved by the agents do not form a compact set brings a difficulty in the proof of existence. The proof also requires closed graph properties of the map which associates to initial conditions the set of optimal trajectories.

Keywords: Mean field games, double integrators, Lagrangian formulation, existence of equilibria, closed graph properties
AMS: 91A13

1. INTRODUCTION

The theory of mean field games (MFGs for short) is more and more investigated since the pioneering works Lasry and Lions (2006a,b, 2007) of Lasry and Lions: it aims at studying the asymptotic behaviour of differential games (Nash equilibria) as the number of agents tends to infinity. The dynamics of the agents can be either stochastic or deterministic. Concerning the latter case, we refer to Cardaliaguet (2010) for a detailed study of deterministic MFGs in which the interactions between the agents are modeled by a nonlocal regularizing operator acting on the distribution of the states of the agents. They are described by a system of PDEs coupling a continuity equation for the density of the distribution of states (forward in time) and a Hamilton-Jacobi (HJ) equation for the optimal value of a representative agent (backward in time). If the interaction cost depends locally on the density of the distribution (hence is not regularizing), then, in the deterministic case, the available theory mostly deals with so-called variational MFGs, see Cardaliaguet et al. (2015).

Part of the research was completed while YA was on leave at INRIA-Paris in the project Matherials. PM and CM were partially supported by GNAMPA-INdAM and by the Fondazione CaRiPaRo Project "Nonlinear Partial Differential Equations: Asymptotic Problems and Mean-Field Games".

The major part of the literature on deterministic mean field games addresses situations when the dynamics of a given agent is strongly controllable: for example, in crowd motion models, this happens if the control of a given agent is its velocity. Under the strong controllability assumption, it is possible to study realistic models in which the agents are constrained to remain in a given region K of the space state, i.e. state constrained deterministic MFGs. An important difficulty in state constrained deterministic MFGs is that nothing prevents the agents from concentrating on the boundary ∂K of the state space; let us call $m(t)$ the distribution of states at time t. Even if $m(0)$ is absolutely continuous, there may exist some $t > 0$, such that $m(t)$ has a singular part supported on ∂K and the absolute continuous part of $m(t)$ with respect to Lebesgue measure blows up near ∂K. This was first observed in some applications of MFGs to macroeconomics, see Achdou et al. (2014, 2021). From the theoretical viewpoint, the main issue is that, as we have already said, the distribution of states is generally not absolutely continuous with respect to Lebesgue measure; this makes it difficult to characterize the state distribution by means of partial differential equations. These theoretical difficulties have been addressed in Cannarsa and Capuani (2018): following ideas contained in Benamou and Brenier (2000); Benamou and Carlier (2015); Cardaliaguet et al. (2016), the authors of Cannarsa and Capuani (2018) introduce a weak or relaxed notion of equilibrium, which is defined in a Lagrangian setting rather than with PDEs. Because there may be several

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

optimal trajectories starting from a given point in the state space, the solutions of the relaxed MFG are probability measures defined on a set of admissible trajectories. Once the existence of a relaxed equilibrium is ensured, it is then possible to investigate the regularity of solutions and give a meaning to the system of PDEs and the related boundary conditions: this was done in Cannarsa et al. (2021).

On the other hand, if the agents control their acceleration instead of their velocity, the strong controllability property is lost. In Achdou et al. (2020), we have studied deterministic mean field games in the whole space $\mathbb{R}^n$ with finite time horizon T in which the dynamics of a generic agent is controlled by the acceleration. In traffic theory and also in economics, the models may require that the positions of the agents belong to a given compact subset $\overline{\Omega}$ of $\mathbb{R}^n$, and state constrained mean field games with control on the acceleration must be considered. In the present paper, we wish to investigate some examples of such mean field games and address the first step of the program followed by the authors of Cannarsa and Capuani (2018) in the strongly controllable case: we wish to prove the existence of a relaxed mean field equilibrium in the Lagrangian setting under suitable assumptions (see Definition 1 below).

The proof of existence of an equilibrium in the Lagrangian setting involves Kakutani's fixed point theorem, see Glicksberg (1952), applied to a multivalued map defined on a convex and compact set of probability measures on a suitable set of admissible trajectories (itself endowed with the $C^1([0,T];\mathbb{R}^n)\times C^0([0,T];\mathbb{R}^n)$-topology). Difficulties in applying Kakutani's fixed point theorem will arise from the fact that all the optimal trajectories do not form a compact subset of $C^1([0,T];\mathbb{R}^n)\times C^0([0,T];\mathbb{R}^n)$ (due to the lack of strong controllability). This explains why we shall need additional assumptions on the support of the initial distribution of states, see hypothesis 3 below.

2. SETTING AND MAIN RESULTS

2.1 Setting and notation

Let Ω be a bounded domain of $\mathbb{R}^n$ with a boundary $\partial\Omega$ of class C^2. For $x\in\partial\Omega$, let $n(x)$ be the unitary vector normal to $\partial\Omega$ pointing outward Ω. We will use the signed distance to $\partial\Omega$, $d:\mathbb{R}^n\to\mathbb{R}$,

$$d(x)=\begin{cases}\min\limits_{y\in\partial\Omega}|x-y|, & \text{if} \quad x\notin\Omega,\\ -\min\limits_{y\in\partial\Omega}|x-y|, & \text{if} \quad x\in\Omega.\end{cases}$$

Since $\partial\Omega$ is C^2, the function d is C^2 near $\partial\Omega$. In particular, for all $x\in\partial\Omega$, $\nabla d(x)=n(x)$.

Given a time horizon T and a pair $(x,v)\in\overline{\Omega}\times\mathbb{R}^n$, we are interested in mean field games in which the dynamics of an agent is of the form:

$$\begin{cases}\xi'(s) = \eta(s), & s\in(0,T),\\ \eta'(s) = \alpha(s), & s\in(0,T),\\ \xi(0) = x,\\ \eta(0) = v.\end{cases}\tag{1}$$

The state space is $\Xi=\overline{\Omega}\times\mathbb{R}^n$. It is convenient to define the set of admissible trajectories as follows:

$$\Gamma=\left\{\begin{array}{l}(\xi,\eta)\in C^1([0,T];\mathbb{R}^n)\times AC([0,T];\mathbb{R}^n),\\ \xi'(s)=\eta(s),\ \forall s\in[0,T],\\ (\xi(s),\eta(s))\in\Xi,\forall s\in[0,T].\end{array}\right\}.\tag{2}$$

It is a metric space with the distance $d((\xi,\eta),(\tilde{\xi},\tilde{\eta}))=\|\xi-\tilde{\xi}\|_{C^1([0,T];\mathbb{R}^n)}$.
For any $(x,v)\in\Xi$, set

$$\Gamma[x,v]=\{(\xi,\eta)\in\Gamma:\ \xi(0)=x,\ \eta(0)=v\}.\tag{3}$$

Note that $\Gamma[x,v]=\emptyset$ if $x\in\partial\Omega$ and v points outward Ω. This is the reason why we introduce $\Xi^{\rm ad}$ as follows:

$$\Xi^{\rm ad}=\{(x,v):x\in\overline{\Omega},\ v\cdot n(x)\le 0 \text{ if } x\in\partial\Omega\}\subset\Xi.\tag{4}$$

Let $\mathcal{P}(\Xi)$ be the set of probability measures on Ξ.
Let $C_b^0(\Xi;\mathbb{R})$ denote the space of bounded and continuous real valued functions defined on Ξ and let $F,G:\mathcal{P}(\Xi)\to C_b^0(\Xi;\mathbb{R})$ be bounded and continuous maps (the continuity is with respect to the narrow convergence in $\mathcal{P}(\Xi)$). Let L be a real valued, continuous and bounded from below function defined on $\Xi\times[0,T]$. Let $F[m]$ and $G[m]$ denote the images by F and G of $m\in\mathcal{P}(\Xi)$. For what follows, it is useful to introduce the positive constant $M=\sup_{(x,v,s)\in\Xi\times[0,T]}L_-(x,v,s)+\sup_{m\in\mathcal{P}(\Xi)}\|F[m]\|_{L^\infty(\Xi)}+\sup_{m\in\mathcal{P}(\Xi)}\|G[m]\|_{L^\infty(\Xi)}$. Let $\mathcal{P}(\Gamma)$ be the set of probability measures on Γ.
For $t\in[0,T]$, the evaluation map $e_t:\Gamma\to\Xi$ is defined by $e_t(\xi,\eta)=(\xi(t),\eta(t))$ for all $(\xi,\eta)\in\Gamma$.
For any $\mu\in\mathcal{P}(\Gamma)$, let the Borel probability measure $m^\mu(t)$ on Ξ be defined by $m^\mu(t)=e_t\sharp\mu$. It is possible to prove that if $\mu\in\mathcal{P}(\Gamma)$, then $t\mapsto m^\mu(t)$ is continuous from $[0,T]$ to $\mathcal{P}(\Xi)$, for the narrow convergence in $\mathcal{P}(\Xi)$. Hence, for all $(\xi,\eta)\in\Gamma$, $t\mapsto F[m^\mu(t)](\xi(t),\eta(t))$ is continuous and bounded by the constant M.

With $\mu\in\mathcal{P}(\Gamma)$ and $(\xi,\eta)\in\Gamma$, we associate the cost
$J^\mu(\xi,\eta)=$

$$\int_0^T\left(F[m^\mu(s)](\xi(s),\eta(s))+L(\xi(s),\eta(s),s)+\frac{1}{2}\left|\frac{d\eta}{dt}(s)\right|^2\right)+G[m^\mu(T)](\xi(T),\eta(T))\tag{5}$$

Definition 1. Given $m_0\in\mathcal{P}(\Xi)$, let $\mathcal{P}_{m_0}(\Gamma)$ denote the set of probability measures μ on Γ such that $e_0\sharp\mu=m_0$.
The probability measure $\mu\in\mathcal{P}_{m_0}(\Gamma)$ is a constrained mean field game equilibrium associated with the initial distribution m_0 if

$$\mathrm{supp}(\mu)\subset\bigcup_{(x,v)\in\mathrm{supp}(m_0)}\Gamma^{\mu,\mathrm{opt}}[x,v].\tag{6}$$

where

$$\Gamma^{\mu,\mathrm{opt}}[x,v]=\left\{(\xi,\eta)\in\Gamma[x,v]\ :\ J^\mu(\xi,\eta)=\min_{(\widetilde{\xi},\widetilde{\eta})\in\Gamma[x,v]}J^\mu(\widetilde{\xi},\widetilde{\eta})\right\},$$

2.2 Closed graph properties and bounds related to optimal trajectories

In all what follows, L,F and G satisfy the assumptions made in §2.1. An important step in the proof of existence of constrained mean field game equilibria is the closed graph property:

Proposition 1. Consider a closed subset Θ of $\Xi^{\rm ad}$. Given $\mu\in\mathcal{P}(\Xi)$, assume that for all sequences $(x^i,v^i)_{i\in\mathbb{N}}$ such that for all $i\in\mathbb{N}$, $(x^i,v^i)\in\Theta$ and $\lim\limits_{i\to+\infty}(x^i,v^i)=(x,v)\in\Theta$, the following holds: if $x\in\partial\Omega$, then

$$\left((v^i \cdot \nabla d(x^i))_+\right)^3 = o\left(\left|d(x^i)\right|\right), \tag{7}$$

(note that (7) is meaningful for i large enough, because d is C^1 near $\partial\Omega$); then the graph of the multivalued map

$$\Gamma^{\rm opt} : \Theta \rightrightarrows \Gamma,$$
$$(x,v) \mapsto \Gamma^{\mu,{\rm opt}}[x,v]$$

is closed, which means: for any sequence $(y^i,w^i)_{i\in\mathbb{N}}$ such that for all $i\in\mathbb{N}$, $(y^i,w^i)\in\Theta$ with $(y^i,w^i)\to(y,w)$ as $i\to\infty$, consider a sequence $(\xi^i,\eta^i)_{i\in\mathbb{N}}$ such that for all $i\in\mathbb{N}$, $(\xi^i,\eta^i)\in\Gamma^{\rm opt}[y^i,w^i]$; if (ξ^i,η^i) tends to (ξ,η) uniformly, then $(\xi,\eta)\in\Gamma^{\mu,{\rm opt}}[y,w]$.

Definition 2. For numbers r and C, let us set

$$K_r = \{(x,v)\in\Xi :\ |v|\le r\}, \tag{8}$$

$$\Gamma_C = \left\{ (\xi,\eta)\in\Gamma : \left| \begin{array}{l} (\xi(t),\eta(t))\in K_C, \quad \forall t\in[0,T], \\ \left\| \dfrac{d\eta}{dt} \right\|_{L^2(0,T;\mathbb{R}^n)} \le C \end{array} \right. \right\} \tag{9}$$

The set Γ_C is a compact subset of Γ.

Proposition 2. Given $r>0$, let us define

$$\Theta_r = \Theta \cap K_r, \tag{10}$$

where K_r is defined by (8) and Θ is a closed subset of $\Xi^{\rm ad}$ which satisfies the assumption in Proposition 1.
The value function

$$u^\mu(x,v) = \inf_{(\xi,\eta)\in\Gamma[x,v]} J^\mu(\xi,\eta,\eta') \tag{11}$$

is continuous on Θ_r and there exists a positive number $C=C(r,M)$ independent of $\mu\in\mathcal{P}(\Xi)$ such that if $(x,v)\in\Theta_r$, then $\Gamma^{\mu,{\rm opt}}[x,v]\subset\Gamma_C$.

Hypothesis 3. There exists a positive number r such that the initial distribution of states is a probability measure m_0 on Ξ supported in Θ_r, where Θ_r is a closed subset of $\Xi^{\rm ad}$ as in (10).

Let $C=C(r,M)$ be the constant appearing in Proposition 2 (uniform w.r.t. μ), and Γ_C be the compact subset of Γ defined by (9); clearly, Γ_C is a Radon metric space. From Prokhorov theorem, see (Ambrosio et al., 2005, Theorem 5.1.3), the set $\mathcal{P}(\Gamma_C)$ is compact for the narrow convergence of measures.

As above, $\mathcal{P}_{m_0}(\Gamma_C))$ denotes the set of probability measures μ on Γ_C such that $e_0\sharp\mu = m_0$.

Remark 1. Note that Γ_C (endowed with the metric of the $C^1\times C^0$-convergence of (ξ,η)) is a Polish space (because it is compact). Using Kuratowski and Ryll-Nardzewski theorem, Kuratowski and Ryll-Nardzewski (1965), it can be proved that there exists a measurable selection $j:\Theta_r\to\Gamma_C$. Then $j\sharp m_0$ belongs to $\mathcal{P}_{m_0}(\Gamma_C)$. The set $\mathcal{P}_{m_0}(\Gamma_C)$ is not empty.

Standard arguments from the calculus of variations yield that for each $\mu\in\mathcal{P}_{m_0}(\Gamma_C)$ and $(x,v)\in\Xi^{\rm ad}$, $\Gamma^{\mu,{\rm opt}}[x,v]$ is not empty. Moreover, from Proposition 2, $\Gamma^{\mu,{\rm opt}}[x,v]\subset\Gamma_C$ for all $(x,v)\in\Theta_r$.

Proposition 4. Under Hypothesis 3, let $C=C(r,M)$ be chosen as in Proposition 2.
Let a sequence of probability measures $(\mu_i)_{i\in\mathbb{N}}$, $\mu_i\in\mathcal{P}_{m_0}(\Gamma_C)$, be narrowly convergent to $\mu\in\mathcal{P}(\Gamma_C)$. Let $(x^i,v^i)_{i\in\mathbb{N}}$ be a sequence with $(x^i,v^i)\in\Theta_r$ which converges to (x,v). Consider a sequence $(\xi^i,\eta^i)_{i\in\mathbb{N}}$ such that for all $i\in\mathbb{N}$, $(\xi^i,\eta^i)\in\Gamma^{\mu_i,{\rm opt}}[x^i,v^i]$. If $(\xi^i,\eta^i)_{i\in\mathbb{N}}$ tends to (ξ,η) uniformly, then $(\xi,\eta)\in\Gamma^{\mu,{\rm opt}}[x,v]$. In other words, the multivalued map $(x,v,\mu)\mapsto\Gamma^{\mu,{\rm opt}}[x,v]$ has closed graph.

2.3 Existence of a mean field game equilibrium

Theorem 5. Under the assumptions made on L, F and G in §2.1 and Hypothesis 3, let $C=C(r,M)$ be chosen as in Proposition 2. There exists a constrained mean field game equilibrium $\mu\in\mathcal{P}_{m_0}(\Gamma_C)$, see Definition 1. Moreover, $t\mapsto e_t\sharp\mu\in C^{1/2}([0,T];\mathcal{P}(K_C))$, ($K_C$ is defined in (8) and $\mathcal{P}(K_C)$ is endowed with the Kantorovitch-Rubinstein distance).

The proof of Theorem 5 is inspired from that of Cannarsa and Capuani in Cannarsa and Capuani (2018). It consists of applying Kakutani's fixed point theorem to the multivalued map E from $\mathcal{P}_{m_0}(\Gamma_C)$ to $\mathcal{P}_{m_0}(\Gamma_C)$ as follows: for any $\mu\in\mathcal{P}_{m_0}(\Gamma_C)$,

$$E(\mu) = \left\{ \hat\mu\in\mathcal{P}_{m_0}(\Gamma_C)\ : \ {\rm supp}(\hat\mu_{(x,v)})\subset\Gamma^{\mu,{\rm opt}}[x,v] \text{ for } m_0\text{-a-a } (x,v)\in\Xi \right\},$$

where $(\hat\mu_{(x,v)})_{(x,v)\in\Xi}$ is the m_0-almost everywhere uniquely defined Borel measurable family of probability measures which disintegrates $\hat\mu$. For that, a key step is Proposition 4.

Remark 2. In dimension one and for a running cost quadratic in α, it is possible to obtain refined results under a slightly stronger assumption on the running cost, namely that it does not favor the trajectories which exit the domain. In particular, the closed graph property can be proved to hold on the whole set $\Xi^{\rm ad}$, and concerning mean field games, no assumptions are needed on the support of m_0 by contrast with Theorem 5.

Definition 3. A pair (u,m), where u is a measurable function defined on $\Xi\times[0,T]$ and $m\in C^0([0,T];\mathcal{P}(\Xi))$, is called *a mild solution of the mean field game*, if there exists a constrained mean fied game equilibrium μ for m_0 (see Definition 1) such that:

i) $m(t)=e_t\sharp\mu$;
ii) $\forall(x,v)\in\Xi^{\rm ad}$, $u(x,v,t)$ is given by

$$u(x,v,t) = \inf_{(\xi,\eta)\in\Gamma[x,v,t]} J^\mu(t,\xi,\eta)$$

where $\Gamma[x,v,t]$ is the set of admissible trajectories starting from (x,v) at $s=t$ and

$$J^\mu(t,\xi,\eta) = \int_t^T F[m(s)](\xi(s),\eta(s)) + L(\xi(s),\eta(s),s) + \frac{1}{2}|\frac{d\eta}{ds}(s)|^2 + G[m(T)](\xi(T),\eta(T)).$$

Remark 3. It is tempting to say that a mild solution (u,m) is a very weak solution of a boundary value problem related to a system of PDEs posed in $\Omega\times[0,T]$, composed of a Hamilton-Jacobi equation for finding the optimal strategies, and of a Fokker-Planck equation for the evolution of m. However, this system should be supplemented with boundary conditions on $\partial\Omega\times(0,T)$. This aspect is particularly tricky because u blows up on some part of the boundary.

A corollary of Theorem 5 is:

Corollary 1. Under the assumptions of Theorem 5, there exists a mild solution (u, m).

Moreover, $m \in C^{\frac{1}{2}}([0,T];\mathcal{P}(K_C))$.

Remark 4. Under classical monotonicity assumptions for F and G, see e.g. Cannarsa and Capuani (2018), the mild solution is unique.

Abstract: Macroscopic, coarse descriptions of microscopic, agent-based dynamical systems are useful for tasks such as optimization, bifurcation analysis, and control. Once suitable coarse variables are defined, their dynamics can be either derived analytically or approximated in a data-driven fashion. For many agent-based systems, this coarse-graining procedure requires appropriate closure terms or stochastic elements on the macroscopic scale to summarize degrees of freedom of the agents. In this contribution, we identify effective stochastic differential equations (SDE) for coarse observables of agent-based simulations. These SDE then act as surrogate models on the macroscopic scale. We approximate the drift and diffusivity functions for these SDE through neural networks. Based on earlier work, the loss function is inspired by the structure of established stochastic numerical integrators, in particular Euler-Maruyama and Milstein schemes. We consider cases where the coarse collective observables are known in advance, and where they must be found with data-driven methods. We demonstrate the feasibility on data from an egress simulation of pedestrians in two-dimensional continuous space (with the crowd simulation software Vadere).

Keywords: Stochastic system identification, Simulation of stochastic systems, Statistical data analysis, Software for system identification, Machine learning for environmental applications

1. INTRODUCTION

Agent-based simulations provide accurate and detailed insights into dynamical systems. However, the simulation time and computational burden of these microscopic simulations often prohibit large-scale parameter studies or overviews on coarser scales. These tasks can be done with newly devised coarser models, but those often suffer from low accuracy compared to the agent-based approach. As a remedy, we aim to learn coarse models directly from the agent-based data. We identify effective stochastic differential equations (SDE) for coarse observables of fine-grained particle- or agent-based simulations. These SDE then provide coarse surrogate models of the fine scale dynamics. The coarse variables in question for this contribution are the infection states for a viral disease that is spreading through a local population. The crowd simulation software Vadere (`www.vadere.org`) is used for the agent-based modelling and simulation. To learn the SDE, we approximate the drift and diffusivity functions of the effective SDE through neural networks, which can be thought of as effective stochastic ResNets. The loss function is inspired by the structure of established stochastic numerical integrators (here, the Euler-Maruyama integrator; more intricate Milstein or Runge-Kutta integrators are considered in our paper, Dietrich et al. (2021)). The SDE approximations can benefit from error analysis of these underlying numerical schemes. They also lend themselves naturally to "physics-informed" gray-box identification when approximate coarse models, such as mean field equations, are available. The learning procedure we use does not require long trajectories, works on scattered snapshot data, and is designed to naturally handle different time steps per snapshot.

In related work, residual networks (ResNets He et al. (2016), but see also Rico-Martínez et al. (1992)) successfully employ a forward-Euler integrator based approach to create very deep architectures. This has inspired followup work to include other integrator schemes for deterministic, ordinary differential equations (ODE) such as symplectic integrators Bertalan et al. (2019); Zhu et al. (2020). From ResNets (He et al., 2016) and Neural ODEs (Chen et al., 2018; Rico-Martínez et al., 1992) to DeepONets (Lu et al., 2021), the identification of dynamical systems from (discrete) spatio-temporal data is a booming business because it is now comparatively easy to program and train neural networks. The time-honored SDE estimation techniques for local drift and diffusivity can now be synthesized in a (more or less global) surrogate model.

The software is available in the following repository: `https://gitlab.com/felix.dietrich/sde-identification`.

2. MATHEMATICAL PROBLEM SETTING

In this section, we follow the setting from our recent paper (Dietrich et al., 2021). We discuss the SDE

⋆ F.D. is funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – 468830823.

$$\mathrm{d}x_t = f(x_t)\mathrm{d}t + \sigma(x_t)\mathrm{d}W_t, \tag{1}$$

where $f : R^n \to R^n$ and $\sigma : R^n \to R^{n\times n}$ are smooth, possibly nonlinear functions; every $\sigma(x)$ is positive and bounded away from zero (and a positive-definite matrix if $n > 1$), and W_t a Wiener process such that for $t > s$, $W_t - W_s \sim \mathcal{N}(0, t-s)$. We assume we have access to a set of N snapshots $D = \{(x_1^{(k)}, x_0^{(k)}, h^{(k)})\}_{k=1}^N$, where $x_0^{(k)}$ are points scattered in the state space of (1) and the value of $x_1^{(k)}$ results from the evolution of Eq. 1 under a small time-step $h^{(k)} > 0$, starting at $x_0^{(k)}$. The snapshots are samples from a distribution, $x_0 \sim p_0$, and the transition densities $x_1 \sim p_1(\cdot|x_0, h)$ are associated with (1) for a given time-step $h > 0$, which in turn is chosen from some distribution p_h. The joint data-generating distribution is therefore given by $p(x_0, x_1, h) = p_1(x_1|x_1, h)p_0(x_0)p_h(h)$. Alternatively, the data could be collected along a long trajectory $\{x_{t_i}\}$ of (1) with sample frequency $h_i > 0$, that is, $t_{i+1} = t_i + h_i$. The problem is to identify the drift f and diffusivity σ through two neural networks $f_\theta : R^n \to R^n$ and $\sigma_\theta : R^n \to R^{n\times n}$, parameterized by their weights θ, only from the data in D. We assume the points in D are sampled sufficiently densely in the region of interest.

2.1 Identification with the Euler-Maruyama scheme

We now formulate and rationalize the loss term that we use to train the neural networks f_θ and σ_θ. The Euler-Maruyama scheme is a simple method to integrate Eq. 1 over a small time $h > 0$:

$$x_1 = x_0 + hf(x_0) + \sigma(x_0)\,\delta W_0, \tag{2}$$

where $h > 0$ is small and δW_0 is a vector of n random variables, all i.i.d. and normally distributed around zero with variance h. The convergence of Eq. 2 for $h \to 0$ has been studied at length; We refer to standard literature (Pavliotis, 2014). We can use this idea to construct a loss function for training the networks σ_θ and f_θ simultaneously. We initially restrict the discussion to the case $n = 1$ for simplicity. Essentially, conditioned on x_0 and h, we can think of x_1 as a point drawn from a multivariate normal distribution

$$x_1 \sim \mathcal{N}\left(x_0 + hf(x_0), h\sigma(x_0)^2\right). \tag{3}$$

In the training data set D, we only have access to triples $(x_0^{(k)}, x_1^{(k)}, h^{(k)})$, and not the drift f and diffusivity σ. To approximate them, we define the probability density p_θ of the normal distribution Eq. 3 and then, given the neural networks f_θ and σ_θ, ask that the log-likelihood of the data D under the assumption in equation Eq. 3 is high:

$$\begin{aligned}\theta := arg\max_{\hat\theta} E\left[\log p_{\hat\theta}\left(x_1|x_0,h\right)\right] \approx \\ arg\max_{\hat\theta} \frac{1}{N}\sum_{k=1}^{N} \log p_{\hat\theta}\left(x_1^{(k)}\,\middle|\,x_0^{(k)}, h^{(k)}\right).\end{aligned} \tag{4}$$

We can now formulate the loss function that will be minimized to obtain the neural network weights θ. The logarithm of the well-known probability density function of the normal distribution, together with the mean and variance from Eq. 3, yields the loss to minimize during training,

$$\begin{aligned}&\mathcal{L}(\theta|x_0, x_1, h) := \\ &\frac{\left(x_1 - x_0 - hf_\theta(x_0)\right)^2}{h\,\sigma_\theta(x_0)^2} + \log\left|h\sigma_\theta\left(x_0\right)^2\right| + \log(2\pi).\end{aligned} \tag{5}$$

This formula can easily be generalized to higher dimensions, and we use such generalizations for examples in more than one dimension. Minimizing $\mathcal{L}$ in Eq. 5 over the data D implies maximization of the log marginal likelihood Eq. 4 with the constant terms removed (as they do not influence the minimization) (Pavliotis, 2014). Likelihood estimation in combination with the normal distribution is used in many variational and generative approaches (Goodfellow et al., 2014; Kingma and Welling, 2014; Li et al., 2020; Yildiz et al., 2018; Yang et al., 2021). Note that here, the step size $h^{(k)}$ is defined *per snapshot*, so it is possible that it has different values for every index k. This is especially useful in simulations where the time step is determined as part of the scheme, e.g. a Gillespie simulation.

3. COMPUTATIONAL EXPERIMENTS

We tested our implementation with examples in one dimension first, with drift f and diffusivity σ defined through $f(x_t) = -2x_t^3 - 4x_t + 1.5$, $\sigma(x_t) = 0.05x_t + 0.5$. A comparison between the learned and true functions is shown in Fig. 1, along with densities obtained from sampling the true and approximate SDE. We trained networks with both Euler-Maruyama and Milstein loss functions, with very comparable results—even the training and validation curves were very similar. When increasing the dimension from $n = 1$ to $n = 20$, approximation quality decreases after $n = 6$.

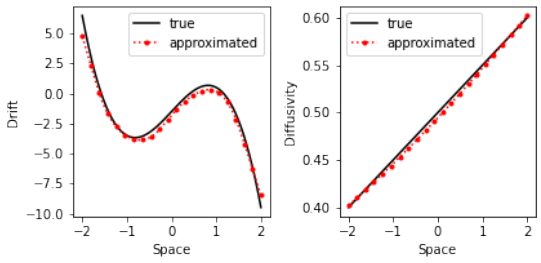

Fig. 1. Approximation vs. true values of f and σ in the first example.

In Fig. 2, we demonstrate that our approach can learn non-diagonal diffusivity matrices. We sample initial points $x_0 \in [-.3, .3]^3$, randomly sample a lower-triagonal diffusivity matrix Σ with positive eigenvalues, which we use as the (constant) diffusivity $\sigma(x) = \Sigma$, and set the drift to be $f(x) = -x$. The absolute error between original and (the average over) identified matrix entries is smaller than 0.01, and the standard deviation of the diffusivity values over the entire data set is smaller than 0.003 for all elements of the matrix. Note that the network σ_θ is still a nonlinear function over the state space, not a constant. To ensure the matrix has positive eigenvalues, we pass the real-valued output of the neurons that encode the diagonal of the matrix through a soft-plus activation function.

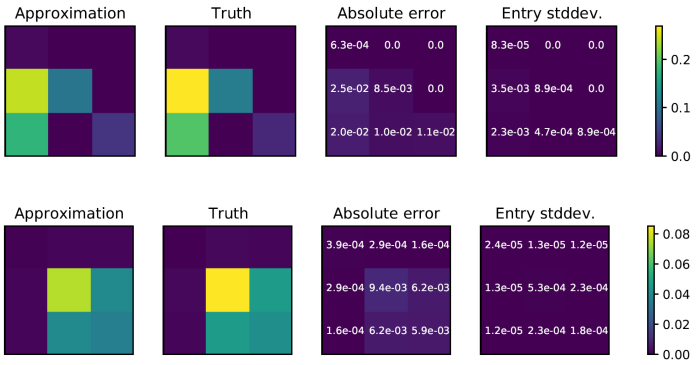

Fig. 2. Lower-triangular (top row) and full symmetric, positive definite (bottom row) diffusivity matrix approximation. The panels show the averaged network output over the uniformly sampled data inside the training region, the true diffusivity matrices, the absolute error between the results shown in the first and second columns, and the deviation of the network matrix output over the training region. The color range is the same for all four plots.

3.1 Toy example: increasing dimension from 1D to 20D

We define $f(x) = -(4x^3 - 8x + 3)/2$ and $\sigma(x) = 5e - 2x + 0.5$, where all operations are meant coordinate-wise (e.g. x^3 computes the third power of each individual coordinate of the vector). Figure 3 (left) illustrates how the training and validation losses change when increasing n from 1 to 20. The loss (Eq. 5) is adapted to the changing dimensionality by re-adding the constant term $\log(2\pi)n$. The increase in loss can be explained by the constant number of points ($N = 10,000$) we used: Increasing the intrinsic dimension of the problem by sampling the input data in the n-dimensional cube $[-2, 2]^n$ causes the data sampling to get sparser and sparser. By increasing the number of training data points linearly with the dimension (while keeping the number of training iterations per dimension constant), we can see that the training loss is relatively small even for $n = 12$ (Fig. 3, right).

3.2 Coarse-graining an agent-based infection model

We now demonstrate that the SDE learning approach can be used to effectively coarse-grain a crowd simulation model. The crowd simulation was performed using the software Vadere (www.vadere.org). Fig. 4 (left) shows our test scenario. Agents are placed in a square box of $30m \times 30m$, and can infect neighbors in a radius of $1.5m$ with a probability of 0.1% every simulated second. The other two panels show scenarios that we are currently investigating: a bottleneck scenario with dynamically changing crowd positions, and a classroom with students moving in and out of the room over the course of multiple days. Fig. 5 shows sample paths of the learned SDE compared to test trajectories sampled with the simulation software.

4. CONCLUSIONS

Training neural networks with loss functions based on numerical integrators such as Euler-Maruyama and Milstein has several limitations. If the time step between many

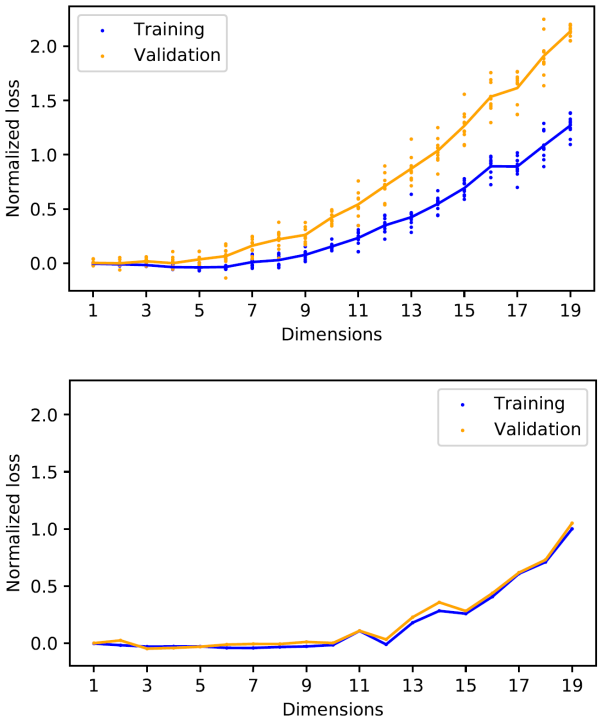

Fig. 3. Normalized training and validation loss when increasing the intrinsic dimension of the problem from $n = 1$ to $n = 20$. The top panel shows results when keeping the number of samples constant at $N = 10,000$, the bottom panel shows what happens when increasing $N = 10,000 \times n$, but training for the same number of iterations per dimension ($Epochs = 1000/n$).

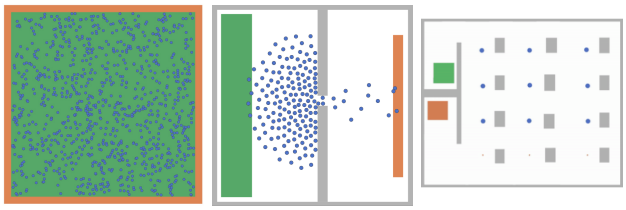

Fig. 4. Crowd scenarios simulated in Vadere. Left; A crowd with 1000 agents is placed in a square that mimics a concert setting. Center: 100 agents move through a bottleneck towards a target. Right: a classroom scenario with students moving in and out of the room over the course of multiple days. For each scenario, we perform 10,000 short simulation runs, and between 0 and 70% of the crowd is infected with an air-borne disease that can spread to neighbors.

samples is too small, we cannot accurately identify the drift, because the diffusivity term will dominate. This could be mitigated by starting with small h, estimating the diffusivity, and then estimating the drift with sub-sampled trajectories. Even with infinite data the drift is difficult to estimate, because the time step also has to go to zero (Pavliotis, 2014). Conversely, if the time step is too big, we cannot accurately identify the diffusivity. If the dynamics of the coarse-grained observables include rare events, then learning the corresponding SDE is a challenge, because these events will not be present in a

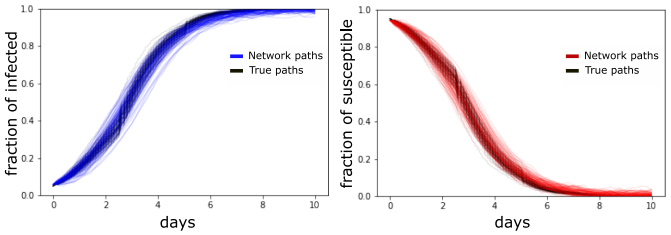

Fig. 5. Sample paths drawn from the learned SDE, compared to measured data, in the concert scenario.

lot of snapshots, and hence not a lot of data is available to learn them. Using a loss function based on Lévy noise SDE integrators might provide a useful surrogate for SDEs with rare-events.

There are many possible extensions and applications of our work. An important task is to find explicit probability density functions for integrators using other noise types, such as Lévy or Poisson noise. Analyzing integrators based on other types of calculus such as Heun's (Burrage et al., 2004) method may help impose more variegated types of priors during training. Using an adjoint method (Liu et al., 2020) can allow us to propagate the loss gradients back through longer time series.

In terms of applications, many more particle- and agent-based models can be coarse grained. For many of these, it is important to find coarse variables, and latent space techniques such as VAE-type architectures and Diffusion Maps (Coifman and Lafon, 2006) will help to identify them. These techniques can help to construct local SDE models in the process of larger-scale simulations to guide sampling and exploration. Another clear next step based on numerical analysis is the identification of stochastic partial differential equations (SPDEs).

Dead-Time Compensation as an Observer-Based Design

Abstract: In this note we study discrete-time dead-time compensation from the viewpoint of the observer-based design procedure. We show that the discrete equivalent of the observer-predictor architecture can be derived *ab initio* via classical state-feedback and observer arguments under mild assumptions. The resulting observer is reduced order and we show that this choice is justifiable even if corresponding state measurement channels are noisy.

Keywords: Time-delay systems, observer-based control, H_2 filtering, reduced-order observers.

1. INTRODUCTION

Since its introduction by Otto J. M. Smith (1957), the notion of delay compensation (or dead-time compensation, DTC) plays an important role in the control of time-delay systems. The use of DTC configurations makes it possible to reduce various delay problems to their delay-free equivalents. Initially, the idea was viewed as an ingenious transformation, simplifying the stability analysis, see (Manitius and Olbrot, 1979; Artstein, 1982; Furukawa and Shimemura, 1983; Fiagbedzi and Pearson, 1990) among other results. Later on, DTC was shown to be an intrinsic part of stabilizing and optimal H_2 (Mirkin and Raskin, 2003), H_∞ (Meinsma and Zwart, 2000; Mirkin, 2003), and L_1 (Mirkin, 2006) controllers in the single I/O delay case, as well as in some multiple I/O delay settings (Meinsma and Mirkin, 2005; Mirkin et al., 2011).

Historically, the emphasis in the DTC research was laid on continuous-time systems. A possible reason is that the delay element is infinite dimensional in continuous time. Hence, the reduction to a finite-dimensional delay-free case is particularly appealing there. Discrete delays are finite dimensional themselves, so the gain in compensating them is less apparent. Moreover, discrete formulae are often bulkier, which is especially hindering in optimization problems. Still, the finite-dimensional nature of discrete delays offers an opportunity to understand the rationale behind DTC via accessible means.

Our first goal in this note is to *derive* a discrete version of the observer-predictor DTC architecture of (Furukawa and Shimemura, 1983) via classical observer-based arguments, from scratch. We show that this derivation involves only two choices, which are justified. The first one is to keep deadbeat modes of the plant, originated in the delay dynamics, untouched in the state-feedback phase of the design. The second choice is to use a reduced-order observer to estimate the state. This is justified by the fact that the history of control inputs, which is a part of the plant state in the delay case, can be expected to be known accurately. We believe that the proposed derivation offers a new insight into the well-studied observer-predictor architecture.

The second, and most important, goal of this note is to demonstrate that the reduced-order observer architecture is *justified* in this case even if the control input itself is noisy. This conclusion may appear counterintuitive. Reduced-order observers are known to be sensitive to measurement noise (Anderson and Moore, 1989). This property was even used in (Krstic, 2009, Sec. 3.3) to justify the adoption of full-order alternatives in continuous-time DTC. We study this issue by posing the observer design problem as an H_2 optimization under noisy measurements. Although the problem is somewhat unorthodox, we end up with its transparent analytic solution, which has a reduced-order observer form regardless the noise intensity. We are not aware of any other problem, where the steady-state Kalman filter is of a reduced-order form under nonsingular measurement noise. This way we show that the single-delay DTC is a rare case where reduced-order observers can be vindicated of their "original guilt."

This is a conference version of (Mirkin and Zanutto, 2022), to which a reader is referred for all proofs.

Notation By $\mathbb{R}$, $\mathbb{Z}$, and $\mathbb{N}$ we indicate the sets of real, integer, and natural (positive integer) numbers, respectively, and $\mathbb{Z}_{i_1..i_2} := \{i \in \mathbb{Z} \mid i_1 \le i \le i_2\}$. The complex-conjugate transpose of a matrix M is denoted by M' and its Frobenius norm $\|M\|_{\mathrm{F}} := \sqrt{\mathrm{tr}(M'M)}$. If a matrix M is square, $\mathrm{spec}(M)$ stands for its spectrum, i.e. the (multi) set of all its eigenvalues. By $\{a\}^n$ we understand the multiset containing n copies of a.

We say that a discrete-time linear shift-invariant system G is an H_2 system if it is causal and its impulse response matrix is square summable. If $G \in H_2$, then its H_2-norm

$$\|G\|_2 = \Big(\frac{1}{2\pi}\int_{-\pi}^{\pi} \|G(\mathrm{e}^{\mathrm{j}\theta})\|_{\mathrm{F}}^2 \mathrm{d}\theta\Big)^{1/2},$$

where $G(z)$ is the transfer function of G. We use the compact notation

$$\left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right] := D + C(zI - A)^{-1}B$$

for transfer functions in terms of their state-space realizations.

2. DTC VIA OBSERVER-BASED DESIGN

Consider an input-delay discrete system described by

$$\begin{cases} x[t+1] = Ax[t] + Bu[t-\tau] \\ y[t] = Cx[t] + Du[t-\tau] \end{cases}, \tag{1}$$

where $u[t] \in \mathbb{R}^m$ is a control input, $y[t] \in \mathbb{R}^p$ is a measured output, $x[t] \in \mathbb{R}^n$ is an internal signal, and $\tau \in \mathbb{N}$ is a delay. We assume hereafter that

$\boldsymbol{\mathcal{A}_1}$: (A, B) is stabilizable and (C, A) is detectable,

which is necessary for stabilization. We also assume that

$\boldsymbol{\mathcal{A}_2}$: (A, B) has no unreachable modes at the origin,

which is required only to simplify the exposition, the results remain qualitatively the same if this assumption is omitted.

The vector x is not a state of (1). Indeed, by the state we understand a history accumulator, whose knowledge at any time instant $t = t_0$ is the only information about the past required to calculate the behavior of the system for $t > t_0$. It is readily seen that the knowledge of $x[t_0]$ in (1) should be complemented by that of $u[t]$ for all $t \in \mathbb{Z}_{t_0-\tau..t_0-1}$. A state of (1) may then be chosen as

$$x_\tau[t] := \begin{bmatrix} x[t] \\ u[t-\tau] \\ \vdots \\ u[t-1] \end{bmatrix} \in \mathbb{R}^{n+m\tau}. \tag{2}$$

With this choice, the measured subset of the state changes as well, because the history of the control signal may be safely assumed to be measurable. Hence, the measured variable is

$$y_\tau[t] := \begin{bmatrix} y[t] \\ u[t-\tau] \\ \vdots \\ u[t-1] \end{bmatrix} \in \mathbb{R}^{p+m\tau}, \tag{3}$$

not just $y[t]$. The state equation of (1) corresponding to the choices above is

$$\begin{cases} x_\tau[t+1] = A_\tau x_\tau[t] + B_\tau u[t] \\ y_\tau[t] = C_\tau x_\tau[t] \end{cases} \tag{4}$$

where

$$\left[\begin{array}{c:c} A_\tau & B_\tau \end{array}\right] := \left[\begin{array}{ccccc:c} A & B & 0 & \cdots & 0 & 0 \\ 0 & 0 & I & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & I & 0 \\ 0 & 0 & 0 & \cdots & 0 & I \end{array}\right], \quad C_\tau := \begin{bmatrix} C & D & 0 & \cdots & 0 \\ 0 & I & 0 & \cdots & 0 \\ 0 & 0 & I & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & I \end{bmatrix}$$

Realization (4) inherits structural properties of the delay-free version of (1), meaning that the augmentation procedure has no redundancy.

Proposition 1. $\lambda \in \mathbb{C}$ is an unreachable mode of (A_τ, B_τ) iff it is an unreachable mode of (A, B) and is an unobservable mode of (C_τ, A_τ) iff it is an unobservable mode of (C, A).

Thus, $\boldsymbol{\mathcal{A}_1}$ implies that we can design a stabilizing controller for (4) under every τ. We follow the observer-based design procedure for that. Although (4) is a standard system, designing state-feedback and observer gains without accounting for the structure of its parameters would be a waste. The dimension of (4) might be very high if the delay is large, which would lead to numerical issues. So the trick is to exploit the structure of the parameters of (4) to end up with calculations independent of τ.

2.1 State feedback with partial pole placement

We start with discussing the design of the state-feedback gain $K_\tau \in \mathbb{R}^{m\times(n+m\tau)}$ for (4). It is readily seen that

$$\operatorname{spec}(A_\tau) = \operatorname{spec}(A) \cup \{0\}^{m\tau}.$$

By Proposition 1, the $m\tau$ deadbeat eigenvalues are reachable via B_τ and can thus be freely moved by state feedback. But a key question is whether we really need to move them. Eigenvalues at the origin are damped and have the fastest possible convergence. As such, having them is normally desirable. Moving non-zero modes to the origin is regarded as expensive and non-robust, for it might require high feedback gains. Yet if such modes are already present in the open-loop system, keeping them is both justified by performance considerations and economical (e.g. they would be kept by the "expensive control" LQR (Anderson and Moore, 1989, Sec. 6.2)). Thus, it is justified to design K_τ that moves only elements of the spectrum of A in $\operatorname{spec}(A_\tau)$.

The lemma below presents a possible approach to designing the state-feedback gain with the required property.

Lemma 1. If there is a rank-n matrix $M_\tau \in \mathbb{R}^{n\times(n+m\tau)}$ such that $M_\tau A_\tau = AM_\tau$ and $M_\tau B_\tau = B$, then $K_\tau = KM_\tau$ renders

$$\operatorname{spec}(A_\tau + B_\tau K_\tau) = \operatorname{spec}(A + BK) \cup \{0\}^{m\tau}$$

for every $K \in \mathbb{R}^{m\times n}$.

The formulation above appears somewhat peculiar. In principle, partial pole assignment would only require the row space of M_τ to match the left eigenspace of the movable part of $\operatorname{spec}(A_\tau)$. Yet the structure of A_τ and B_τ facilitates an explicit construction of the required M_τ even in this restrictive form.

Lemma 2. The matrix

$$M_\tau = \begin{bmatrix} A^\tau & A^{\tau-1}B & \cdots & AB & B \end{bmatrix}$$

satisfies the conditions of Lemma 1 iff $\boldsymbol{\mathcal{A}_2}$ holds.

Thus, we need to choose a state-feedback gain K rendering $A + BK$ Schur, which is always possible by $\boldsymbol{\mathcal{A}_1}$, and then use

$$K_\tau = K \begin{bmatrix} A^\tau & A^{\tau-1}B & \cdots & AB & B \end{bmatrix}.$$

Taking into account the structure of the state vector in (2), this gain results in the control law

$$u[t] = K_\tau x_\tau[t] = K\Big(A^\tau x[t] + \sum_{i=1}^{\tau} A^{i-1}Bu[t-i]\Big). \tag{5}$$

The signal in the parentheses above is the prediction of $x[t+\tau]$. As such, (5) is the discrete counterpart of the predictive control law, like that in (Furukawa and Shimemura, 1983, Eqns. (25) and (26)).

2.2 Reduced-order observer

Consider now the observer design for the case when the whole x_τ is not measurable. Like in the state-feedback case, Proposition 1 implies that a full-order observer can always be constructed for (4). But the structure of the parameters of (4) can again be used to simplify the result. A key observation now is that the last $m\tau$ components of the measured signal in (3) coincide with those of the state vector in (2). They are the history of the control signal u generated by the controller. We may then expect that no measurement noise corrupts these component of

the state in many applications. Hence, the use of a reduced-order observer is a natural choice for (4).

The specific form of reduced-order observer that we use is not the one with a minimal order, because we do not reduce measured parts of x from it. But this does not affect its design qualitatively. Repeating the derivation in (Friedland, 1986, Sec. 7.5) for this choice, we end up with the observer of x in the form

$$\hat{x}[t+1] = A\hat{x}[t] + Bu[t-\tau] - L(y[t] - C\hat{x}[t] - Du[t-\tau]) \quad (6)$$

whose $\hat{x}$ converges asymptotically to x, provided $L \in \mathbb{R}^{n\times p}$ is such that $A + LC$ is Schur (exists by $\boldsymbol{\mathcal{A}_1}$).

2.3 Observer-based controller

Finally, combining (5) with (6) we end up with the observer-based control law for (1) in the form

$$\begin{cases} \hat{x}[t+1] = (A+LC)\hat{x}[t] + (B+LD)u[t-\tau] - Ly[t] \\ u[t] = K\Big(A^{\tau}\hat{x}[t] + \sum_{i=1}^{\tau} A^{i-1}Bu[t-i]\Big) \end{cases} \quad (7)$$

which is the discrete counterpart of the observer-predictor controller in (Furukawa and Shimemura, 1983, Eqns. (36)–(38)). The control law (7) is stabilizing, with the closed-loop spectrum

$$\operatorname{spec}(A+BK) \cup \operatorname{spec}(A+LC) \cup \{0\}^{m\tau},$$

which follows by separation arguments as in (Friedland, 1986, Sec. 8.3).

Remark 1. (multiple input delays). The arguments above can be extended to processes of the form

$$x[t+1] = Ax[t] + \sum_{i=0}^{\tau} B_i u[t-i].$$

In the state-feedback part, we essentially only need to replace the matrix M_τ in Lemma 2 with

$$M_\tau = \begin{bmatrix} A^{\tau} & \bar{M}_\tau & \cdots & \bar{M}_2 & \bar{M}_1 \end{bmatrix},$$

where $\bar{M}_i = A^{-1}\bar{M}_{i+1} + A^{\tau-1}B_i$ for $i \in \mathbb{Z}_{1..\tau}$ with $\bar{M}_{\tau+1} = 0$, and design K on the basis of the pair $(A, \sum_{i=0}^{\tau} A^{\tau-i}B_i)$, rather than (A, B). Assumptions $\boldsymbol{\mathcal{A}_{1,2}}$ should then be adapted to these changes, of course. The observer part does not alter. ▽

3. NOISY MEASUREMENTS OF THE CONTROL INPUT

Although the assumption that u is measured perfectly can be justified in many situations, we may think of applications where this is not the case. For example, the control signal generated by the controller may be transmitted to the plant by a noisy communication channel. A way to formalize this is to assume that the control signal applied to the plant is

$$u[t] = u_{\mathrm{c}}[t] + v_u[t],$$

where u_{c} is the (measured) output of the controller and v_u is some noise. In such situations delayed u's in measured variable (3) become delayed $(u - v_u)$'s. And this alteration questions the use of observer (6) in the studied context, because reduced-order observers tend to be sensitive to measurement noise in reduced channels, see (Anderson and Moore, 1989, Sec. 7.2).

Our goal in this section is to shed light on this issue. To this end, we consider the system

$$\begin{cases} x[t+1] = Ax[t] + Bu[t-\tau] + B_w w[t] \\ y_x[t] = Cx[t] + Du[t-\tau] + D_w w[t] \\ y_u[t] = u[t] - D_v v[t] \end{cases} \quad (8)$$

and study the reconstruction of its state x_τ, as in (2), from measurements y_x and y_u. The signal w in the first two equations of (8) can be thought of as comprising plant disturbances and a measurement noise in the y-channel. Its introduction is required to render the state reconstruction problem well posed. The signal v, assumed to be independent of w, represents measurement imperfections in the u-channel and is the main focus below. It is convenient to use normalized w and v, so matrices B_w, D_w, and D_v reflect intensities of physical signals and their mutual relations (for parts of w), as well as design considerations. In particular, $v_u = D_v v$ for a fictitious unit-intensity v. Note that we consider only the measurement of $u[t]$ rather than of the whole τ-history of it as in (3). The reason is that we do not impose any structure on a reconstructor in the analysis below. In this case an explicit account for delayed versions of y_u would introduce redundancy, without affecting the performance.

By the reconstruction of x_τ we understand the generation of its estimate $\hat{x}_\tau$ from the measurements (y_x, y_u) in (8) by a linear system (filter) F. The goal is to choose F so that the reconstruction error $x_\tau - \hat{x}_\tau$ is small, in whatever sense. The size of the error can be quantified in terms of the *error system* G_{e}, which connects exogenous inputs, u, w, and v, with the error. To construct G_{e}, introduce the transfer functions

$$\begin{bmatrix} G_{xw} & G_{xu} \\ G_{yw} & G_{yu} \end{bmatrix} := \left[\begin{array}{c|cc} A & B_w & B \\ \hline I & 0 & 0 \\ C & D_w & D \end{array}\right], \quad W_\tau := \begin{bmatrix} z^{-\tau}I \\ \vdots \\ z^{-1}I \end{bmatrix}. \quad (9)$$

It is then readily verified that

$$x_\tau = \begin{bmatrix} G_{xu}z^{-\tau} & G_{xw} & 0 \\ W_\tau & 0 & 0 \end{bmatrix} \begin{bmatrix} u \\ w \\ v \end{bmatrix}$$

and

$$\begin{bmatrix} y_x \\ y_u \end{bmatrix} = \begin{bmatrix} G_{yu}z^{-\tau} & G_{yw} & 0 \\ I & 0 & -D_v \end{bmatrix} \begin{bmatrix} u \\ w \\ v \end{bmatrix}.$$

Hence, the error system

$$G_{\mathrm{e}} = \begin{bmatrix} G_{xu}z^{-\tau} & G_{xw} & 0 \\ W_\tau & 0 & 0 \end{bmatrix} - F \begin{bmatrix} G_{yu}z^{-\tau} & G_{yw} & 0 \\ I & 0 & -D_v \end{bmatrix}.$$

We consider the following requirements in the design of F:

(1) both G_{e} and F itself are stable,
(2) F is strictly causal,
(3) the error $x_\tau - \hat{x}_\tau$ is decoupled from u,
(4) the H_2-norm $\|G_{\mathrm{e}}\|_2$ is minimized.

The first requirement should be evident, an unstable F cannot be safely implemented in open loop and the norm of an unstable error system is not well defined. The second and third requirements are motivated by the compatibility with the observer-based design in Section 2. The observer there is strictly causal, by construction, and the control signal does not affect the observation error. Moreover, the part of F acting on y_u must be strictly causal because the control signal $u[t]$ is only generated at the time instance t. An additional motivation for the third

requirement is that u has normally a different nature than disturbances, so mixing them in the analysis of the reconstruction performance is not justified. The fourth item is the standard steady-state Kalman filtering objective. If w and v are unit-variance white processes, then $\|G_e\|_2^2$ equals the steady-state variance of the reconstruction error.

To solve this problem, we need to assume that

$\boldsymbol{\mathcal{A}_3}$: $\begin{bmatrix} A-zI & B_w & BD_v \\ C & D_w & DD_v \end{bmatrix}$ has full row rank for all $|z|=1$.

This condition can always be warranted by a choice of B_w and D_w. Together with the detectability of (C,A), already included into $\boldsymbol{\mathcal{A}_1}$, assumption $\boldsymbol{\mathcal{A}_3}$ guarantees (Saberi et al., 2007, Thm. 4.79) that the discrete algebraic Riccati equation (DARE)

$$\begin{aligned} Y = {} & AYA' + B_w B_w' + BD_v D_v' B' \\ & - (B_w D_w' + BD_v D_v' D' + AYC')R^{-1} \\ & \times (D_w B_w' + DD_v D_v' B' + CYA'), \end{aligned} \quad (10)$$

where $R := D_w D_w' + DD_v D_v' D' + CYC'$, admits a stabilizing solution $Y = Y' \geq 0$ such that $R > 0$ and $A + LC$ is Schur, where $L := -(B_w D_w' + BD_v D_v' D' + AYC')R^{-1}$.

The main res

Theorem 1. If $\boldsymbol{\mathcal{A}_{1,3}}$ hold, then the strictly causal filter solving the problem of H_2-optimal reconstruction of the state x_τ of (8) is

$$\begin{cases} \hat{x}[t+1] = A\hat{x}[t] + By_u[t-\tau] - L\hat{y}[t] \\ \hat{u}[t-i] = y_u[t-i], \qquad \forall i \in \mathbb{Z}_{1..\tau} \end{cases} \quad (11)$$

where $\hat{y}[t] := y_x[t] - C\hat{x}[t] - Dy_u[t-\tau]$.

A remarkable outcome of Theorem 1 is that the optimal reconstruction of the τ-history of the control input from noisy measurements of u is still provided by the reduced-order observer having the same structure as that in §2.2. This is not an expectable result. Kalman filters may have a reduced-order observer form in some situations. However, this normally happens when noise vanishes in certain measurement channels, see (Friedland, 1986, Sec. 11.6). Our case is unusual, for the reduced-order structure is maintained for any noise intensity weight D_v. The latter still affects the optimal solution, via influencing the DARE (10) and thus the observer gain L.

Remark 2. (causal F_x). Allowing the first component of F, that generating x, to have a nonzero feedthrough part may change the solution structure. It can be shown that in this case the optimal filter is

$$\begin{cases} x_F[t+1] = Ax_F[t] + By_u[t-\tau] - L\hat{y}[t] \\ \hat{x}[t] = x_F[t] + YC'R^{-1}\hat{y}[t] \\ \hat{u}[t-i] = y_u[t-i], \qquad \forall i \in \mathbb{Z}_{1..\tau-1} \\ \hat{u}[t-\tau] = y_u[t-\tau] + D_v D_v' D' R^{-1}\hat{y}[t] \end{cases}$$

and the optimal cost attained by it is reduced by the quantity $\mathrm{tr}(R^{-1}(CY^2C' + D(D_vD_v')^2D'))$. If $D = 0$ we still have the reduced-order observer structure of the optimal strictly causal filter in (11), bar a change in generating $\hat{x}$. But if $D \neq 0$, the filter is no longer the reduced-order observer for the oldest estimated element of u, which is $u[t-\tau]$. ▽

4. CONCLUDING REMARKS

This note has studied discrete-time dead-time compensation from the perspective of the orthodox observer-based controller design. It has been shown that the discrete equivalent of the observer-predictor architecture can be derived from scratch via such arguments under mild assumptions. Specifically, only two choices had to be made. First, the deadbeat modes of the plant that originate in the delay element are not shifted by the state feedback. Second, delayed control inputs, which are parts of the state and measured directly, are excluded from the state observer (hence, the use of a reduced-order observer). The sensitivity of the last choice to measurement noise has also been investigated via posing and solving an H_2 filtering problem for the studied delayed setup. Remarkably, the H_2-optimal strictly causal filter is always of the reduced-order observer form, regardless the measurement noise intensity. This offers a solid justification for the observer-predictor setup, showing that it is not sensitive to measurement noise.

Abstract: During the last years, Hamiltonian neural networks (HNN) have been introduced to incorporate prior physical knowledge when learning dynamical systems. Hereby, the symplectic system structure is preserved despite the data-driven modeling approach. However, preserving symmetries requires additional attention. In this research, we enhance the HNN with a Lie algebra framework to detect and embed symmetries in the neural network. This approach allows to simultaneously learn the symmetry group action and the total energy of the system.

Keywords: Physics informed neural networks, Hamiltonian systems, Hamiltonian learning, system identification, symmetry action identification

1. INTRODUCTION

Modeling mechanical system dynamics has a long history, many physical principles have been prescribed in detail and from different perspectives, e.g. the Hamiltonian and the Lagrangian viewpoint as well as the Newton-Euler modeling approach. However, also data-based modeling techniques have recently gained attention within this area. Reasons might range from bypassing complex physical modeling which requires domain-specific knowledge, e.g. in novel materials, to finding reduced-order models of e.g. multi-physics systems.

Mechanical systems are well-known to possess characteristic properties, such as symplecticity of the Hamiltonian/Lagrangian flow, symmetries which lead to the preservation of momentum maps, and energy-preservation in the absence of external forcing. In physics-based modeling, differential geometry allows to generate structure-preserving models, e.g. variational integrators provide discrete-time analogs to the original system structures. In data-based modeling, standard methods such as neural network approximations of vector fields or flows do not preserve these structures. Physics-informed neural networks were introduced by Raissi et al. (2019), in which the unknown parts of a PDE are learned by adding the expression of the PDE to the loss function and using automatic differentiation properties. The SINDy approach, proposed by Brunton et al. (2016) applies sparse regression to get a symbolic representation of the system's ODE based on suitable basis functions, without focusing on mechanical systems. However, Udrescu and Tegmark (2020) presented an approach where deep learning is used to find symmetries in the data in order to reduce the exponentially large search space of all possible basis functions.

The learning of Hamiltonian systems is addressed in Zhong et al. (2019). Within this work, the scalar valued Hamiltonian is learned by using neural networks to model the typical components of the Hamiltonian separately, such as the potential energy or the mass matrix. A more general approach was proposed by Greydanus et al. (2019) and named *Hamiltonian Neural Networks (HNN)*, since the Hamiltonian is learned such that the system's symplecticity and energy conservation are preserved by design. Extending this approach, Dierkes and Flaßkamp (2021) shows how to learn a symmetry-preserving Hamiltonian, if the symmetry is known a priori.

Rather than learning the continuous Hamiltonian, Offen and Ober-Blöbaum (2022) learn a Hamiltonian tailored to symplectic integration schemes. In this way, discretization errors in the integration step are eliminated and trajectory observations instead of observations of the Hamiltonian vector field can be used in the learning process. A similar strategy can be employed on the Lagrangian side (see Ober-Blöbaum and Offen, 2022).

Another approach to preserve symplectic structure when learning dynamical systems is to learn the system's Hamiltonian flow map by learning its generating function (cf. Rath et al., 2021) or by using symplectic neural networks (cf. Jin et al., 2020), where symplecticity is guaranteed by the network architecture. Moreover, symmetries have been embedded into learning vector fields using group integration matrix kernels (GIM kernels) and Gaussian Processes (cf. Ridderbusch et al., 2021). Lie algebra convolutional neural networks (cf. Dehmamy et al., 2021) can automatically discover symmetries and preserve them by using suitable localizations of the kernels present in CNNs and making them group invariant.

In this article, we will learn the Hamiltonian of a system and use a Lie algebra framework to detect and embed

symmetries into a neural network that models the Hamiltonian of a dynamical system. For proposed Lie group actions, such as the action of affine linear transformations, our network automatically detects subgroups under which the Hamiltonian function is invariant. This is achieved by learning the Hamiltonian along with a spanning set of generators of invariant vector fields and testing via a loss function whether the derivatives of H along the invariant vector fields vanish. Utilising Noether's theorem, the two ingredients, symmetries and symplectic structure, then allow us to identify integrals of motions. We exemplify the concept by the cart–pendulum example, for which we train a symmetry-symplecticity-preserving neural network.

2. LEARNING DYNAMICS AND SYMMETRIES

Consider an orientable, Riemannian manifold Q with phase space $(\mathcal{M}, \omega) = (T^*Q, \omega)$, where T^*Q denotes the cotangent bundle and ω the canonical symplectic structure. Let $\mathfrak{X}(\mathcal{M})$ denote the set of vector fields on $\mathcal{M}$.

In the following, we develop a loss function to learn a Hamiltonian $H\colon \mathcal{M} \to \mathbb{R}$ modelled as a neural network based on observations $(\dot{z}^{(k)})_{k=1}^N$ of a Hamiltonian vector field $X_H \in \mathfrak{X}(\mathcal{M})$ at positions $(z^{(k)})_{k=1}^N \subset \mathcal{M}$. If $Q = \mathbb{R}^n$, $X_H(q,p) = (\nabla_p H(q,p), -\nabla_q H(q,p))^\top$ in standard (Darboux) coordinates $z = (q,p) \in \mathcal{M} \cong \mathbb{R}^{2n}$.

Our loss function will guide the network towards a symmetric Hamiltonian function: given a symplectic action of a Lie group G on $\mathcal{M}$, the minimization procedure identifies a subgroup of G which acts by symmetries. Once the symmetries are known, conserved quantities can be derived by Noether's theorem. If, for instance, the Hamiltonian is invariant under translations, i.e. the directional derivative $\nabla_{(w,0)} H(q,p) = \sum_{j=1}^n w^j \frac{\partial H}{\partial q^j}(q,p)$ vanishes for a translation direction $w \in Q = \mathbb{R}^n$ and all $(q,p) \in \mathcal{M} \cong \mathbb{R}^{2n}$, then the quantity $I(q,p) = w \cdot p$ is conserved under motions.

The loss function ℓ consists of a dynamical part ℓ_{dynamics} and a part related to symmetries ℓ_{sym}. We have

$$\ell_{\text{dynamics}} = \sum_{k=1}^N \|\dot{z}^{(k)} - X_H(z^{(k)})\|^2_{T\mathcal{M}},$$

which corresponds to HNN. In the following, we show how to construct ℓ_{sym} to a given Lie group, whose actions are possible symmetries.

2.1 Background on Lie-group actions

Let us briefly introduce Lie group actions and invariant vector fields. For details we refer to the book by Marsden and Ratiu (1999).

For a Lie group G, let $\mathfrak{g}$ denote its Lie algebra and $\exp\colon \mathfrak{g} \to G$ the exponential map. Consider a symplectic group action $L\colon G \to \mathrm{Symp}(\mathcal{M})$, $g \mapsto L_g$. Here $\mathrm{Symp}(\mathcal{M})$ denotes the group of symplectic diffeomorphisms. If $Q = \mathbb{R}^n$, as before, this means that L_g is required to preserve the symplectic structure, i.e. $DL_g^T J DL_g = J$, where DL_g is the Jacobian matrix of L_g and J is the symplectic structure matrix $J = \begin{pmatrix} 0 & -I_n \\ I_n & 0 \end{pmatrix}$ with the n-dimensional identity matrix I_n. For $v \in \mathfrak{g}$ the left invariant vector field $\hat{v} \in \mathfrak{X}(\mathcal{M})$ is defined by

$$\hat{v}_z = \frac{\mathrm{d}}{\mathrm{d}t}\bigg|_{t=0} L_{\exp(tv)}(z) \in T_z\mathcal{M}, \quad z \in \mathcal{M}.$$

These vector fields can be thought of as infinitesimal actions of the Lie group G on $\mathcal{M}$. Invariance of H can be tested by computing directional derivatives of H in the directions given by these vector fields.

Example 1. (Affine linear transformations). Let $Q = \mathbb{R}^n$ and $\mathcal{M} = T^*Q \cong \mathbb{R}^{2n}$ with Darboux coordinates (q,p). The group of affine transformations $G = \mathrm{Aff}(Q)$ on Q can be represented as

$$G = \left\{ \begin{pmatrix} A & w \\ 0 & 1 \end{pmatrix} \,\middle|\, A \in \mathrm{Gl}(\mathbb{R}, n),\, w \in \mathbb{R}^n \right\},$$

where the group operation is matrix multiplication and $\mathrm{Gl}(\mathbb{R}, n)$ denotes the general linear group. Its Lie algebra is

$$\mathfrak{g} = \left\{ \begin{pmatrix} M & w \\ 0 & 0 \end{pmatrix} \,\middle|\, M \in \mathrm{Mat}(\mathbb{R}, n),\, w \in \mathbb{R}^n \right\}$$

and $\exp\colon \mathfrak{g} \to G$ is the matrix exponential. G acts on $\mathcal{M} = T^*Q$ as

$$L_{(A,w)}(q,p) = \left(A^{-1}(q-w),\, A^\top p\right),$$

where $g = (A,w)$ is a shorthand for $\begin{pmatrix} A & w \\ 0 & 1 \end{pmatrix}$. The action is symplectic as it arises as the cotangent lifted action of the action $G \to \mathrm{Diff}(Q)$, $(A,w) \mapsto L^Q_{(A,w)}$, with $L^Q_{(A,w)}(q) = Aq + w$. The invariant vector field $\widehat{v} = \widehat{(M,w)}$ corresponding to the action $L\colon G \to \mathrm{Symp}(\mathcal{M})$ at $(q,p) \in \mathcal{M}$ is given as

$$\widehat{v}_{(q,p)} = \widehat{(M,w)}_{(q,p)} = \left(-Mq - w,\, M^\top p\right).$$

Vector fields can be interpreted as derivations: if $\widehat{v} = \widehat{(M,w)}_{(q,p)}$ is applied to $H\colon \mathcal{M} \to \mathbb{R}$ we obtain the directional derivative

$$\begin{aligned}\widehat{v}_{(q,p)}(H) &= \widehat{(M,w)}_{(q,p)}(H) = \nabla_{\widehat{(M,w)}} H(q,p) \\ &= (-Mq - w)^\top \nabla_q H(q,p) + (M^\top p)^\top \nabla_p H(q,p).\end{aligned}$$

Example 2. (Translations). Restricting to translations $G \cong (\mathbb{R}^n, +)$, we have $\widehat{v}_{q,p} = \widehat{w}_{q,p} = (-w, 0)$ with $\widehat{w}_{q,p}(H) = -w^\top \nabla_q H(q,p)$.

2.2 Incorporation of symmetry into the loss function

Simultaneously to learning H, we aim to learn an orthonormal basis $v^{(1)}, \ldots, v^{(K)}$ of $\mathfrak{g}$ spanning a subspace $V \subset \mathfrak{g}$ such that H is invariant under actions with elements g of the subgroup $\exp(V) \subset G$.

Let $\mathcal{M}^{\mathrm{o}} \subset \mathcal{M}$ be open, pre-compact, and contain the parts of interest of the phase space $\mathcal{M}$. Let dvol be a volume form on $\mathcal{M}$. For $k = 1, \ldots, K$ define

$$\ell_{\text{sym}}^{(k)} = \frac{1}{\mathrm{dvol}(\mathcal{M}^{\mathrm{o}})} \int_{\mathcal{M}^{\mathrm{o}}} |\hat{v}^{(k)}(H)|^2 \,\mathrm{dvol}. \tag{1}$$

Here $\hat{v}^{(k)}$ denotes the invariant vector field to v. The term $\ell_{\text{sym}}^{(k)}$ measures how invariant H is under actions with group elements of $\exp(tv^{(k)} | t \in \mathbb{R})$. Equip $\mathfrak{g}$ with an inner product $\langle \cdot, \cdot \rangle$ and norm $\| \cdot \|$. Given weights $\alpha^{(k)}, \beta^{(k)} > 0$ define

$$\ell_{\text{sym}} = \sum_{k=1}^{K} \left(\ell_{\text{sym}}^{(k)} + \alpha^{(k)} |\|v^{(k)}\| - 1|^2 + \beta^{(k)} \sum_{s=1}^{k-1} \langle v^{(k)}, v^{(s)} \rangle \right). \tag{2}$$

The last two terms of ℓ_{sym} measure the orthonormality of the spanning set $v^{(1)}, \dots, v^{(K)}$ while the first term measures how well infinitesimal actions by elements of $\exp(V)$ preserve H.

Example 3. If we look for a 1-dimensional subgroup of $G = (\mathbb{R}^n, +)$, where G acts by translations on $Q = \mathbb{R}^n$ (example 2), we have for a Lie algebra element $v = w \in \mathfrak{g}$

$$\ell_{\text{sym}} = \frac{1}{\operatorname{dvol}(\mathcal{M}^{\circ})} \int_{\mathcal{M}^{\circ}} \left| \sum_{j=1}^{n} w^j \frac{\partial H}{\partial q^j}(q,p) \right|^2 \mathrm{d}q\, \mathrm{d}p,$$

where $\mathrm{d}q\, \mathrm{d}p = \mathrm{d}q^1 \dots \mathrm{d}q^n\, \mathrm{d}p_1 \dots \mathrm{d}p_n$.

2.3 Training and further remarks

The Hamiltonian H and the spanning set $v^{(1)}, \dots, v^{(K)}$ can now be learned using the loss function $\ell = \ell_{\text{dynamics}} + \ell_{\text{sym}}$, where H is modelled as a neural network and $v^{(1)}, \dots, v^{(K)}$ are additional parameters. Alternatively to learning all at once, the training can be performed with a low value for K first. (For $K = 0$ our method corresponds to HNN.) Then K is increased and the training repeated using the pre-trained network and $v^{(1)}, \dots, v^{(K-1)}$ as priors.

Remark 4. The integral in (1) can be approximated by averaging the integrand over a few points in the phase space $\mathcal{M}$, randomly drawn in each epoch of the minimization procedure.

Remark 5. Let $\mu\colon \mathcal{M} \to \mathfrak{g}^*$ be the momentum map of the considered group action and $\langle \cdot, \cdot \rangle_{\text{pair}}$ the dual pairing of the Lie algebra $\mathfrak{g}$ and its dual $\mathfrak{g}^*$. Provided that H accurately describes the Hamiltonian of the system and $\exp(V)$ its symmetry group, then the components $\mu^{(j)} = \langle \mu, v^{(j)} \rangle_{\text{pair}}$ of the momentum map are conserved quantities of the system's Hamiltonian motions. In case of example 2, the conserved quantities are $(q,p) \mapsto w_1^{(j)} p_1 + \dots + w_n^{(j)} p_n$, where $v^{(j)} = (w_1^{(j)}, \dots, w_n^{(j)})$.

Remark 6. Our framework works without any changes for general symplectic group actions, i.e. for actions which are not cotangent lifted actions. Indeed, the Riemannian symplectic manifold $(\mathcal{M}, \omega)$ does not need to have the structure of a cotangent bundle.

3. NUMERICAL RESULTS

The framework introduced in the previous section is now applied to the example of a planar pendulum mounted on a cart (cf. e.g. Bloch, 2003). Since the dynamics are translational invariant, i.e. independent of the cart's position, we restrict ourselves to learn the correct translation group.

The generalized coordinates are $q = (s, \varphi)$, where s is the position of the cart and φ is the angle to the upper vertical of the pendulum. Since this system is well studied, we can use the true Hamiltonian for, firstly, generating data points and, secondly, evaluating the performance of our data-based approach. It is given by

$$H(\varphi, p_s, p_\varphi) = \frac{a p_s^2 + 2 b p_s p_\varphi \cos\varphi + c p_\varphi^2}{2ac - b^2 \cos^2\varphi} - D \cos\varphi, \tag{3}$$

with the constants $a = ml^2$, $b = ml$, $c = M + m$ and $D = -mgl$, using l as the length and m as the mass of the pendulum, M corresponds to the mass of the cart and $g = 9.81$ to gravitation. For simplicity, all remaining constants are set to one, i.e. $m = l = M = 1$.

To generate a data set, 1500 trajectories are generated using random initial values with $|s| < 5$, $|\varphi| < \pi$, $|p_s| < 1$ and $|p_\varphi| < \pi$. Each trajectory has a length of 3 s and a sampling rate of 15 Hz. A fourth-order Runge–Kutta scheme is applied with a low error tolerance of 1e−10 and using the (exact) vector field induced by H (cf. Runge, 1895). To each sample of the resulting data set, Gaussian noise with $\sigma^2 = 1\text{e}{-2}$ is added.

The network architecture is similar to the proposed network by Greydanus et al. (2019), which consists of 2 layers with 512 neurons each, using tanh as an activation function. For the training, an Adam optimizer (proposed by Kingma and Ba (2017)) and a reduce on plateau learning rate scheduler (cf. Ayyadevara and Reddy, 2020) with an initial learning rate of 1e−3, a reduction factor of 0.8 is used. For the training of our proposed symmetry HNN (SymHNN) we set $K = 2$ and in (2) the scaling factor $\beta^{(k)}$ is set to 0.001 for all k. This allows the network to choose $v^{(1)} = v^{(2)}$ in case that the translational invariant only exists in one direction.

For the numerical comparison a dense neural network (DenseNN), without learning the Hamiltonian but directly learning the dynamics, and a HNN are trained. For each model the same Runge–Kutta scheme, as for data generation, is used to evaluate the performance. The resulting trajectories for the states are shown in Figure 1 for (randomly chosen) initial configuration $[q,p] = [3.89, 3.68, -0.95, -1.67]$. The true Hamiltonian (3) is evaluated for the states of Figure 1 and shown in

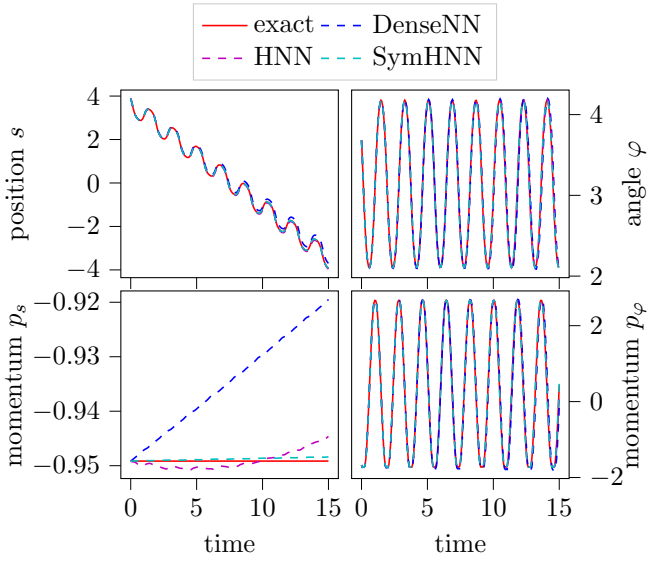

Fig. 1. Evaluated states of different (learned) models for the cart-pendulum.

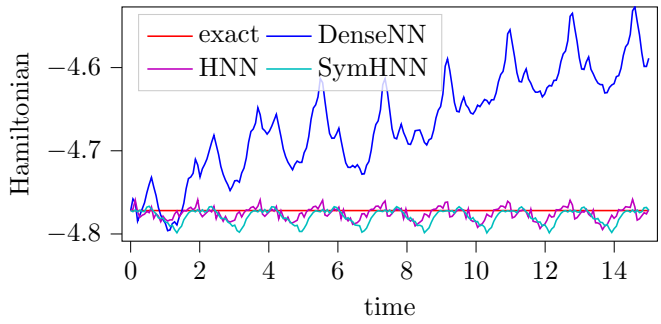

Fig. 2. True Hamiltonian evaluated for the states shown in Figure 1.

Figure 2. One can observe that the Hamiltonian is learned as successfully with SymHNN as with HNN.

Since this example is known to be invariant in the position s, the momentum p_s is conserved, which leads to a constant p_s for each trajectory. In Figure 1 it can be seen that the momentum for the DenseNN and the HNN are not conserved, whereas the momentum for our proposed SymHNN is preserved more effectively. To confirm this, the values for $\ell_{\text{sym}}^{(k)}$ are computed with the reference value $v = [1, 0]$ for all models. An improvement by a factor of 10 is observed (DenseNN: 0.0125, HNN: 0.0196 and SymHNN: 0.0012).

It should be highlighted that SymHNN learns correctly to choose $v^{(1)} = v^{(2)} = [0.990, -1.775\text{e}{-05}]$, since this example only has one translational invariant in s-direction. The learned v is close to the reference value of $[1, 0]$. However, since the integration in (1) is not performed exactly and the symmetry losses $\ell_{\text{sym}}^{(k)}$ are not precisely zero, the conjugate momentum p_s is not exactly but only approximately conserved in Figure 1.

4. CONCLUSION

We propose a neural network approach for simultaneously learning a system's Hamiltonian and its symmetries based on trajectory data. To preserve the symplectic structure encoded in the data, the NN is trained to learn the Hamiltonian, since the vector field can then be generated via automatic differentiation (cf. Greydanus et al., 2019; Dierkes and Flaßkamp, 2021). Extending this approach, which as coined the HNN method, we simultaneously identify inherent symmetries. Since we focus on the Hamiltonian setting, according to Noether's theorem, symmetries present themselves in term of invariances. However, we go another step forward and learn basis vectors of a Lie algebra subspace. These define the Lie subgroup, which belongs to actions (e.g. affine linear transformations) leaving the Hamiltonian invariant. In other words, we identify the integrals of motions such as the cart position in the studied cart-pendulum example. Future work will address the combination with symplectic discretization, e.g. via symplectic partitioned Runge-Kutta schemes. A discrete-time variant of this approach might directly learn modified Hamiltonian and discerete-time symmetries (cf. Offen and Ober-Blöbaum, 2022; Ober-Blöbaum and Offen, 2022). Symmetry in Hamiltonian systems give rise to relative equilibria, to which the learning framework can be extended in future.

Abstract: We study time minimal control problem for quantum systems whose dynamics are governed by the Bloch equation with interaction. The dynamics of the quantum systems are analyzed as affine control systems on the Bloch ball using parametrizations of the density matrix. The influence of Coulomb energies during a process of population transfer for a quantum system with several energy levels is shown and time minimal trajectories are given.

Keywords: Optimal control, Quantum dots, Bloch models, Elliptic functions.

1. INTRODUCTION

In the last few decades control of quantum systems has been widely studied from both theoretical and interdisciplinary points of view. Recently, there has been a growing interest in optimal control of quantum systems because of their applications to biology, physics, chemistry and quantum computing. Also, studies on the manipulation of quantum systems have given rise to several models allowing the description of certain physical phenomena. For example, the Landau-Zener and Lindblad equations which describe the evolution of quantum systems interacting with their environment are given in Morzhin et al. (2021). Other applications include control of spin dynamics by magnetic fields in nuclear magnetic resonance in Ernst et al. (1987). We are interested in the time minimal control problem for quantum systems at several energy levels given by quantum dots and whose dynamics are described by the Bloch equation with interaction, taking Coulomb parameters into account.
The control of quantum systems and time minimum population transfer problem has attracted interest of many authors. For example, in Sugny et al. (2007) the problem of achieving the optimal synthesis of a dissipative quantum system at two energy levels is treated. In Boscain et al. (2006) the authors consider the time minimum population transfer problem for a spin particle driven by a magnetic field on the Bloch sphere where the population dynamics are influenced by a parameter which depends on the maximum amplitude of the control field and energy levels. In Bonnard et al. (2009) and in Lapert et al. (2013) the problem of time minimal control with dissipative terms, and the damping effects which act on the dynamics of the populations is studied. In Khaneja et al. (2001) the authors deal with the problem of finding the time optimal control of spin quantum systems to produce unit operators.

In this paper we are interested in the study of time minimal control problem for quantum systems given by quantum dots, which are nonlinear Bloch models with interaction. We consider a Bloch model given by the complex matrix differential equation:

$$i\hbar\dot{\rho} = [H + V(\rho), \rho],$$

where state ρ is the density matrix, H is the Hamiltonian and $V(\rho)$ is the Coulomb interaction matrix depending on Coulomb parameters. A parameterization of density matrix ρ verifying physical properties, allows to write the Bloch model as an affine control system with some constraints. It is well-known that for a two-level system, the parameterization of ρ is in bijection with the Bloch vector, but for a system with three levels there exist different geometries and the parametrization is not unique (see Brning et al. (2012)). The influence of Coulomb parameters on time minimal trajectories for two-level systems is studied in Zibo et al. (2020).

Here we consider a four-level quantum system, to simplify the study of the system a choice of block parameterization of two-level systems is made. Then by a choice of the energies of the free Hamiltonian of the system, we show a symmetry in the dynamics of the system which evolves on a sphere of R^6. Also, we highlight the Coulomb interaction between two Bloch vectors. We apply Pontryagin's Maximum Principle to determine the minimum transfer time trajectories from an initial to a final pur or mixed states. We show that the trajectories of time minimal control problem are expressed as elliptic functions. Many authors (Brockett et al. (1993), D'Alessandro et al. (2001), Jurdjevic (2001) and Yuan et al. (2007)) were interested in elliptic functions and in more interesting cases, the solutions are expressible in terms of elliptic functions. In El Assoudi-Baikari et al. (2021) and (2016), it is shown that the solutions are not always elliptic, this depends of some geometrical parameters characterizing the state space.

2. MAIN RESULTS

We present briefly the nonlinear Bloch model. Parametrization of the density matrix give an affine control system that we will consider to study the transfer problem in minimal time using Pontryagin's Maximum Principle.

2.1 Nonlinear Bloch model

We present a nonlinear Bloch model that takes into account Coulomb effects in a quantum system called a quantum dot. In Bidgaray et al. (2014) a model of quantum dots which contain N^c energy levels in the conduction band and N^v energy levels in the valence band is provided. This modeling leads to a nonlinear Bloch type equation whose nonlinear terms come from the Coulomb interaction. This model is given by:

$$i\hbar\dot{\rho} = [H + V(\rho), \rho]$$

where $\hbar$ is constant of Planck, (we assume $\hbar = 1$), ρ is the density matrix, that is Hermitian, positive semi-definite and it has a trace equal to one. The state ρ represents pure and mixed quantum states if $trace(\rho^2) \leq 1$.
The matrix $H{=}H_0 + H_L$ is the total Hamiltonian, H_0 is the free energy Hamiltonian in the quantum dot and H_L is the laser-quantum dot interaction Hamiltonian. H_0 is a diagonal matrix whose coefficients are $(E_i^c)_{i\in I^c}$ and $(E_j^v)_{j\in I^v}$, real numbers representing the free energies of electrons in the conduction band and the valence band, respectively. The inter-band transition frequency of the quantum dots is the energy $E_{kj} = E_j^c - E_k^v$. Moreover, taking the Coulomb interaction into account modifies the energy levels, for example by causing them to tend downwards, and $E_{kj} = E_j^c - E_k^v - R_{jkjk}^{c-v}$, where R_{jkjk}^{c-v} account for the Coulomb interactions called Coulomb parameters (see Bidgaray et al. (2014)).
$H_L = \begin{pmatrix} 0 & E(t)M \\ \overline{E(t)M} & 0 \end{pmatrix}$, where $E(t)$ is the electric field and M the dipolar matrix.
The Coulomb interaction matrix $V(\rho)$ is Hermitian, depending on Coulomb parameters (see Bidgaray et al. (2014) and Zibo (2021)).

2.2 Parametrization of a model with four energy levels.

In this section we consider the evolution of a quantum dot with four energy levels described by the transitions between the level 1 in the conduction band and the level 2 in the valence band and the transitions between the level 2 in the conduction band and level 1 in the valence band. We consider a Hamiltonian matrix, density matrix and Coulomb interaction matrix per block of two matrices. Here we give a parametrization of this model as an affine control system with two controls.

We choose the Hamiltonian of the form $H = \begin{pmatrix} H_1 & 0 \\ 0 & H_2 \end{pmatrix}$, with $H_1 = \begin{pmatrix} E_1^c & \omega_1(t) \\ \omega_1(t) & E_2^v \end{pmatrix}$ and $H_2 = \begin{pmatrix} E_2^c & \omega_2(t) \\ \omega_2(t) & E_1^v \end{pmatrix}$, where E_1^c, E_2^v, E_2^c and E_1^v are the free energies for the conduction and valence bands, and $\omega_i(t)$, $i \in \{1, 2\}$ are real bounded valued controls.

$\rho = \begin{pmatrix} \rho_{11}^c & \rho_{12}^{cv} & 0 & 0 \\ \rho_{21}^{vc} & \rho_{22}^v & 0 & 0 \\ 0 & 0 & \rho_{22}^c & \rho_{21}^{cv} \\ 0 & 0 & \rho_{12}^{vc} & \rho_{11}^v \end{pmatrix}$ et $V(\rho) = \begin{pmatrix} V_{11}^c & V_{12}^{cv} & 0 & 0 \\ V_{21}^{vc} & V_{22}^v & 0 & 0 \\ 0 & 0 & V_{22}^c & V_{21}^{cv} \\ 0 & 0 & V_{12}^{vc} & V_{11}^v \end{pmatrix}$.
We write
$\rho = \begin{pmatrix} \rho(x) & 0 \\ 0 & \rho(y) \end{pmatrix}$, $\rho(x) = \frac{1}{4}\begin{pmatrix} 1+x_3 & x_1 - ix_2 \\ x_1 + ix_2 & 1 - x_3 \end{pmatrix}$.
where $x = (x_1, x_2, x_3)^t$, $y = (x_4, x_5, x_6)^t$ are Bloch vectors.

In Zibo (2021), we give in detail the associated Coulomb interaction matrix $V(\rho)$, we calculate its coefficients using the the properties of Coulomb parameters. We obtain:

$V_{11}^c = \frac{1}{2}(c_0 - c_1) - \frac{3}{4}(c_2 + c_3) - \frac{c_3}{4}x_3 + (\frac{1}{2}(c_0 - c_1) - \frac{c_2}{4})x_6$
$V_{22}^v = \frac{3}{2}(c_1' - c_0') + \frac{1}{4}(c_3 + c_4) + \frac{c_3}{4}x_3 + (\frac{1}{2}(c_1' - c_0') + \frac{c_4}{4})x_6$
$V_{12}^{cv} = -\frac{1}{4}(c_3x_1 + c_5x_4) + \frac{i}{4}(c_3x_2 + c_5x_5)$
$V_{22}^c = \frac{1}{2}(c_0 - c_1) - \frac{3}{4}(c_3 + c_4) + (\frac{1}{2}(c_0 - c_1) - \frac{c_4}{4})x_3 - \frac{c_3}{4}x_6$
$V_{11}^v = \frac{3}{2}(c_1' - c_0') + \frac{1}{4}(c_3 + c_2) + (\frac{1}{2}(c_1' - c_0') + \frac{c_2}{4})x_3 + \frac{c_3}{4}x_6$
$V_{21}^{cv} = -\frac{1}{4}(c_3x_4 + c_5x_1) + \frac{i}{4}(c_3x_5 + c_5x_2)$.
where c_j, c_j', for $0 \leq j \leq 5$ are constant depending on the Coulomb parameters.

Also, by identifying the matrices $\dot{\rho} = \dot{\rho}(x, y)$ and the bracket $-i[H + V(\rho), \rho]$ we obtain following system that highlights the interaction between the two blocks of ρ.

$\dot{x}_1 = a_1x_2 - cx_3x_5 + bx_2x_6$,
$\dot{x}_2 = -a_1x_1 + cx_3x_4 - bx_1x_6 - 2\omega_1x_3$,
$\dot{x}_3 = c(x_1x_5 - x_2x_4) + 2\omega_1x_2$,
$\dot{x}_4 = a_2x_5 - cx_2x_6 + bx_3x_5$,
$\dot{x}_5 = -a_2x_4 + cx_1x_6 - bx_3x_4 - 2\omega_2x_6$,
$\dot{x}_6 = c(x_2x_4 - x_1x_5) + 2\omega_2x_5$,
with reel constants a_1, a_2, b, c given by Coulomb parameters and the transition frequencies.

It is easy to verify that for any control functions ω_1, ω_2, we have $x_1\dot{x}_1 + x_2\dot{x}_2 + x_3\dot{x}_3 = 0$ and $x_4\dot{x}_4 + x_5\dot{x}_5 + x_6\dot{x}_6 = 0$ which implies $\sum_{j=1}^6 x_j\dot{x}_j = 0$. Hence for $x(0) = (0, 0, 1)^t$ and $y(0) = (0, 0, 1)^t$, one has that $\|x(t)\|^2 = \|x(0)\|^2 = 1$ and $\|y(t)\|^2 = \|y(0)\|^2 = 1$, and then $x(t)$, $y(t) \in S^2 \subset R^3$. Set $z = \begin{pmatrix} x \\ y \end{pmatrix}$, clearly $\|z(t)\|^2 = \|z(0)\|^2 = 2$. So $z(t)$ belongs to the sphere of radius $\sqrt{2}$ in R^6.
Notice that $x(t)$ and $y(t)$ do not independently evolve, there is an interaction between these two Bloch vectors.

2.3 Symmetry and interaction in the dynamics

We choose the free Hamiltonian $H_0 = diag(E_1^c, E_2^v, E_2^c, E_1^v)$ such that the two energy differences $E_1^c - E_2^v$ and $E_2^c - E_1^v$ being equal and then we get that $a_1 = a_2 = a$. In this case the following proposition shows a symmetry in the dynamics of the Bloch vectors $x(t)$ and $y(t)$ and that the linear part of the above system corresponds to a two-level system for each Bloch vector $x(t)$ and $y(t)$ and the nonlinear part representing the Coulomb interaction, is a vector product of the two vectors $x(t)$ and $y(t)$. Set

$A = \begin{pmatrix} 0 & a & 0 \\ -a & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$, $B = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$ and $C = \begin{pmatrix} c & 0 & 0 \\ 0 & c & 0 \\ 0 & 0 & b \end{pmatrix}$.
Set $u_1(t) = 2\omega_1(t)$ and $u_2(t) = 2\omega_2(t)$ and assume $|u_i| \leq 1$.

Proposition 1 The dynamic of this quantum system with four energy levels, when $a_1 = a_2 = a$, is given by

$$(\Sigma) \quad \dot{z} = \begin{pmatrix} A + u_1 B & 0 \\ 0 & A + u_2 B \end{pmatrix} z + \begin{pmatrix} x \wedge Cy \\ y \wedge Cx \end{pmatrix}.$$

2.4 Time minimal trajectories

We present some basic notions of the optimal control problem (see for more details Pontryagin et al. (1962) and Boscain et al. (2004)). Consider an affine control system with m control functions $\dot{z} = F(z) + \sum_{i=1}^{m} u_i G_i(z)$, where $z \in R^n$ and $F, G_1, ..., G_m$ are smooth vector fields and control functions $u = (u_1, ..., u_m)^t$ are bounded measurable functions, with values in a domain $\mathcal{U} \subset R^m$. An optimal control problem consists to find a trajectory $z(\cdot)$ associated with a control $u(\cdot)$, solution of this system verifying $z(0) = z_0$ and $z(T) = z_1$ and minimizing a functional cost $C(u) = \int_0^T L(z(t), u(t))dt$, where $L : R^n \times R^m \longrightarrow R$ is a criterion function. The pair $(z(\cdot), u(\cdot))$ is called optimal. If $L(z(t), u(t)) = 1$, then $C(u) = T$ and we have a time minimal control problem.

We apply Pontryagin's Maximum Principle (PMP) which is a generalization of the Hamiltonian formulation of the classical calculus of variations and it gives necessary conditions that a trajectory must satisfy in order to minimize a functional cost. The Hamiltonian function associated to the system with the cost $C(u) = T$ is defined as follows for all $(z, p, u) \in T^*R^n \times \mathcal{U}$, where $p(t)$ is a row vector (the adjoint vector), and p_0 a constant, $p_0 \leq 0$.

$$\mathcal{H}(z, p, u) = p(t)(F(z(t)) + \sum_{i=1}^{m} u_i G_i(z(t))) + p_0$$

Pontryagin's Maximum Principle says that if a pair $(z(\cdot), u(\cdot))$ is optimal, then there exists a non zero absolutely continuous function $p(\cdot) : [0, T] \longrightarrow T^*_{z(t)}R^n$, and a constant $p_0 \leq 0$, such that for almost all $t \in [0, T]$ we have

$\dot{z}(t) = \frac{\partial \mathcal{H}}{\partial p}(z(t), p(t), u(t))$, $\dot{p}(t) = -\frac{\partial \mathcal{H}}{\partial z}(z(t), p(t), u(t))$
and $\mathcal{H}(z, p, u) = max_{v \in \mathcal{U}} \{\mathcal{H}(z, p, v)\}$.

The maximization condition of (PMP) can be written as $\max_{v \in \mathcal{U}} \{\mathcal{H}(z, p, v)\} = max_{v \in \mathcal{U}} \{\sum_{i=1}^{m} v_i \Phi_i\}$,

where the functions $\Phi_i = pG_i(z)$ are called switching functions. If the controls are bounded, optimal controls are given by bang-bang controls as follows:
if $\Phi_i(t) > 0$ (resp. $\Phi_i(t) < 0$) for $t \in]t_1, t_2[\subset [0, T]$, then the optimal control is bang $u_i(t) = 1$, (resp. $u_i(t) = -1$). If Φ_i is zero over an interval $[t_1, t_2]$, we say that $z(\cdot)$ is a singular extremal trajectory.

For our system (Σ), we write the adjoint vector by bloc $p(s) = (P_1(s), P_2(s))$, with $P_i^t(s) \in R^3$ for $i = 1, 2$ and then $\mathcal{H}(z, p, u) = p_0 + p\dot{z} = p_0 + P_1\dot{x} + P_2\dot{y} =$
$p_0 + P_1((A + u_1 B)x + x \wedge Cy) + P_2((A + u_2 B)y + y \wedge Cx)$.

Proposition 2 The dynamic of the adjoint equation of (Σ) is given by
$\dot{P}_1^t = (A + u_1 B)P_1^t + (P_1^t \wedge Cy) - C(P_2^t \wedge y)$ *and*
$\dot{P}_2^t = (A + u_2 B)P_2^t + (P_2^t \wedge Cx) - C(P_1^t \wedge x)$.

The proof of this proposition uses the following lemma.

Lemma For all $x, y \in R^3$ and for any row vector $q \in R^3$, and for all $(3, 3)$ matrix D with real coefficients one has
1. $x \wedge y = \begin{pmatrix} 0 & y_3 & -y_2 \\ -y_3 & 0 & y_1 \\ y_2 & -y_1 & 0 \end{pmatrix} x$, for $y = (y_1, y_2, y_3)^t$.
2. $\frac{\partial}{\partial x} q(x \wedge y) = -(q^t \wedge y)^t$.
3. $\frac{\partial}{\partial x} q(Dx \wedge y) = -(q^t \wedge y)^t D = -(Dq^t \wedge y)^t$.

The (PMP) maximization condition gives switching functions $\Phi_1 = P_1 Bx$ and $\Phi_2 = P_2 By$. Note that each switching function corresponds to a two-level system. Also, if $\Phi_i(t) > 0$ then $u_i = 1$ and if $\Phi_i(t) < 0$ then $u_i = -1$.

(Σ) is an affine system with two controls that evolves on the sphere of R^6 with radius $\sqrt{2}$. Despite the fact that the Bloch vectors x and y play the same role in the dynamics of (Σ), it is difficult to make an optimal study, since $z \in R^6$ and there is an interaction between x and y which appears in the vector product. Here we consider a particular case to simplify the study of System (Σ). We choose the density matrix $\rho(x, y)$ such that $x = y$ and $u_1 = u_2 = u$. Then the two sub-systems of (Σ) for each Bloch vector follows the same dynamic

$$(\Sigma') \quad \dot{x} = (A + uB)x + x \wedge Cx$$

which represents a system with a Coulomb interaction (when $b \neq c$) and which evolves on the sphere S^2 of R^3. Hamiltonian function is given by

$$\mathcal{H}(x, p, u) = p_0 + p\dot{x} = p_0 + p(A + uB)x + p(x \wedge Cx).$$

The switching function is $\Phi = pBx$ and the adjoint dynamic associated with (Σ') is given by

$$\dot{p^t} = (A + uB)p^t + (p^t \wedge Cx) - C(p^t \wedge x),$$

Note that in this case if in addition $b = c$, then we obtain the same dynamic obtained for the two-level system, and for the state $x(t)$ and for the adjoint vector we have $\dot{x} = (A + uB)x$ *and* $\dot{p^t} = (A + uB)p^t$. But in practice and by definition of the Coulomb parameters, the constants b and c are not necessarily equal.

Theorem For (Σ') $\dot{x} = (A + uB)x + x \wedge Cx$, when $b \neq c$, the coordinate functions $x_i(t)$, $1 \leq i \leq 3$, of the optimal trajectories $x(t)$ associated with $u = \pm 1$ are elliptic functions.

Proof of Theorem We have for a constant control $u = 1$, $\dot{x}_3(t) = x_2(t)$ *and* $\dot{x}_1(t) = ax_2 + (b - c)x_2x_3$. We deduce that $\dot{x}_1(t) = a\dot{x}_3(t) + (b - c)\dot{x}_3x_3$ and hence $x_1(t) = ax_3(t) + \frac{1}{2}(b - c)x_3^2 + k$, *with* $k = -a - \frac{1}{2}(b - c)$, (for $x(0) = (0\,0\,1)^t$). So, $\ddot{x}_3 = \dot{x}_2 = -ax_1 - (b - c)x_1x_3 - x_3$.

We express x_1 as a function of x_3 and we obtain

$$\ddot{x}_3 = \alpha x_3^3 + \beta x_3^2 + \gamma x_3 - ak,$$

with $\alpha = -\frac{1}{2}(b-c)^2$, $\beta = -\frac{3}{2}a(b-c)$ and $\gamma = -a^2 - 1 - (b-c)(a+\frac{1}{2}(b-c))$). It's clear that $\alpha \neq 0$ and $\beta \neq 0$, when $b \neq c$ and $a \neq 0$. It is well-known (see Siegel (1962)) that if $(\alpha, \beta) \neq (0,0)$ then the solutions of this 2-order differential equation, are elliptic and in particular if $(\gamma, ak) = (0,0)$ then the solutions of $\ddot{x}_3 = \alpha x_3^3 + \beta x_3^2$ when $\alpha \neq 0$ are Jacobi elliptic functions.
Notice that $k = 0$ if $2a = c - b$ and then $\gamma = -(a^2+1) \neq 0$ and $\beta = \frac{3}{4}(b-c)^2$ and $\ddot{x}_3 = \alpha x_3^3 + \beta x_3^2 + \gamma x_3$. Recall that Weierstrass elliptic functions are solutions of $\ddot{v} = 4v^3 + g_2 v^2 + g_3 v$, for specific known constants g_2 and g_3.
For the constant control $u = -1$, we find the same coefficients α, β, k and $\ddot{x}_3 = \alpha x_3^3 + \beta x_3^2 + \tilde{\gamma} x_3 - ak$, with $\tilde{\gamma} = -a^2 + 1 - (b-c)(a + \frac{1}{2}(b-c)) = -a^2 + 1 + (b-c)k$. In this case if $k = 0$, $(2a = c - b)$ then $\tilde{\gamma}$ vanishes for $a^2 = 1$ and in this case x_3 is a Jacobi elliptic function.
We deduce that for $u = \pm 1$, x_3 is elliptic and therefore x_2 is elliptic since the derivative of an elliptic function is also elliptic, and x_1 is elliptic since the product and the sum of elliptic functions are elliptic. This proves the theorem.

Recall that for the two-level quantum system, which corresponds to (Σ) when $b = c$, we have found in Zibo et al. (2020) that the coordinate functions $x_i(t)$ for $1 \leq i \leq 3$, of the optimal trajectories $x(t)$ associated with $u = \pm 1$ are trigonometric functions. We can find this result using the above 2-order differential equations with $\alpha = \beta = 0$, $\gamma = -(a^2+1)$, $k = -a$ and $\tilde{\gamma} = -a^2 + 1$.

3. CONCLUSION

This work shows that the geometric study of time minimal control for a two-level quantum system whose dynamic is given by a bilinear control system, which interested many authors, is more simpler than the study of a system with four energy levels. This is due to the presence of several Coulomb physical parameters characterizing the quantum dots and adding nonlinear terms which represent the interaction between energy levels.

Abstract: We analyse the turnpike properties for a general, linear-quadratic (LQ) optimal control problem. We assume that the system under consideration is governed by an infinite-dimensional differential equation with a generator A of a strongly continuous semi-group. The objective function is the sum of a control cost and a tracking term for an observation of the state.
The novelty of the results is twofold. Firstly, it obtains positive turnpike results for systems that are (partially) uncontrollable. Secondly, it provides turnpike results for optimal averaged control associated to a family of problems that depend on a random parameter, which is the first turnpike type result that extends the averaged controllability approach to optimal control problems. In both cases, the results do not require assumptions on stabilizability and detectability, which are most commonly used in the study of turnpike phenomena.
Examples supporting the theoretical findings will be presented as well.

Keywords: turnpike phenomenon, LQ optimal control problem, infinite-time admissibility, controllability Gramian, observability Gramian.

1. INTRODUCTION

The turnpike property refers to the tendency of optimal controls and trajectories to remain nearly stationary most of the time. It occurs in many optimal control problems associated with a time-evolution system and objective functionals of integral type with a tracking term. It can be interpreted as the property of the optimal control system that the influence of the initial state decays rapidly with time and the same holds for the terminal state backwards in time. This allows a time-dependent control problem to be reduced, at least approximately on the largest part of the time interval, to the corresponding stationary one. Such a simplification is of great interest, both from an application and computational point of view. The term 'turnpike' was coined by economists more than half a century ago and introduced in the context of finite-dimensional, discrete-time optimal control problems. However, it remained out of focus of the mathematical and control community for several decades.

⋆ This work was supported by Deutsche Forschungsgemeinschaft (DFG) in the Collaborative Research Centre CRC/Transregio 154, Mathematical Modelling, Simulation and Optimization Using the Example of Gas Networks, Projects C03 and C05, Projektnummer 239904186.
The research was done while the second author was visiting Chair of Dynamics, Control and Numerics (Alexander von Humboldt Professorship) at Friedrich-Alexander-Universität Erlangen-Nürnberg, with the support of the DAAD (Research Stays for University Academics and Scientists, 2021 programme) and Alexander von Humboldt-Professorship.

Rigorous analysis of the turnpike property started to develop recently in the context of mean field games and model predictive controls (e.g. Cardaliaguet et al. (2012)). A large theory on the topic related to the calculus of variations and optimal control problems has been developed independently by A. Zaslavski in a series of works (cf. Zaslavski (2015) and the references therein). Since then, numerous results have been published in this area, both in finite and infinite dimensional context, as well as for time-discrete and time-continuous systems. The notion has been applied in various contexts: shape design problems, residual neural networks, heat conduction etc. For a detailed introduction we refer an interested reader to some recent, extensive surveys on the topic given in Faulwasser and Grüne (2021); Gershovski and Zuazua (2022).

Most of the results on this topic require the system to be both stabilizable and detectable. In order to obtain the corresponding turnpike properties, the authors analyse the optimality system and explore stabilization properties of the corresponding Riccati operator by using sophisticated functional analysis tools.

Recently, we proposed a new approach based on an estimate for optimal controls that holds in general, without any restrictions on the operators and data that enter the problem (Gugat and Lazar (2021)). One obtains the measure and the integral turnpike property as a direct consequence of the estimate, just by assuming infinite-time admissibility of the control and the observation operator. The results are obtained for systems of both determinis-

tic and stochastic nature. However, the question of the exponential turnpike property, which is stronger than the obtained ones, remained open.

2. PROBLEM SETTING AND THE MAIN RESULT

We consider the control system

$$\begin{aligned} x'(t) + Ax(t) &= Bu(t) \\ x(0) &= x_0, \end{aligned} \tag{1}$$

whose dynamics is governed by an unbounded operator A on a Hilbert space X. Here $u \in L^2_{\text{loc}}([0,\infty);U)$ denotes the control function, U is a Hilbert space, B is a bounded control operator from $\mathcal{L}(U,X)$, and $x^0 \in H$ denotes the initial state.

We consider the optimal control problem

$$\begin{aligned} \min_u J_T(u) = \min_u \frac{1}{2}\int_0^T \left(|u(t)-u_d|_U^2 + |Cx(t)-z_d|_Z^2\right) dt \\ + p_d \cdot y(T), \end{aligned} \tag{2}$$

in which the minimization is taken over the space $L^2_{\text{loc}}([0,\infty);U)$. Here C is an observation operator from $L(X,Z)$, with Z being a Hilbert space, x is the state determined by control u, i.e. it is the solution to (1), u_d and z_d stand for a time independent desirable control and observation, respectively, while $p_d \in X$ determines a linear regularization of the final state.

Using classical convex optimization techniques (e.g. Peypouquet (2015)), the problem (2) is well posed and admits the unique solution given by the formula

$$u_T = -B^* p_T + u_d,$$

where p_T is obtained by solving the corresponding optimality system

$$\begin{aligned} x_T'(t) + Ax_T(t) &= -B(B^*p_T(t) - u_d) \\ x_T(0) &= x_0 \\ -p_T'(t) + A^*p_T(t) &= C^*(Cx_T(t) - z_d) \\ p_T(T) &= p_d. \end{aligned}$$

We also consider the corresponding stationary problem

$$\min_{u\in U} J_s(u) = \min\left\{\frac{1}{2}\left(|u-u_d|_U^2 + |Cx-z_d|_Z^2\right) | Ax = Bu\right\}. \tag{3}$$

Assuming that the stationary state equation $Ax = Bu$ is well posed, the problem (3) admits the unique solution given by

$$\bar{u} = -B^*\bar{p} + u_d,$$

where $\bar{p}$ satisfies the corresponding stationary optimality system

$$A\bar{x} = -B(B^*\bar{p} - u_d) \qquad A^*\bar{p} = C^*(C\bar{x} - z_d),$$

while $\bar{x}$ is the optimal stationary state.

Our examples are motivated by the following result ((Gugat and Lazar, 2021, Theorem 2.1)).

Theorem 1. The difference of solutions to optimal control problems (2) and (3), together with the difference of the corresponding optimal states, satisfies the estimate

$$\begin{aligned} &\|u_T - \bar{u}\|^2_{L^2(0,T;U)} + \|C(x_T - \bar{x})\|^2_{L^2(0,T;Z)} \\ &\le 2\Big(Q_T(x_0-\bar{x})\cdot(x_0-\bar{x}) + \Lambda_T(p_d-\bar{p})\cdot(p_d-\bar{p})\Big), \end{aligned}$$

where Q_T is the observability Grammian for the pair (A,C), while Λ_T stands for the controllability Grammian corresponding to the pair (A,B).

From the last result the basic turnpike properties follow dirrectly ((Gugat and Lazar, 2021, Theorems 2.2-2.3)).

Integral turnpike. The time averages of optimal controls and observations converge strongly:

$$\begin{aligned} \frac{1}{T}\int_0^T u_T &\xrightarrow[T\to\infty]{} \bar{u} \qquad \text{strongly in } U, \\ \frac{1}{T}\int_0^T Cx_T &\xrightarrow[T\to\infty]{} C\bar{x} \qquad \text{strongly in } Z, \end{aligned} \tag{4}$$

with the convergence rate of $O(1/\sqrt{T})$.

Measure turnpike. For every $\varepsilon > 0$ there exists a constant $C_\varepsilon > 0$ such that

$$\mu\big\{t \in [0,T] \big|\ |u_T - \bar{u}|^2 + |C(x_T - \bar{x})|^2 \ge \varepsilon\big\} < C_\varepsilon. \tag{5}$$

Convergence of the (normalized) minimal values.

$$\frac{1}{T}\min J_T \xrightarrow[T\to\infty]{} \min J_s, \tag{6}$$

with the convergence rate of order $1/\sqrt{T}$.

The same kind of results also hold in the stochastic case, i.e. when the dynamics, control and observation operator depend on a random parameter. However, the optimal control is assumed to be parameter independent, which leads to the notion of the optimal averaged control. The turnpike properties (4)-(6) are preserved, with the observation terms being replaced by their averaged values with respect to the parameter, assuming the control and observation operator are infinite-time admissible for almost every value of the random parameter.

Input Parametrizations and Their Numerical Implementation in Structure-Preserving Optimal Control

Markus Herrmann-Wicklmayr * **Kathrin Flaßkamp** *

* *Systems Modeling & Simulation, Saarland University, Saarbrücken, Germany (e-mail: markus.herrmannwicklmayr@uni-saarland.de)*

Abstract: Motivated by the advantages of structure-preserving integration for applications ranging from molecular dynamics to astrodynamics, geometric integration has been brought into optimal control in the past two decades. Advantages over conventional methods have been shown in biomechanics, robotics, automotive applications, and space mission design. The implicit midpoint method, that is a member of the class of symplectic (partitioned) Runge-Kutta methods but also possess a variational derivation and thus is symmetry-preserving, is widely used due to its many favorable properties. In particular, efficient computations can be achieved by coarse discretizations of state and control signals, since structure preservation does not have to be ensured by small step sizes, as it is the case in conventional methods. Then, specific input parametrizations become an issue when implementing optimized signals in control architectures. We show numerical studies for piecewise linear control signals used in energy optimal control problems.

Keywords: Energy Optimal Control, Structure-Preserving Integration, Implicit Midpoint Method, Input Parametrization, Direct Methods for Optimal Control

1. INTRODUCTION

In the context of structure-preserving (optimal) control the (symplectic) implicit midpoint rule is a popular choice (Ober-Blöbaum et al. (2011), Nair (2012), Leyendecker et al. (2010), Kotyczka and Thoma (2021)) due to its simplicity and many favorable properties (see Section 2). When using the associated Runge-Kutta method to discretize an energy optimal control problem (OCP) in combination with a piecewise linear input parametrization, i.e. a first-order hold (FOH) input signal, undesired oscillatory effects can occur in the computed optimal input trajectory. This extended abstract aims at explaining the origins of the effect and goes into detail on how it can be damped or eliminated. We demonstrate our findings in numerical experiments based on an orbit transition for the Kepler problem.
Notation: We define $[v_1, \dots, v_r] = (v_1^\top, \dots, v_r^\top)^\top$ as the vertical concatenation of the vectors $v_i,\ i = 1, \dots, r$.

2. MOTIVATING THE IMPLICIT MIDPOINT METHOD

The implicit Runge-Kutta method known as *implicit midpoint method (IMP)* (with the Butcher Tableau coefficients $(\mathsf{A}, \mathsf{b}, \mathsf{c}) = (\frac{1}{2}, 1, \frac{1}{2})$) has the following properties. It is of second order, has $s = 1$ stages, is A-stable, symmetric and symplectic. A special feature is that the implicit stage equation can be eliminated for any nonlinear system dynamics. This results in the implicit difference equation

$$x_{k+1} = x_k + hf\left(t_{k+\frac{1}{2}}, \frac{x_{k+1} + x_k}{2}\right), \quad t_{k+\frac{1}{2}} := \left(k + \tfrac{1}{2}\right)h,$$

where h is the step size. Then, for a full discretization of the OCP, the IMP requires just as many optimization variables (OVs) as an explicit Runge-Kutta method.

The A-stability of the method allows larger step sizes where explicit methods would become numerically unstable. By this, the size of the optimization problem can be kept small. This typically results in shorter optimization times. The before-mentioned properties are particularly suitable for real-time optimal control schemes, like model predictive control, or if a solution on a coarse time grid is required as a warmstart to an OCP on a finer time grid.

3. MOTIVATING FIRST-ORDER HOLD CONTROL

When solving an OCP for a non-autonomous continuous time (CT) system $\dot{x}(t) = f(t, x(t), u(t)),\ x \in \mathbb{R}^n,\ u \in \mathbb{R}^m$ via a direct method one needs to use a discrete time (DT) approximation of the CT dynamics. When using a s-stage Runge-Kutta method the time dependent parts of the vector field $f(t, x(t), u(t))$ are evaluated at s points to compute the next state. This requires the knowledge of $u(t)$ over the whole prediction horizon. Since the infinite-dimensional CT OCP needs to be approximated by a finite-dimensional optimization problem, the number of variables that parametrize the input has to be limited. The most common approach is to define the input to be constant on the time interval between two time instances. Then, for N time instances there are at most $N - 1$ inputs or $(N - 1) \cdot m$ variables that parametrize the input trajectory. This easy-to-implement approach is known as zero-order hold (ZOH) and it comes with some drawbacks. The ZOH approach

a) implicitly assumes that the input of the plant system, that is to be controlled, can jump between two values,
b) can lead to a large overshoot / peak in the states when applied to the plants (Herrmann-Wicklmayr et al. (2022)),
c) and thus would require a very fine time grid to capture this behavior.

These points mean that for a sufficiently large step size and/or *jump height* the behavior of the DT model and the CT plant might differ significantly. Consequently, the computed costs do not predict the true costs sufficiently accurate, the tracking performance might be poor, and unpredicted damaging of systems components might occur.

One now could argue that the above-mentioned problems can be circumvented by linearly connecting the computed inputs of the ZOH OCP. However, this would mean that the input trajectory implicitly assumed within the OCP, $u_{\mathrm{OCP}}(t) = u_k = const.$, $t \in [t_k; t_{k+1}) \coloneqq \mathcal{T}_k$, and the actually applied input trajectory

$$u_{\mathrm{plant}}(t) = u_k + \frac{u_{k+1} - u_k}{t_{k+1} - t_k}(t - t_k),\ t \in \mathcal{T}_k$$

differ (unless $u_{k+1} = u_k$). The CT trajectory error is

$$e_{\Delta u,\mathrm{CT}}(k) = \int_{t_k}^{t_{k+1}} |u_{\mathrm{plant}}(t) - u_{\mathrm{OCP}}(t)|\,\mathrm{d}t = \tfrac{h_k}{2}|u_{k+1} - u_k|$$

and it grows linearly with the step size $h_k = t_{k+1} - t_k$ and with the input difference. It only vanishes for $h_k \to 0$ and/or $|u_{k+1} - u_k| \to 0$. The DT input trajectory error is

$$e_{\Delta u,\mathrm{DT}}(k) = \sum_{i=1}^{s} \left|u_{\mathrm{plant}}(t_{k,i}) - u_{\mathrm{OCP}}(t_{k,i})\right| = \sum_{i=1}^{s} c_i\,|u_{k+1} - u_k|,$$

with $t_{k,i} = t_k + c_i h_k$. The error is only guaranteed to be zero if $\sum_{i=1}^{s} c_i = 0$. However, that is solely fulfilled by the first-order explicit Euler method. In summary, this implies that a linear interpolation only avoids imposing additional errors, if the explicit Euler method is used for the discretization.

For these reasons, the next logical step is to directly consider a FOH input trajectory within the OCP, i.e.

$$\tilde{u}(t) = u_k + \frac{u_{k+1} - u_k}{t_{k+1} - t_k}(t - t_k), \quad t \in \mathcal{T}_k$$

defined on a not necessarily equidistant time grid $t_0, \dots, t_N$ and via the nodes $u_0, \dots, u_N$. This approach comes at the negligible cost of m more OVs, representing the input at the final time instance, and possibly an m-dimensional equality constraint, expressing the initial condition of the input, and a slightly more involved implementation. Although not necessary, it might be useful to constrain the inputs rate of change in additional inequality constraints.

4. OPTIMAL INPUT TRAJECTORIES WITH ARBITRARY LARGE OSCILLATIONS

Consider the CT OCP

$$\begin{aligned} \min_{u(\cdot)}\ & J\big(u(\cdot)\big) = \int_0^T \ell(t)\,\mathrm{d}t \\ \text{s.t.}\ & \dot{x}(t) = f(t, x(t), u(t)), \quad x(0) = x^0, \\ & x(t) \in \mathbb{X}\ \forall\ t \in [0; T], \quad x(T) = x^T, \end{aligned} \qquad \left(\mathfrak{P}^{\mathrm{CT}}\right)$$

with the running cost $\ell(t) \coloneqq u(t)^\top R u(t)$ and the state constraint set $\mathbb{X}$. W.l.o.g. we assume that $R = I_m$. This is justified since with any positive definite matrix and its decomposition $\hat{R} = B^\top B$ (B is invertible) we can write $\hat{u}^\top \hat{R} \hat{u} = \left(B\hat{u}\right)^\top B\hat{u} = u^\top I_m u$ with $u = B\hat{u}$.

Let $\varphi\left(x^0, 0, t, u|_{[0;t]}\right) = x(t)$ be the flow of the CT system starting at $x(0)$ under the control $u|_{[0;t]}$ that is, in general, not available in closed form. Then, with $\tilde{\varphi}\left(x^0, 0, k, u|_{[0;t_k]}\right) = x_k$ we denote a DT approximation of the flow that depends on the chosen Runge-Kutta method. We apply the same method to the cost functional and obtain the approximation

$$\tilde{J} = \sum_{k=0}^{N-1} \sum_{i=1}^{s} b_i h \ell(t_k + c_i h) = \sum_{i=1}^{s} b_i \sum_{k=0}^{N-1} h u_{k,i}^\top u_{k,i}$$

with $u_{k,i} = u(t_k + c_i h)$. Using the IMP and defining $u_{k,1}$ as $u_{k+\frac{1}{2}} = \tilde{u}(t_k + \frac{1}{2}h)$ we obtain the DT OCP

$$\begin{aligned} \min_{U}\ & \tilde{J}(U) = h \sum_{k=0}^{N-1} u_{k+\frac{1}{2}}^\top u_{k+\frac{1}{2}} \\ \text{s.t.}\ & x_{k+1} = \tilde{\varphi}_{\mathrm{IMP}}\left(x_k, k, k+1, \tilde{u}|_{\mathcal{T}_k}\right), \quad x_0 = x^0, \\ & x_k \in \mathbb{X}\ \forall\ k \in \mathbb{N}_{1,N-1}, \quad x_N = x^T, \\ & \tilde{u}(t) = u_k + \tfrac{u_{k+1} - u_k}{h}(t - t_k), \quad t \in \mathcal{T}_k \end{aligned} \qquad \left(\mathfrak{P}^{\mathrm{IMP}}\right)$$

with $U = [u_0, u_1, \dots, u_N]$.

Remark. *As $h \to 0$, the solution of $\mathfrak{P}^{\mathrm{IMP}}$ does not necessarily converge to the one of $\mathfrak{P}^{\mathrm{CT}}$. This is caused by the non-coercivity of the discretized cost summands*

$$u_{k+\frac{1}{2}}^\top u_{k+\frac{1}{2}} = \tfrac{1}{4}(u_{k+1} + u_k)^\top (u_{k+1} + u_k)$$

as pointed out in Campos et al. (2015). This is due to the combination of the chosen Runge-Kutta scheme and input parametrization.

Proposition 4.1. *Assume that U^* is a local optimal solution to $\mathfrak{P}^{\mathrm{IMP}}$ and results in the cost $\tilde{J}^* = \tilde{J}\left(U^*\right)$. Then, for every optimal solution U^*, there exist infinitely many optimal solutions $\check{U}^*(A)$, $A \in \mathbb{R}^m$ that result in the same cost $\tilde{J}^* = \tilde{J}\left(\check{U}^*(A)\right)$, $i \in \mathbb{N}$.*

Proof. We define $\tilde{u}^*(\cdot)$ to be the optimal trajectory fully determined by U^*. Now $\tilde{u}^*(\cdot)$ is additively perturbed by

$$\Delta u(t, A) = A(-1)^k \left(1 - \tfrac{2}{h}(t - t_k)\right), \quad t \in \mathcal{T}_k$$

resulting in $u^d(t, A) = \tilde{u}^*(t) + \Delta u(t, A)$. The function $u^d(t, A)$ is piecewise linear by construction and has the property that $u^d(t_{k+\frac{1}{2}}, A) = \tilde{u}^*(t_{k+\frac{1}{2}})\ \forall k \in \mathbb{N}_{0,N},\ \forall A \in \mathbb{R}^m$. Equivalently, one can say that with $u_k^d = u_k^* + A(-1)^k$ the equality

$$u_{k+1}^d + u_k^d = u_{k+1}^* + A(-1)^{k+1} + u_k^* + A(-1)^k = u_{k+1}^* + u_k^* \quad (2)$$

holds. Then, $U^d = U^* + [A, -A, \dots, A \cdot (-1)^N]$ and the resulting state sequences $X^d = [x_0^d, \dots, x_N^d]$ are the same for U^* and U^d, i.e. $X^d = X^*$. Hence, $Z^d = [U^d, X^*]$ is a feasible solution to the nonlinear program (NLP) detailed out below.

Next, we show the optimality of the solution. We assume that $x_k \in \mathbb{X}$ can be expressed via an inequality and define

$$\begin{aligned} c_k &= c(x_k, x_{k+1}, u_k, u_{k+1}) \\ &= x_{k+1} - x_k - h f\left(t_{k+\frac{1}{2}}, \tfrac{x_{k+1} + x_k}{2}, \tfrac{u_{k+1} + u_k}{2}\right) \end{aligned}$$

for all $k \in \mathbb{N}_{0,N-1}$, representing the continuity constraint of the states. Then, with $Z = [U, X]$ the function $\hbar(Z)$

and vector λ represents all equality constraints (continuity constraints & initial/terminal constraint) and their corresponding Lagrange multipliers, the function $g(Z)$ and vector μ all inequality constraints (state constraints) and their corresponding Lagrange multipliers in the NLP derived from $\mathfrak{P}^{\mathrm{IMP}}$.

Then, $\mathfrak{P}^{\mathrm{IMP}}$ can be written as a nonlinear optimization problem or NLP of the form

$$\min \tilde{J}(Z) \;\text{ s.t. } \hbar(Z) = 0,\; g(Z) \leq 0$$

with $Z = [U, X]$. Since U^* was an optimal solution to $\mathfrak{P}^{\mathrm{IMP}}$ the DT dynamics output an optimal state sequence X^* and we know that there exist Lagrange multipliers λ^*, μ^* such that the triple (Z^*, λ^*, μ^*) satisfies all Karush-Kuhn-Tucker (KKT) conditions.

Based on the definition of $u_{k+\frac{1}{2}}$ and the chosen input parametrization we can rewrite the cost functional as

$$\tilde{J}(Z) = \tilde{J}(U) = \frac{h}{4} \sum_{k=0}^{N-1} u_{k+1}^\top u_{k+1} + 2u_{k+1}^\top u_k + u_k^\top u_k.$$

Then the Lagrangian of the NLP is

$$L(Z, \lambda, \mu) = \tilde{J}(Z) + \lambda^\top \hbar(Z) + \mu^\top g(Z).$$

With the placeholder $(*) := \left(t_{k+\frac{1}{2}}, \frac{\bar{x}_{k+1}+\bar{x}_k}{2}, \frac{\bar{u}_{k+1}+\bar{u}_k}{2}\right)$, it follows that

$$\begin{aligned} \nabla_{x_k} c_k\big|_{(*)} &= -I - \tfrac{h}{2}\, \nabla_{x_k} f\big|_{(*)}, \quad \nabla_{u_k} c_k\big|_{(*)} = -\tfrac{h}{2}\, \nabla_{u_k} f\big|_{(*)}, \\ \nabla_{x_{k+1}} c_k\big|_{(*)} &= I - \tfrac{h}{2}\, \nabla_{x_{k+1}} f\big|_{(*)}, \end{aligned} \tag{3}$$

for all $k \in \mathbb{N}_{0,N-1}$ and $k \in \mathbb{N}_{0,N}$, respectively. In the same manner we obtain

$$\begin{aligned} \nabla_{u_k} \tilde{J}(Z)\big|_{\bar{Z}} &= h\left(\bar{u}_k + \tfrac{1}{2}\left(\bar{u}_{k-1} + \bar{u}_{k+1}\right)\right) \quad \forall\; k \in \mathbb{N}_{1,N-1}, \\ \nabla_{u_0} \tilde{J}(Z)\big|_{\bar{Z}} &= \frac{1}{2} h \cdot (\bar{u}_1 + \bar{u}_0), \\ \nabla_{u_N} \tilde{J}(Z)\big|_{\bar{Z}} &= \frac{1}{2} h \cdot (\bar{u}_N + \bar{u}_{N-1}). \end{aligned} \tag{4}$$

With a slightly more compact notation, the Lagrange condition is

$$\nabla_Z L(Z^*, \lambda^*, \mu^*) = \nabla_Z \tilde{J}(Z^*) + \nabla_Z \hbar(Z^*)\lambda^* + \underbrace{\nabla_Z g(Z^*)}_{=\nabla_Z g(X^*)} \mu^* \overset{!}{=} 0.$$

We refrain from explicitly writing down the primal feasibility, dual feasibility and complementary slackness conditions (remaining KKT conditions). Now set the dynamically feasible choice of OVs $\bar{Z} = Z^d = [U^d, X^*]$. From (2) and the definition of f we can conclude that (3) and (4) evaluated at $(t_{k+\frac{1}{2}}, x_k^*, x_{k+1}^*, u_k^d, u_{k+1}^d)$ or $(t_{k+\frac{1}{2}}, x_k^*, x_{k+1}^*, u_k^*, u_{k+1}^*)$ yield the same results and it follows

$$\nabla_Z Y\left(Z^*\right) = \nabla_Z Y\left(Z^d\right), \quad Y = \{\tilde{J}, \hbar, g\}.$$

Hence, if the Lagrange condition is fulfilled for (Z^*, λ^*, μ^*), then it is fulfilled for $(Z^d, \lambda^d, \mu^d) = ([U^d, X^*], \lambda^*, \mu^*)$. The same holds true for the remaining KKT conditions. Moreover, all previous arguments are valid for any $A \in \mathbb{R}^m$ and $\tilde{U}^*(A) = U^d$. □

Next, among all the possible input trajectories $\tilde{u}^{\bigstar}(t) = \tilde{u}^*(t) + \Delta u(t, A)$, $A \in \mathbb{R}^m$, where $\tilde{u}^*(t)$ is any known (locally) optimal solution to $\mathfrak{P}^{\mathrm{IMP}}$, we determine the one optimizing the *actual* cost $J^{\bigstar} = \int_0^T \left(\tilde{u}^{\bigstar}(t)\right)^\top \tilde{u}^{\bigstar}(t)\,\mathrm{d}t$ from $\mathfrak{P}^{\mathrm{CT}}$. The choice of the parameter A neither affects the cost nor the state trajectory (in $\mathfrak{P}^{\mathrm{IMP}}$). We now determine A such that $J^{\bigstar}$ is minimized. First we compute the cost

$$\begin{aligned} J^{\bigstar} &= \int_0^T \left(\tilde{u}^{\bigstar}\right)^\top \tilde{u}^{\bigstar}\,\mathrm{d}t \\ &= \int_0^T \left(\tilde{u}^*\right)^\top \tilde{u}^* + 2\left(u^*\right)^\top \Delta u + \Delta u^\top \Delta u\,\mathrm{d}t \\ &= \ldots = \frac{h}{3}\left(N \cdot A^\top A + \sum_{k=0}^{N-1} (-1)^k A^\top \left(u_k^* - u_{k+1}^*\right)\right) + J^*. \end{aligned}$$

Finding the extremum of $J^{\bigstar}$ yields the optimal parameter choice

$$\frac{\partial J^{\bigstar}}{\partial A}\left(A^{\bigstar}\right) \overset{!}{=} 0 \;\Leftrightarrow\; A^{\bigstar} = -\frac{1}{2N} \sum_{k=0}^{N-1} (-1)^k \left(u_k^* - u_{k+1}^*\right). \tag{5}$$

This resolves the ambiguity of the DT OCP based on the IMP by adding a *post-processing* step.

Besides this post-processing ansatz, there are (at least) two approaches on how to prevent the oscillatory behavior:
a) Directly use the analytical solution of the cost functional. Consider the piecewise linear function $z(t) \in \mathbb{R}^m$ that is defined as $\tilde{u}(t)$ in $\mathfrak{P}^{\mathrm{IMP}}$. Then we can easily compute the integral

$$J = \int_0^T z(t)^\top z(t)\,\mathrm{d}t = \frac{h}{3} \sum_{k=0}^{N-1} z_{k+1}^\top z_{k+1} + z_k^\top z_{k+1} + z_k^\top z_k.$$

b) Use an integrator that *evaluates* the input trajectory $\tilde{u}(t)$ at *multiple* points $t_{k,i} := t_k + c_i h$, $i = 1, \ldots, s$ and weighs these points with (optimally) non-vanishing coefficients $b_i > 0$:

$$\tilde{J}(U) = \sum_{k=0}^{N-1} \sum_{i=1}^{s} b_i h \ell(t_k + c_i h) = \sum_{i=1}^{s} b_i \sum_{k=0}^{N-1} h u_{k,i}^\top u_{k,i} =: \sum_{i=1}^{s} b_i \tilde{J}_{u,i} \tag{6}$$

with $u_{k,i} := u(t_k + c_i h)$. At least one of the points should be *sufficiently far* away from the midpoint and have a *sufficiently large* weight, i.e. there exists at least one coefficient pair (b_i, c_i) that satisfies $|c_i - \frac{1}{2}| \cdot |b_i| > \Delta_{\mathrm{MP}} > 0$. A priori it is not clear what *sufficiently far* and *large* means, i.e. how large Δ_{MP} has to be. Assuming the inequality is satisfied, arbitrary large oscillations in the input trajectory would be captured and, in conclusion, be damped or eliminated as a consequence of the optimization process.

As an example, consider the generic second order Runge-Kutta method with the Butcher tableau

$$\begin{array}{c|c} \mathsf{c} & \mathsf{A} \\ \hline & \mathsf{b} \end{array} \;\hat{=}\; \begin{array}{c|ccc} 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ \frac{1}{2} & \alpha_1 & \alpha_2 & 0 \\ \hline & \delta_{\mathrm{MP}} & \delta_{\mathrm{MP}} & 1 - 2\delta_{\mathrm{MP}} \end{array} \;\hat{=}\; \mathrm{BT}^{\mathrm{EMP}_\delta}$$

with $\delta_{\mathrm{MP}} \in [0; \frac{1}{2}]$ and $\alpha_1 + \alpha_2 = \frac{1}{2}$. We set $\alpha_2 = 0$ which results in $\alpha_1 = \frac{1}{2}$. For $\delta_{\mathrm{MP}} = 0$ we obtain the explicit midpoint method (EMP). Otherwise for $i = 1, 2$ we have $|c_i - \frac{1}{2}| \cdot |b_i| = \frac{1}{2}\delta_{\mathrm{MP}}$. Using the parameter δ_{MP}, this allows us to control how much the method, which we call EMP_δ, deviates from the EMP. We replace the cost computation in $\mathfrak{P}^{\mathrm{IMP}}$ with (6) and with the coefficients of $\mathrm{BT}^{\mathrm{EMP}_\delta}$. We denote the resulting OCP as $\mathfrak{P}^{\mathrm{IMP,EMP}_\delta}$.

5. NUMERICAL RESULTS

For our numerical investigation we use the Kepler problem dynamics (in Hamilton formulation)

$$\dot{x} = \frac{\mathrm{d}}{\mathrm{d}t}\left[r,\ \theta,\ p_r,\ p_\theta\right] = \left[\tfrac{p_r}{m},\ \tfrac{p_\theta}{mr^2},\ \tfrac{1}{mr^3}p_\theta^2 - \tfrac{\gamma mM}{r^2} + u_r,\ u_\theta\right]$$

with parameters $k = \gamma mM = 1 \cdot 10^3$ and $m = 1$. An energy-optimal (in the sense of $\mathfrak{P}^{\mathrm{CT}}$) transition from one circular orbit $x_s(r,\theta_s) = \left[r_s, \theta_s, 0, mr_s^2\sqrt{\frac{k}{mr_s^3}}\right]$ to another one should be finished in $T = 3\,\mathrm{s}$. We set the initial state condition to $x^0 = x_s(5,0)$, the terminal one to $x^T = x_s(6,\theta^T)$ with $\theta^T \in \mathbb{R}$, i.e. θ^T is unconstrained. We discretize the CT OCP by using the IMP for both dynamics and running cost. If additionally an FOH input parametrization is assumed, we obtain a problem of the type $\mathfrak{P}^{\mathrm{IMP}}$.

We solve the corresponding NLP for multiple numbers of shooting nodes and compare the resulting input trajectory with a reference solution $u_{\mathrm{ref}} = [u_{r,\mathrm{ref}}, u_{\theta,\mathrm{ref}}]$ (obtained from solving a DT OCP using the classical RK4 scheme and a step size $h = 10^{-3}\,\mathrm{s}$). The difference of the trajectories is evaluated at the nodes, i.e. $e_k = u_k - u_{\mathrm{ref}}(t_k)$, and the mean square error (MSE) is computed. The results are shown in Fig. 1. No systematic change in the MSE with increasing N, i.e. decreasing h, can be observed. This is plausible since, as it was shown in Section 4, all oscillation amplitudes are – in theory – equally likely. The obtained solution *highly* depends on the chosen hyperparameters of the solver and numerical noise. This behavior is not observed in general.

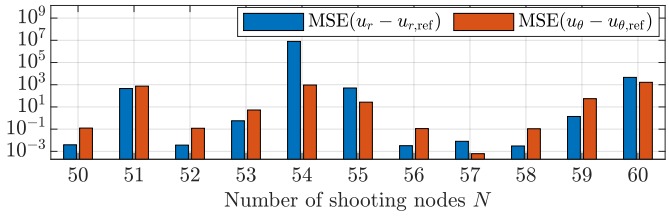

Fig. 1. The OCP $\mathfrak{P}^{\mathrm{IMP}}$ is solved for different number of shooting nodes, resulting in different step sizes $h = \frac{T}{N}$ that range from 0.05 s to 0.06 s.

Next, we show the effect of post-processing the previously found solutions by computing $A^\star$ and adding $u^d(t, A^\star)$ to them. This results in Fig. 2. The errors are in the same order and a trend – the error decreases as N increases – can be observed.

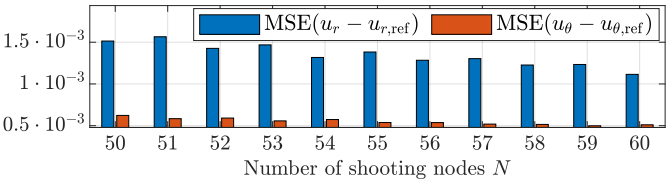

Fig. 2. The solution used to generate Fig. 1 were post-processed by adding $\Delta u(t, A^\star)$, where $A^\star$ is computed as shown in (5). The y-axis is non-logarithmic.

Our next investigation concerns the effect of using $\mathfrak{P}^{\mathrm{IMP,EMP}_\delta}$ with different parameters δ_{MP}, i.e. a different (generic) Runge-Kutta method with the Butcher tableau $\mathrm{BT}^{\mathrm{EMP}_\delta}$ was used to integrate the running costs. We choose $N = 60$ shooting nodes which corresponds to one of the worst solutions of Fig. 1. The results are shown in Fig. 3. Even a small weight $b_1 = b_2 = \delta_{\mathrm{MP}} \geq 4 \cdot 10^{-4}$ on the cost parts $\tilde{J}_{u,i}$, see (6), results in a MSE smaller than 10^{-4} for both inputs u_r, u_θ. It is clearly visible that the larger the deviation δ_{MP} becomes, the smaller the MSE of the inputs. This confirms the intuition that the sensitivity of the solution is a result of the EMP/IMP, rather than the chosen hyperparameters of the solver.

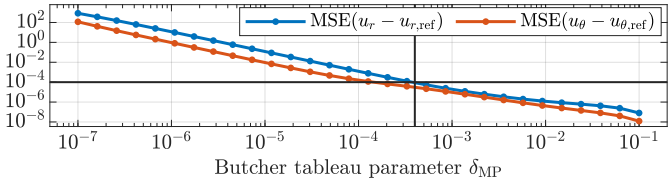

Fig. 3. MSEs when solving the $\mathfrak{P}^{\mathrm{IMP,EMP}_\delta}$ for various δ_{MP}.

6. CONCLUSION

In this extended abstract we showed that the popular choice of the implicit midpoint method (in the context of energy optimal control) can lead to undesired and unpredictable numerical effects in the form of arbitrarily large oscillations. Thereby one possible effect of the non-coercivity, as described in Campos et al. (2015), was presented. We then demonstrate how the oscillations can be damped or eliminated a) by post-processing the OCP solution and b) by removing the non-coercivity property. We conjecture that similar effects for other types of problems, e.g. discretizing holonomic constraints (Johnson and Murphey (2009)), result from applying the IMP.

Abstract: The prospect and demand of using the Lee metric to construct public-key encryption schemes and digital signature schemes have immensely grown in recent times. This leads the researchers to ask about the hardness of decoding a general Lee metric code. In this work, we answer this question by showing that the syndrome decoding problem over the Lee metric is NP-complete. Moreover, we will quantify the computational hardness of the syndrome decoding problem with respect to the best-known ISD algorithms.

Keywords: Lee metric, Information-set decoding, Syndrome decoding problem
2010 MSC: 11T71, 94B35

1. INTRODUCTION

The problem of decoding a general linear code has recently gained immense interest due to its cryptographic applications. McEliece, in [11], proposed a public-key encryption scheme whose security is based on the hardness of decoding a general linear code over the Hamming metric. Currently, this cryptosystem stands as one of the most promising candidates for post-quantum cryptography [6]. However, McEliece's cryptosystem comes with one drawback of having large key sizes. This has encouraged many researchers to look for an alternative way to create code-based cryptosystems. One such way is to change the underlying metric, such as to rank metric or Lee metric.

In this work, we study the hardness of decoding a general linear code over the Lee metric. We first show that the Lee metric syndrome decoding problem (L-SDP) is NP-complete, which follows a similar proof as in the case of the Hamming metric. Next, we discuss the computational hardness of solving the L-SDP problem for a random instance case. In particular, we discuss all the recently developed decoding algorithms and compare their performance. We further provide some new ideas to improve the existing algorithms and develop new algorithms for L-SDP.

2. PRELIMINARIES

In this section, we present some preliminaries about the Lee metric and linear codes over an integer residue ring. Throughout this section, let m, n be positive integers.

Definition 1. (1) For $x \in \mathbb{Z}/m\mathbb{Z}$, the *Lee weight* of x is given by

$$\mathrm{wt}_L(x) := \min\{x, |m-x|\}.$$

(2) For a vector $\mathbf{x} = (x_1, x_2, \ldots, x_n) \in (\mathbb{Z}/m\mathbb{Z})^n$, the *Lee weight* of $\mathbf{x}$ is given by

$$\mathrm{wt}_L(\mathbf{x}) := \sum_{i=1}^{n} \mathrm{wt}_L(x_i).$$

Definition 2. A *linear code* $\mathcal{C}$ of length n over $\mathbb{Z}/m\mathbb{Z}$ is a $\mathbb{Z}/m\mathbb{Z}$-submodule of $(\mathbb{Z}/m\mathbb{Z})^n$.

Let $m = p_1^{s_1} p_2^{s_2} \cdots p_\ell^{s_\ell}$ be the prime factorization of m. Then, by Chinese remainder theorem, we know that $\mathbb{Z}/m\mathbb{Z} \cong (\mathbb{Z}/p_1^{s_1}\mathbb{Z}) \times (\mathbb{Z}/p_2^{s_2}\mathbb{Z}) \times \cdots \times (\mathbb{Z}/p_\ell^{s_\ell}\mathbb{Z})$. Moreover, $\mathcal{C} \cong \mathcal{C}_1 \times \mathcal{C}_2 \times \cdots \times \mathcal{C}_\ell$, where $\mathcal{C}_i$ is a linear code over $\mathbb{Z}/p_i^{s_i}\mathbb{Z}$ for each $i = 1, \ldots, \ell$. Hence, we may restrict our study to $m = p^s$, for some prime p and integer s.

Definition 3. Let $\mathcal{C}$ be a linear code of length n over $\mathbb{Z}/p^s\mathbb{Z}$. Then,

(1) The *type* of $\mathcal{C}$ is the partition $\lambda = (\lambda_1, \ldots, \lambda_K)$ such that
$$\mathcal{C} \cong (\mathbb{Z}/p^{\lambda_1}\mathbb{Z}) \times (\mathbb{Z}/p^{\lambda_2}\mathbb{Z}) \times \cdots \times (\mathbb{Z}/p^{\lambda_K}\mathbb{Z}),$$
with $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_K \geq 0$. The type λ can also be denoted by $(s^{k_1}, (s-1)^{k_2}, \ldots, 1^{k_s})$, where k_i is the multiplicity of the part of size $s-i+1$ in λ.
(2) The number of parts K of λ is called the *rank* of $\mathcal{C}$.
(3) A *generator matrix* of $\mathcal{C}$ is a matrix $\mathbf{G}$ over $\mathbb{Z}/p^s\mathbb{Z}$ such that its rows generate $\mathcal{C}$.
(4) A *parity-check matrix* of $\mathcal{C}$ is a matrix $\mathbf{H}$ over $\mathbb{Z}/p^s\mathbb{Z}$ such that its nullspace is $\mathcal{C}$.
(5) An *information set* is a subset I of $\{1, 2, \ldots, n\}$ having minimal size such that
$$|\{\mathbf{c}_I : \mathbf{c} \in \mathcal{C}\}| = |\mathcal{C}|,$$
where $\mathbf{c}_I$ is a vector with entries from $\mathbf{c}$ that are indexed in I.

⋆ Corresponding author.

For a code $\mathcal{C}$ of rank K, it is easy to see that the cardinality of an information set is K.

3. LEE SYNDROME DECODING PROBLEM

Let n, m, k be positive integers with $k \leq n$. Then the syndrome decoding problem over the Lee metric is defined as follows.

Problem 1. (Lee syndrome decoding problem (L-SDP)). Given a parity-check matrix $\mathbf{H} \in (\mathbb{Z}/m\mathbb{Z})^{(n-k)\times n}$, a syndrome $\mathbf{s} \in (\mathbb{Z}/m\mathbb{Z})^{n-k}$ and a positive integer t, find $\mathbf{e} \in (\mathbb{Z}/m\mathbb{Z})^n$ such that $\mathrm{wt}_L(\mathbf{e}) \leq t$ and $\mathbf{e}\mathbf{H}^\top = \mathbf{s}$.

In [14, Proposition 2], it is proved that L-SDP is NP-complete, by reducing the 3-dimensional matching (3DM) problem to SDP. The proof is very similar to the proof of NP-completeness of SDP for the Hamming metric binary codes [4] and non-binary codes [1].

4. LEE INFORMATION SET DECODING ALGORITHMS

Many of the information set decoding (ISD) algorithms over the Hamming metric have been adapted to the Lee metric. In this section, we discuss some these adaptations.

Two-blocks algorithm It is an adaptation of Stern's Hamming ISD algorithm [12] for the Lee metric codes over the ring $\mathbb{Z}/p^s\mathbb{Z}$. This algorithm also generalizes the Lee-Brickell's and Prange's ISD algorithms.

The idea of Stern's algorithm is to partition the chosen information set I into two sets X and Y containing v_1 and v_2 errors, respectively. Moreover, it is assumed that there exists a zero-window Z of size z outside of the information set where no errors happen. For a complete description of the algorithm, see [14, Algorithm 1].

s-blocks algorithm In this algorithm, we use the structure of the ring $\mathbb{Z}/p^s\mathbb{Z}$. For a linear code $\mathcal{C}$ over $\mathbb{Z}/p^s\mathbb{Z}$ of length n and type $(s^{k_1}, \ldots, 1^{k_s})$, a parity-check matrix can be written in the following systematic form (up to permutation of columns):

$$\mathbf{H} = \begin{pmatrix} \mathbf{A}_{1,1} & \mathbf{A}_{1,2} & \cdots & \mathbf{A}_{1,s} & \mathrm{Id}_{n-K} \\ p\mathbf{A}_{2,1} & p\mathbf{A}_{2,2} & \cdots & p\mathrm{Id}_{k_s} & \mathbf{0}_{k_s\times(n-K)} \\ p^2\mathbf{A}_{3,1} & p^2\mathbf{A}_{3,2} & \cdots & \mathbf{0}_{k_{s-1}\times k_s} & \mathbf{0}_{k_{s-1}\times(n-K)} \\ \vdots & \vdots & & \vdots & \vdots \\ p^{s-1}\mathbf{A}_{s,1} & p^{s-1}\mathrm{Id}_{k_2} & \cdots & \mathbf{0}_{k_2\times k_s} & \mathbf{0}_{k_2\times(n-K)} \end{pmatrix}$$

Using this structure, we split the error vector into $s+1$ parts, i.e., $\mathbf{e} = (\mathbf{e}_1, \ldots, \mathbf{e}_{s+1})$ with $\mathbf{e}_i \in (\mathbb{Z}/p^s\mathbb{Z})^{k_i}$ for $1 \leq i \leq s$ and $\mathbf{e}_{s+1} \in (\mathbb{Z}/p^s\mathbb{Z})^{n-K}$. Next, we assume a fixed weight distribution on the $s+1$ parts of the error vector, and find the error vector satisfying all the s equations obtained using the systematic form.

Partial Gaussian elimination algorithms In this class of algorithms, the method of partial Gaussian elimination is used to reduce the original SDP into a smaller SDP instance. The smaller SDP instance is then solved using different approaches:

- *Wagner's approach*: The main idea of Wagner's approach [13], which has been applied to the syndrome decoding problem in [7], on a levels, is to partition the error vector into 2^a sub-vectors and to store them in a list together with their corresponding partial syndromes. After this, on each level, the lists are merged until a list of the solutions to the smaller SDP is obtained. Lastly, we go through this list to look for the solution to the original SDP.
- *Representations technique approach*: This technique was introduced in [10, 3], where we allow the sub-vectors of the error vector to overlap; this is called the subset sum representation technique. Due to the overlaps, the technique to merge two lists changes in this case.
- *Mixed approach (BJMM)*: In this approach, we allow both the above stated techniques. On the base level, we use the Wagner's approach and on the other levels we use the representation technique. This method for the Hamming metric was proposed in [3], also known as BJMM algorithm.

Following is the list of all the Lee metric ISD algorithms proposed so far:

- Lee-Brickell's algorithm and Stern's algorithm were adapted for codes over $\mathbb{Z}/4\mathbb{Z}$ in [8].
- Stern's algorithm was generalized for codes over $\mathbb{Z}/p^s\mathbb{Z}$ in [14], named as two-block algorithm.
- Furthermore, in [14], ISD algorithms based on new approaches, such as Wagner's algorithm, BJMM algorithm, and representation technique based algorithms, were adapted for codes over $\mathbb{Z}/p^s\mathbb{Z}$.
- In [5], the classical and quantum ISD algorithms based on Wagner's approach were presented for codes over finite fields, thus restricting to $\mathbb{Z}/p\mathbb{Z}$.
- s-blocks algorithm, based on the structure of the ring $\mathbb{Z}/p^s\mathbb{Z}$, was proposed in [14].
- Another algorithm based on the ring structure of $\mathbb{Z}/p^s\mathbb{Z}$ was proposed in [9], which splits the decoding problem over $\mathbb{Z}/p^s\mathbb{Z}$ into two successive decoding problems: the first one over $\mathbb{Z}/p^j\mathbb{Z}$ and the second one over $\mathbb{Z}/p^{s-j}\mathbb{Z}$ for some fixed $j \in \{1, 2, \ldots, s-1\}$.

Other techniques In the following, we present some ideas that may be used to either construct new decoding algorithms or speed-up ISD algorithms.

- *Scalar multiplication*: Recently in [2], the effect of scalar multiplication was studied for a random vector of a constant Lee weight. The results suggest that, using a suitable scalar $a \in \mathbb{Z}/p^s\mathbb{Z}$, the decoding of syndrome $a\mathbf{s}$ can be faster than the original $\mathbf{s}$ itself. This idea is specific for Lee metric, as in the Hamming metric case, scalar multiplication is a weight preserving map.
- *Lattice-based techniques*: Coding theory has strong resemblance with the lattice theory. In particular, the Lee metric can be seen as the metric induced by ℓ_1-norm. Due to this resemblance, new decoding techniques can be developed by adapting the lattice-reduction based algorithms from the ℓ_2-norm to the Lee metric.

Complexity In order to decode a code of length n over $\mathbb{Z}/q\mathbb{Z}$, the average-case time complexity of an ISD algorithm is given by

$$q^{(e(R,q)+o(1))n},$$

where R is the rate of the code, and the exponent $e(R,q)$ depends on the ISD algorithm. In Figure 1, we compare the asymptotic complexity of some ISD algorithms at different rates R by optimizing the internal parameters of each algorithm. From the comparison, we observe that the complexity of BJMM algorithm at level 2 is significantly lower than the other algorithms.

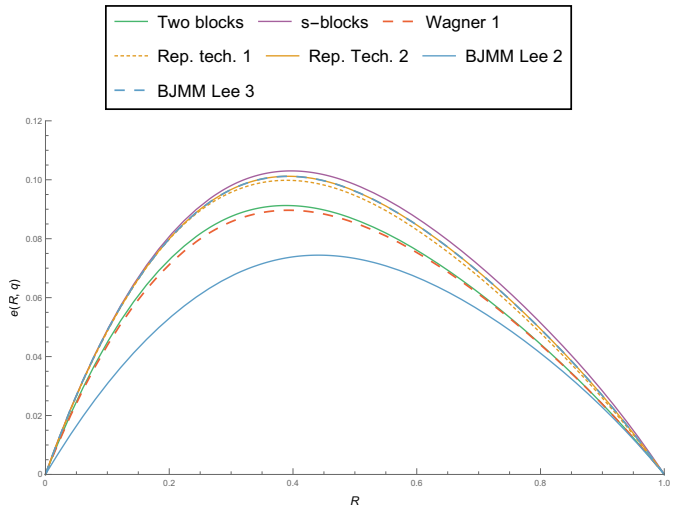

Fig. 1. Comparison of the asymptotic complexity of different Lee metric ISD algorithms for half-distance decoding of a free code over $\mathbb{Z}/7^2\mathbb{Z}$ that achieves the Gilbert-Varshamov bound.

On Cameron-Liebler sets of k-spaces in finite projective spaces (Part II)

Jonathan Mannaert *

* *Vrije Universiteit Brussel, Pleinlaan 2, B–1050 Brussel (e-mail: Jonathan.Mannaert@vub.be).*

Abstract: Cameron-Liebler sets of lines in a finite 3-dimensional space $\mathrm{PG}(3,q)$ originate from the study by Cameron and Liebler in 1982 of groups of collineations with equally many orbits on the points and the lines of $\mathrm{PG}(3,q)$. These objects have some interesting equivalent characterizations, and are examples of Boolean functions of degree one. In this talk, we focus on these objects and their generalisation from a geometric perspective, and report on several existence and non-existence results, including a lower bound on the existence of the parameter x (besides trivial examples).

Keywords: low degree Boolean functions, irreducible groups, Cameron-Liebler sets, extremal sets, strongly regular graphs.

1. INTRODUCTION

In Cameron and Liebler (1982) tried to classify specific orbits of subgroups of $\mathrm{PGL}(4,q)$ that admit the same number of orbits on lines then on points. In this study it was observed that these orbits on the lines satisfy diverse conditions. These line classes later obtained the name of *Cameron-Liebler line classes* in $\mathrm{PG}(3,q)$. These objects are in fact broader concepts then the original obits, yet they are nevertheless usefull in the classification of the subgroups. Each Cameron-Liebler line class $\mathcal{L}$ has a certain parameter x, for which holds that $|\mathcal{L}| = x(q^2+q+1)$. This integer x also denotes the intersection size of $\mathcal{L}$ with line spreads in $\mathrm{PG}(3,q)$.
Since a classification of these orbits or line classes would aid their research question, this classification was briefly conducted in Cameron and Liebler (1982). Here they classified all Cameron-Liebler line classes of parameter $x \in \{0,1,2,q^2-1,q^2,q^2+1\}$. They also conjectured that the only line classes of this form that exist are: (1) the empty set, (2) all lines through a point, (3) all lines in a plane, (4) all lines through in a plane π or all lines through a point $p \notin \pi$ and (4) the complements of the previous examples. These examples are also known as the *trivial examples*. The conjecture was later disproven in Drudge (1999) who gave a first example of a non-trivial Cameron-Liebler line class in $\mathrm{PG}(3,3)$ of parameter $x = 5$. This example was later generalized to an infinite famely in $\mathrm{PG}(n,q)$ for n odd in A. Bruen and Drudge (1999)

Now we switch the viewpoint to coding theory. Let $n \geq 1$ and A be a set of q symbols. The Hamming graph $H(n,q)$ is the graph with vertex set the set of words of length n over A and two vertices being adjacent if and only if their Hamming distance is 1. The Hamming graph $H(n,2)$ is the hypercube. Clearly, a q-ary code of length n can be considered as a subset of the vertex set of $H(n,q)$. So it is quite natural to translate properties of the code C into graph theoretical properties. Conversely, it is natural to define codes as substructures in graphs different from the Hamming graph as well, replacing the Hamming distance by the graph distance. Let C be a code in a regular graph Γ with vertex set V. We follow the definition found in e.g. Neumaier (1992). Let x be any vertex of Γ, then $d(x,C) = \min\{d(x,y)|y \in C\}$. The covering radius $\rho = \max\{d(x,C)|x \in \Gamma\}$, it is the minimal integer ρ such that the spheres of radius ρ around the codewords of C cover the vertices of Γ. For a code C, minimum distance $d(C)$ and covering radius $\rho(C)$ are related by $d(C) \leq 2\rho(C)+1$. The code C is called *perfect* in case of equality, which is equivalent with the property that the spheres with radius $\rho(C)$ around the codewords partition the vertex set V.

Completely regular codes have been introduced in Delsarte (1973) as a generalization of perfect codes. Assume that C is a code in a distance regular graph. Let $C_i = \{x \in \Gamma | d(x,C) = i\}$, then $C_i \neq \emptyset \iff 0 \leq i \leq \rho(C)$, and $C_0 = C$. The sets C_i partition the vertex set of Γ. The code C is called *completely regular* if every vertex $x \in C_i$ has a constant number of neighbors a_i, b_i, respectively c_i in C_{i-1}, C_i, respectively C_{i+1}. This is equivalent with the partition of the vertex set of Γ into the components C_i being equitable.

In I.Mogilnykh (2022) a very nice connection is made between complete regular codes and Cameron-Liebler line classes. In order to understand this connection, we require the definition of a t-desing. In general a t-(v,k,λ) desing, or t-design for short, is a set of points and blocks with v points, each block contains k points and through every t points there are λ blocks. It is discussed that Cameron-Liebler line classes $\mathcal{L}$ in $\mathrm{PG}(n,q)$ are in fact special completly regular codes where the points of $\mathrm{PG}(n,q)$ and the lines of $\mathcal{L}$ do not admit to the blocks of a t-desing. It can be shown that these codes have covering radius 1.

2. A GENERALISATION TO N-DIMENSIONAL PROJECTIVE SPACES

Let $q = p^h$ be a prime power, and denote the finite field of order q as $\mathrm{GF}(q)$. The n-dimensional projective space over $\mathrm{GF}(q)$ is the geometry consisting of all i-dimensional subspaces of the $n+1$-dimensional vector space $V(n+1,q)$ over $\mathrm{GF}(q)$, $1 \leq i \leq d$, and is denoted by $\mathrm{PG}(n,q)$. The fundamental theorem of projective geometry states that all isomorphisms of $\mathrm{PG}(n,q)$ are induced by the semi-linear maps of the underlying vector space. Note that we call the i-dimensional subspaces of $V(n+1,q)$, $1 \leq i \leq n$, the points, lines, planes, etc. of $\mathrm{PG}(n,q)$. In general we define the set of i-spaces in $\mathrm{PG}(n,q)$ by Π_i.
The concepts of Cameron-Liebler line classes have been generalized to $\mathrm{PG}(n,q)$, see Blokhuis et al. (2018) and Rodgers et al. (2018). In order to do so, we will need the concept of a *characteristic vector* of a set of k-spaces $\mathcal{S}$. This $0,1$ valued vector of size $|\Pi_k|$ has a one on a certain position if and only if the corrsponding k-spaces lies inside $\mathcal{S}$. Using this vector, we can define Cameron-Liebler sets of k-spaces.

2.1 Definition

Suppose that P_n is the point-(k-space) incidence matrix of $\mathrm{PG}(n,q)$. This matrix is the $0,1$ values matrix where the rows correspond with the points and the columns with the k- dimensional subspaces of $\mathrm{PG}(n,q)$. A certain position (p,K) has value one if and only if $p \in K$. Using this matrix, a *Cameron-Liebler set of k-spaces* in $\mathrm{PG}(n,q)$ is a set of k-spaces such that the characteristic vector is contained in $\mathrm{Im}(P_n^T)$.
We say that the Cameron-Liebler set of k-spaces $\mathcal{L}$ has parameter x, if and only if

$$|\mathcal{L}| = x \begin{bmatrix} n \\ k \end{bmatrix}_q .$$

Recall the Gaussian binomial coefficient, for $a \leq b$ be natural numbers,

$$\begin{bmatrix} b \\ a \end{bmatrix}_q = \frac{(q^b-1)\dots(q^{b-a+1}-1)}{(q^a-1)\dots(q-1)}$$

which represents the number of $(a-1)$-dimensional projective spaces in a projective space of dimension $b-1$. This definition automatically implies that $0 \leq x \leq \frac{q^{n+1}-1}{q^{k+1}-1}$.

2.2 Connection with Boolean functions

Another way to formalize the definition of these Cameron-Liebler sets of k-spaces is by using *Boolean degree 1 functions*. A Boolean degree 1 function f on the k-spaces of $\mathrm{PG}(n,q)$, is a boolean function that is a linear combination of boolean functions of point-pencils, i.e. sets of k-spaces through a fixed point. In particular, this means that

$$f = \sum_{p \in \mathrm{PG}(n,q)} c_p x_p^+,$$

Here c_p are constants and x_p^+ corresponds to the boolean function of the set $[p]_k := \{K \in \Pi_k \mid p \in K\}$. Consequently, we have that if χ_p is the characteristic vector of $[p]_k$ then $x_p^+(K) = \chi_p(K)$. Cameron-Liebler sets of k-spaces and Boolean degree 1 functions are in fact equivalent statements. This implies that every result of one can be transformed to the the other. Yet studying these objects in both ways can yield powerfull results. For more information we refer to Filmus and Ihringer (2019).

2.3 Other properties and examples

Besides this definition other equivalent versions are also known. The following Theorem will list some of those, here a *k-spread* $\mathcal{S}$ denotes a set of k-spaces that partition the point in $\mathrm{PG}(n,q)$. In particular, it is know that these spreads exist if and only if $(k+1) \mid (n+1)$.

Theorem 1. (Blokhuis et al., 2018, Theorem 2.2) Let $\mathcal{L}$ be a non-empty set of k-spaces in $\mathrm{PG}(n,q)$, $n \geq 2k+1$, with characteristic vector $\chi_{\mathcal{L}}$, and x so that $|\mathcal{L}| = x \begin{bmatrix} n \\ k \end{bmatrix}_q$. Then the following properties are equivalent.

(1) $\chi_{\mathcal{L}} \in \mathrm{Im}(P_n^T) = (\ker(P_n))^{\perp}$, with P_n the point-(k-space) incidence matrix of $\mathrm{PG}(n,q)$.
(2) For every k-space K, the number of elements of $\mathcal{L}$ disjoint from K is equal to $(x - \chi_{\mathcal{L}}(K)) \begin{bmatrix} n-k-1 \\ k \end{bmatrix}_q q^{k^2+k}$.
(3) If $k+1 \mid n+1$, i.e. if and only if $\mathrm{PG}(n,q)$ has k-spreads, then $|\mathcal{L} \cap \mathcal{S}| = x$ for any k-spread $\mathcal{S}$.

It is also clear that this theorem induces that if $(k+1) \mid (n+1)$, then x is in fact a positive integer. This condition only holds for this particular case. Because as we will see in the next example, for $(k+1) \nmid (n+1)$ we always find non-integer parameters.

Fact 2. The *trivial* examples of Cameron-Liebler line classes in $\mathrm{PG}(3,q)$ are easily generalized to sets of k-spaces in $\mathrm{PG}(n,q)$. In particular, using Theorem 1, we can obtain the following examples.

(1) The empty set is a Cameron-Liebler set of k-spaces of parameter $x = 0$.
(2) A point-pencil is an example of parameter $x = 1$.
(3) The set of k-spaces inside a hyperplane is an example of parameter $x = \frac{q^{n-k}-1}{q^{k+1}-1}$.
(4) The disjoint union of examples (2) and (3) is a Cameron-Liebler set of k-spaces of parameter $x = \frac{q^{n-k}-1}{q^{k+1}-1} + 1$.
(5) Complements of these examples are also Cameron-Liebler sets of k-spaces of parameter $\frac{q^{n+1}-1}{q^{k+1}-1} - x$.

As previously noted, it can be seen that examples (3), (4) and (5) have a parameter that is only an integer if and only if $(k+1) \mid (n+1)$.

3. NON-EXISTENCE RESULTS

In this section we consider some known non-existence results and classifications. We combine the results that were obtained for Boolean degree 1 functions and Cameron-Liebler sets directly. The following theorem follows (partially) immediately from Theorem 1.

Theorem 3. (Blokhuis et al., 2018, Theorem 4.3) There do not exist Cameron-Liebler k-sets in $\mathrm{PG}(n,q)$ of parameter $x \in]0,1[$ and if $n \geq 3k+2$, then there are no Cameron-Liebler sets of k spaces with parameter $x \in]1,2[$.

In order to prove that $x \notin]0,1[$, we can simply consider Theorem 1 (2) and obtain that for these values the number of skew k-spaces of $\mathcal{L}$ to a fixed k-space K is a negative number. This is a contradiction. A second classification results makes use from some Erdös-Ko-Rado results and is as follows.

Theorem 4. (Blokhuis et al., 2018, Theorem 4.1) Let $\mathcal{L}$ be a Cameron-Liebler set of k-spaces with parameter $x = 1$ in $\mathrm{PG}(n,q)$, $n \geq 2k+1$. Then $\mathcal{L}$ consists out of all the k-spaces through a fixed point or $n = 2k+1$ and $\mathcal{L}$ is the set of all the k-spaces in a hyperplane of $\mathrm{PG}(2k+1,q)$.

Besides these rather small classifications, there also exist stronger non-existence conditions. These are in fact the results which we want to improve.

Theorem 5. (Blokhuis et al., 2018, Theorem 4.9) There are no Cameron-Liebler sets of k-spaces in $\mathrm{PG}(n,q)$, with $n \geq 3k+2$ (and $q \geq 3$), of parameter x if

$$2 \leq x \leq \frac{1}{\sqrt[8]{2}} q^{\frac{n}{2}-\frac{k^2}{4}-\frac{3k}{4}-\frac{3}{2}} (q-1)^{\frac{k^2}{4}-\frac{k}{4}+\frac{1}{2}} \sqrt{q^2+q+1}.$$

Note that this upper bound has size roughly $q^{\frac{n}{2}-k}$.

Fact 6. The condition that $q \geq 3$ is in brackets because this was in the original theorem, but it has been proven in Filmus and Ihringer (2019) that for $q \leq 3$ all Cameron-Liebler sets of k-spaces are trivial examples.

Theorem 7. (Ihringer, 2020, Theorem 7) Let $n \geq 2k+1$ and suppose that $\mathcal{L}$ is a Cameron-Liebler set of k-spaces in $\mathrm{PG}(n,q)$ of parameter x. If $16x \leq \min\{q^{\frac{n-k-l+2}{3}}, q^{\frac{n-2k-r}{3}}\}$, where $n+1 = m(k+1)-r$ with $0 \leq r < k+1$ and $\frac{q^{l-1}-1}{q-1} < x \leq \frac{q^l-1}{q-1}$, then $x \leq 2$ and $\mathcal{L}$ is trivial.

This bound would in the best case scenario have size roughly $\min\{q^{\frac{n-k+1}{3}}, q^{\frac{n-2k}{3}}\} = q^{\frac{n-2k}{3}}$.
In general no theorem of these above excludes the other, because both have different strengths in different cases of (n,k).

4. NEW RESULTS

This is joint wok with Jan De Beule and Leo Storme. In order to soften the notation, we will denote $[\pi]_k$ as the set of k-spaces in $\mathrm{PG}(n,q)$ that are contained in the i-dimensional subspace π, $i > 0$. Similarly, $[p]_p$ denotes the set of k-spaces containing the point p.

4.1 Induces Cameron-Liebler sets

The main idea for this improved lower bound on x comes from Boolean degree 1 functions, see Filmus and Ihringer (2019), and the thesis of Drudge, see Drudge (1998). Both describe a version of the following theorem. In Filmus and Ihringer (2019) it is described more subtly, while in Drudge (1998) it is only denoted for lines.

Theorem 8. (Folklore). Consider a Cameron-Liebler sets of k-spaces $\mathcal{L}$ in $\mathrm{PG}(n,q)$, with $n \geq 2k+1$, and let π be a subspace of dimension $i \geq k+1$. Then $\mathcal{L} \cap [\pi]_k$ is also a Cameron-Liebler set of k-spaces in π.

Proof. We will show this using Boolean functions. Suppose that $\chi_{\mathcal{L}}$ is a Boolean degree 1 function, then we have, with a similar notation as above, that

$$\chi_{\mathcal{L}} = \sum_{p \in \mathrm{PG}(n,q)\setminus\pi} c_p x_p^+ + \sum_{p \in \pi} c_p x_p^+.$$

The restriction of $\chi_{\mathcal{L}}$ to π is cleary $\sum_{p\in\pi} c_p x_p^+$.

The main idea, using this theorem, is to consider the Cameron-Liebler sets of k-spaces that are induced in subspaces and try to translate classification results using this connection. However, we should be very carefull because Theorem 8 does not give a connection between the parameter of $\mathcal{L}$ and the parameter of the induced set. This will be our focus now.

4.2 Connecting the parameter with parameters of induced sets

The main result of this section is the following lemma.

Lemma 9. (De Beule et al., 2022, Lemma 4.1) Suppose that $\mathcal{L}$ is a Cameron-Liebler set of k-spaces in $\mathrm{PG}(n,q)$ of parameter x. Then for every t, such that $2k+1 \leq t \leq n-1$ and $n \geq 2k+2$, and an arbitrary k-space K in $\mathrm{PG}(n,q)$,

$$x = \frac{\left(\sum_{K\in\pi_i} x_{\pi_i} - \begin{bmatrix} n-k \\ t-k \end{bmatrix}_q \chi_{\mathcal{L}}(K)\right)}{\begin{bmatrix} n-k-1 \\ t-k-1 \end{bmatrix}_q} + \chi_{\mathcal{L}}(K), \qquad (1)$$

where $\chi_{\mathcal{L}}(K)$ is the value of the characteristic vector of $\mathcal{L}$ at position K, x_{π_i} the parameter of the Cameron-Liebler k-set induced in π_i, and where the sum runs over all t-spaces π_i through K.

Proof. The proof is based on a counting argument, where we count the pairs (K', π), with $K' \in \mathcal{L}$ a k-dimensional subspace inside π skew to K, and π a t-dimensional subspace containing both K and K'. Important to know is that the number of skew k-spaces to K is denoted in Theorem 1 (2) and since $\mathcal{L}$ restricted to every t-space π also induces a Cameron-Liebler set of k-space of a certain parameter x_π a similar number of skew k-spaces can be found depending on x_π.

4.3 Using Classification results in smaller subspaces

The strength of Lemma 9 is the fact that t can be chosen freely within the possible range. This implies that we can use some non-existence conditions while playing with this dimension t. In general we have that if we choose $K \in \mathcal{L} \neq \emptyset$ that all $x_{\pi_i} \neq 0$, since all induced sets are not empty. In addition, we also have, due to Theorem 3 that $x_{\pi_i} \geq 1$. Now we will make use of the following theorem, which is a generalisation of a result from Drudge Drudge (1998) who proved this for lines.

Theorem 10. (De Beule et al., 2022, Theorem 3.4) Let $n \geq 2k+1$. Suppose that $\mathcal{L}$ is a Cameron-Liebler set of k-spaces in $\mathrm{PG}(n,q)$, such that there exists an i-space π, with $i \geq k+1$, and such that $\mathcal{L} \cap [\pi]_k$ consists of the set of k-spaces through a point $p \in \pi$. Then $\mathcal{L}$ is the set of k-spaces through this same point p.

An important consequence of this theorem is the following. Let $t > 2k+1$ and suppose that there exist a $x_{\pi_i} = 1$, then from Theorem 4 we obtain that the induced Cameron-Liebler set is a point-pencil. Consequently, using Theorem 10 we have that $\mathcal{L}$ is a point-pencil. So if we pose the restriction that $\mathcal{L}$ is not a point-pencil, we can say that

every $x_{\pi_i} \neq 1$.
Finaly, if $t \geq 3k+2$, we also obtain, by Theorem 3 that $x_{\pi_i} \geq 2$.
Filling in these bounds in Lemma 9, we obtain that

$$x \geq \frac{\begin{bmatrix} n-k \\ t-k \end{bmatrix}_q}{\begin{bmatrix} n-k-1 \\ t-k-1 \end{bmatrix}_q} + 1 = \frac{\begin{bmatrix} n-k \\ 2k+2 \end{bmatrix}_q}{\begin{bmatrix} n-k-1 \\ 2k+1 \end{bmatrix}_q} + 1 = \frac{q^{n-k}-1}{q^{2k+2}-1} + 1,$$

where in the last two formulas, we let $t = 3k+2$.

Fact 11. The reason why $t = 3k+2$ is due to the fact that this value gives the best lower bound. Filling in $t > 3k+2$ would only increase the nominator of the previous equation.

This results in the following theorem.

Theorem 12. (De Beule et al., 2022, Theorem 6.2) Suppose that $n \geq 3k+3$ and $k \geq 1$. Let $\mathcal{L}$ be a Cameron-Liebler set of k-spaces of parameter x in $\mathrm{PG}(n,q)$ such that $\mathcal{L}$ is not a point-pencil, nor the empty set. Then it holds that

$$x \geq \frac{q^{n-k}-1}{q^{2k+2}-1} + 1.$$

4.4 A direct improvement

Theorem 12 was stated in De Beule et al. (2022) but can be improved using Theorem 5. Due to Fact 6, this follows for every q and $t \geq 3k+2$. Filling in this better bound for every x_{π_i}, we obtain that

$$x_{\pi_i} \geq C(t,k,q),$$

with $C(t,k,q) = \frac{1}{\sqrt[8]{2}} q^{\frac{t}{2} - \frac{k^2}{4} - \frac{3k}{4} - \frac{3}{2}} (q-1)^{\frac{k^2}{4} - \frac{k}{4} + \frac{1}{2}} \sqrt{q^2+q+1}$.
Again we choose $t = 3k+2$. This results in the following Theorem.

Theorem 13. Suppose that $n \geq 3k+3$ and $k \geq 1$. Let $\mathcal{L}$ be a Cameron-Liebler set of k-spaces of parameter x in $\mathrm{PG}(n,q)$ such that $\mathcal{L}$ is not a point-pencil, nor the empty set. Then it holds that

$$x \geq C(k,q) \left(\frac{q^{n-k}-1}{q^{2k+2}-1} \right) + 1,$$

for $C(k,q) = \frac{1}{\sqrt[8]{2}} q^{\frac{3k}{4} - \frac{k^2}{4} - \frac{1}{2}} (q-1)^{\frac{k^2}{4} - \frac{k}{4} + \frac{1}{2}} \sqrt{q^2+q+1} - 1$.

This lower bound is roughly of size $q^{n - \frac{3k}{2} - \frac{1}{2}}$, which is a direct improvement of Theorem 5 and Theorem 7 if $n \geq 3k+2$, so for all possible values of (n,k).

Positive semidefinite quadratic forms on varieties defined by quadratic forms

Sarah Hess *

* *University of Konstanz, 78457 Konstanz, Germany*
(e-mail: sarah.hess@uni-konstanz.de).

Abstract: For a fixed number of $n+1$ ($n \geq 1$) variables and even degree $2d$ ($d \geq 1$), the SOS cone $\Sigma_{n+1,2d}$ of all real forms representable as finite sums of squares (SOS) of half degree d real forms is included in the PSD cone of all positive semidefinite (PSD) real forms $\mathcal{P}_{n+1,2d}$. Hilbert (1888) states that both cones coincide if and only if $n+1=2$, $d=1$ or $(n+1,2d)=(3,4)$. In this talk, we discuss necessary or sufficient conditions to extend local positive semidefiniteness of real quadratic forms along projective varieties generated by s ($s \geq 0$) real quadratic forms. Those conditions allow us to construct an explicit filtration of intermediate cones $\Sigma_{n+1,2d} = C_0 \subseteq C_1 \subseteq \ldots \subseteq C_{s-1} \subseteq C_s = \mathcal{P}_{n+1,2d}$ (between the SOS and PSD cone) along the Veronese variety. Indeed, the latter is known to be a projective variety finitely induced by real quadratic forms. We analyze this filtration for proper inclusions. In fact, after applying an inductive argument, it suffices to investigate the situation for a truncated subfiltration of the former. A result of Blekherman et al. (2016) on projective varieties of minimal degree permits us to handle the inclusion $C_0 \subseteq C_1$. Generalizing this observation, we are able to show $\Sigma_{n+1,2d} = C_0 = \ldots = C_n$. Finally, we lay out the situation in the basic non Hilbert case of quaternary quartics by identify exactly two strictly separating intermediate cones in the particular filtration of $\Sigma_{4,4}$ and $\mathcal{P}_{4,4}$ via considerations of real forms based on techniques due to Robinson (1969) and Choi and Lam (1977a,b). This is a work in progress with Salma Kuhlmann and Charu Goel.

Keywords: Real quadratic forms, projective varieties generated by real quadratic forms, positive semidefinite forms, sums of squares, intermediate cones, varieties of minimal degree

1. INTRODUCTION

For $n \geq 0$, let $\mathbb{R}[X]$ be the polynomial ring in $n+1$ variables with coefficients in $\mathbb{R}$. If all monomials appearing in $f \in \mathbb{R}[X]$ are of the same total degree d ($d \geq 1$), then f is a *(real) form (of total degree d)*. The set of all real forms of total degree d in $\mathbb{R}[X]$ is $\mathcal{F}_{n+1,d}$. In particular, $f \in \mathcal{F}_{n+1,2}$ is a *(real) quadratic form*. Moreover, if for $f \in \mathcal{F}_{n+1,2d}$ there exist some $t \geq 1$ and $g_1, \ldots, g_t \in \mathcal{F}_{n+1,d}$ such that $f = \sum_{i=1}^{t} g_i^2$, then f is a *sum of squares (SOS)*. The cone of all SOS forms in $\mathcal{F}_{n+1,2d}$ is $\Sigma_{n+1,2d}$. Moreover, $f \in \mathcal{F}_{n+1,2d}$ is *locally positive semidefinite on* $W \subseteq \mathbb{R}^{n+1}$ if $f(x) \geq 0$ holds for all $x \in W$. In this case we write $f|_W \geq 0$, respectively, $f \geq 0$ for $W = \mathbb{R}^{n+1}$. In the latter case, f is *(globally) positive semidefinite (PSD)*. The cone of all PSD forms in $\mathcal{F}_{n+1,2d}$ is $\mathcal{P}_{n+1,2d}$. It is clear that $\Sigma_{n+1,2d} \subseteq \mathcal{P}_{n+1,2d}$ always holds true and, especially, $\Sigma_{1,2d} = \mathcal{P}_{1,2d}$ in the univariate case (see Marshall (2008)). However, the situation is more evolved in the multivariate cases. Hence, from now on we assume $n \geq 1$.

Theorem 1. (Hilbert (1888)) Let n and d be positive integers. Then $\Sigma_{n+1,2d} = \mathcal{P}_{n+1,2d}$ if and only if $n+1=2$ or $d=1$ or $(n+1,2d)=(3,4)$.

All cases in which the SOS and PSD cone coincide are called *Hilbert cases*, whereas all others are refered to as *non Hilbert cases*. The two simplest non Hilbert cases $(3,6)$ and $(4,4)$ are the *basic* non Hilbert cases.

Let $(n+1,2d)$ from now on denote a non Hilbert case and $\{m_0(X), \ldots, m_k(X)\}$ be an ordered monomial basis of $\mathcal{F}_{n+1,d}$ with $k := \dim(\mathcal{F}_{n+1,d}) - 1$. For $l \in \{n,k\}$, let $\mathbb{P}^l$ be the l-dimensional projective space of the complex numbers and the set of all real points of W is denoted by $W(\mathbb{R})$ for any $W \subseteq \mathbb{P}^l$. Implicitly $x \in \mathbb{R}^{l+1}$ is assumed for any $[x] \in W(\mathbb{R})$. A form $f \in \mathcal{F}_{l+1,2d}$ is *locally positive semidefinite on* $W(\mathbb{R}) \subseteq \mathbb{P}^n(\mathbb{R})$ if $f(x_0, \ldots, x_l) \geq 0$ holds for any $[x_0 : \ldots : x_l] \in W(\mathbb{R})$ and we write $f|_{W(\mathbb{R}))} \geq 0$. This is a well defined expression due to the homogeneity of f in even degree. In particular, the cone of all forms in $\mathcal{F}_{l+1,2d}$ which are locally positive semidefinite on $\mathbb{P}^n(\mathbb{R})$ is the former PSD cone $\mathcal{P}_{l+1,2d}$.
In a Gram matrix approach (see Choi et al. (1995), Powers and Wörmann (1998)), we consider the isomorphism

$$Q\colon \mathrm{Sym}_{k+1}(\mathbb{R}) \to \mathcal{F}_{k+1,2}$$
$$A \mapsto q_A,$$

where $q_A(Z_0, \ldots, Z_k) := (Z_0 \ldots Z_k) A (Z_0 \ldots Z_k)^t$, and the surjective linear *Gram map*

$$\mathcal{G}\colon \mathrm{Sym}_{k+1}(\mathbb{R}) \to \mathcal{F}_{n+1,2d}$$
$$A \mapsto f_A,$$

where $f_A(X) := (m_0(X)\dots m_k(X))A(m_0(X)\dots m_k(X))^t$ for the indeterminantes $X = (X_0, \dots, X_n)$, over the $\mathbb{R}$-vector space $\mathrm{Sym}_{k+1}(\mathbb{R})$ of real symmetric $(k+1)\times(k+1)$ matrices. Then a generic $A_f \in \mathcal{G}^{-1}(f)$ for any $f \in \mathcal{F}_{n+1,2d}$ can be fixed. In fact, any $A \in \mathcal{G}^{-1}(f)$ is a *Gram matrix associated to* f and for any such, $q_A := Q(A) \in \mathcal{F}_{k+1,2}$ is a *(real) quadratic form associated to* f.

Proposition 2. A form $f \in \mathcal{F}_{n+1,2d}$ is SOS if and only if there exists a real quadratic form associated to f which is locally positive semidefinite on $\mathbb{P}^k(\mathbb{R})$.

Under the consideration of the *(projective) Veronese embedding*

$$\begin{aligned} V\colon \mathbb{P}^n &\to \mathbb{P}^k \\ [x] &\mapsto [m_0(x) : \dots : m_k(x)] \end{aligned}$$

and its image the *(projective) Veronese variety* $V(\mathbb{P}^n)$, the PSD forms in $\mathcal{F}_{n+1,2d}$ can be characterized.

Proposition 3. A form $f \in \mathcal{F}_{n+1,2d}$ is PSD if and only if there exists a real quadratic form associated to f which is locally positive semidefinite on $V(\mathbb{P}^n)(\mathbb{R})$.

2. THE MAIN QUESTIONS

The previous two propositions reveal that the question of whether or not a given PSD form is SOS is equivalent to asking whether or not a given locally on $V(\mathbb{P}^n)(\mathbb{R})$ positive semidefinite real quadratic form can be extended to a real quadratic form locally positive semidefinite on $\mathbb{P}^k(\mathbb{R})$ over the set of real points of the Veronese variety. Indeed, the latter is a projective variety finitely generated by real quadratic forms of a specific structure imposed by the Gram map (see Plaumann (2020)). More precisely, the projective variety $V(\mathbb{P}^n)$ is induced by

$$\begin{aligned} \mathcal{S} := \{q(Z_0, \dots, Z_k) := Z_iZ_j - Z_sZ_t \mid \mathrm{LE}(m_i) + \mathrm{LE}(m_j) \\ = \mathrm{LE}(m_s) + \mathrm{LE}(m_t)\} \subseteq \mathbb{R}[Z_0, \dots, Z_k], \end{aligned}$$

where LE denotes the (leading) exponent of the indicated monomial. In general, the following question has to be answered.

Question 1. Let $W_0 \subseteq W_1$ be projective varieties finitely induced by real quadratic forms with non-empty sets of real points. Assume that a real quadratic form q is locally positive semidefinite on $W_0(\mathbb{R})$. When exactly does there exist a real quadratic form q_0 vanishing on $W_0(\mathbb{R})$ such that $q + q_0$ is locally positive semidefinite on $W_1(\mathbb{R})$?

Under the assumption of W_0 being an irreducible projective variety with Zariski dense set of real points $W_0(\mathbb{R})$ and W_1 being the projective space $\mathbb{P}^k$, Blekherman et al. (2016) give an answer to the above question. They establish that any real quadratic form q which is locally positive semidefinite on $W_0(\mathbb{R})$ is already SOS in the respective real homogeneous coordinate ring if and only if W_0 is a projective variety of minimal degree, i.e. a nondegenerate (not contained in any hyperplane of $\mathbb{P}^k$) irreducible projective variety with $\deg(W_0) = 1 + \mathrm{codim}(W_0)$. This result provides an alternative proof of Hilbert's 1888 Theorem by setting W_0 to be the Veronese variety and observing it being a projective variety of minimal degree exactly in the Hilbert cases.

Any subset $\mathcal{S}'$ of $\mathcal{S}$ naturally induces a supvariety W of the Veronese variety, which is consequently again finitely induced by real quadratic forms of the specific structure imposed by the Gram map. The kernel of the Gram map can be described via the set of real points of the Veronese variety. Indeed, the set $Q(\mathcal{G}^{-1}(f))$ of all quadratic forms associated to $f \in \mathcal{F}_{n+1,2d}$ is completely determined by

$$\mathcal{G}^{-1}(f) = \{A \in \mathrm{Sym}_{k+1}(\mathbb{R}) \mid q_A = q_{A_f} \text{ on } V(\mathbb{P}^n)(\mathbb{R})\}.$$

Hence, given a quadratic form locally positive semidefinite on $W(\mathbb{R})$, we can ask under exactly what conditions this form extends to a quadratic form locally positive semidefinite on $\mathbb{P}^k(\mathbb{R})$ over the set of real points of the Veronese variety. Set

$$\begin{aligned} C_W &:= \{f \in \mathcal{F}_{n+1,2d} \mid \exists A \in \mathcal{G}^{-1}(f)\colon q_A|_{W(\mathbb{R})} \geq 0\} \\ &= \{f \in \mathcal{F}_{n+1,2d} \mid \exists A \in \mathcal{G}^{-1}(f)\colon q_A|_{W(\mathbb{R})} \geq 0 \\ &\qquad \wedge\ q_A = q_{A_f} \text{ on } V(\mathbb{P}^n)(\mathbb{R})\}. \end{aligned}$$

Then by Proposition 2 and Proposition 3, it is clear that C_W is an intermediate cone of the SOS and PSD cone. We especially investigate the inclusions in

$$\Sigma_{n+1,2d} \subseteq C_W \subseteq \mathcal{P}_{n+1,2d}$$

for strictness. Indeed, at least one of these inclusions has to be strict because $(n+1, 2d)$ is assumed to be a non Hilbert case. The following question has to be answered.

Question 2. Let $W_0 \subseteq W_1 \subseteq W_2$ be projective varieties finitely induced by real quadratic forms with non-empty sets of real points. Assume that a real quadratic form q is locally positive semidefinite on $W_1(\mathbb{R})$. When exactly does there exist a real quadratic form q_0 vanishing on $W_0(\mathbb{R})$ such that $q + q_0$ is locally positive semidefinite on $W_2(\mathbb{R})$?

3. A FILTRATION OF INTERMEDIATE CONES

We algorithmically construct a particular $\mathcal{S}' \subseteq \mathcal{S}$ with a fixed numeration $\mathcal{S}' = \{p_1, \dots, p_s\}$ ($s := \#\mathcal{S}'$) such that the zero set of $\mathcal{S}'$ is the Veronese Variety and

$$V(\mathbb{P}^n) = W_s \subsetneq W_{s-1} \subsetneq \dots \subsetneq W_1 \subsetneq W_0 = \mathbb{P}^k$$

for $W_i := \mathcal{V}(p_1, \dots, p_i)$ ($i \in \{1, \dots, s\}$) and $W_0 := \mathbb{P}^k$. This leads to a corresponding strict filtration of sets of real points

$$V(\mathbb{P}^n)(\mathbb{R}) = W_s(\mathbb{R}) \subsetneq \dots \subsetneq W_0(\mathbb{R}) = \mathbb{P}^k(\mathbb{R}).$$

Setting $C_i := C_{W_i}$ we thus obtain a filtration of intermediate cones of the SOS and PSD cone, namely

$$\Sigma_{n+1,2d} = C_0 \subseteq C_1 \subseteq \dots \subseteq C_{s-1} \subseteq C_s = \mathcal{P}_{n+1,2d} \quad (1)$$

(see Goel (2020)). Since $(n+1, 2d)$ is a non Hilbert case by choice, at least one inclusion in (1) has to be strict. An answer to Question 2 in particularly provides a tool for identifying all strict inclusions in (1). Yet, it is not compulsory to investigate each inclusion in (1).

In the explicit construction of $\mathcal{S}'$, we determine

$$s = \#\mathcal{S}' = \sum_{m=1}^{n} 2(k(m) - m) - (k(m-1) + 1)$$

with

$$\begin{aligned} k\colon \mathbb{Z}_{\geq 0} &\to \mathbb{Z}_{\geq 0} \\ m &\mapsto \binom{m+d}{m} - 1. \end{aligned}$$

Setting $\tau := 2(k(n) - n) - (k(n-1) + 1)$, we are able to identify the filtration of the last $s - \tau + 1$ cones

$$C_\tau \subseteq \ldots \subseteq C_s = \mathcal{P}_{n+1,2d} \tag{2}$$

with the $(n, 2d)$ case. This ensures the elimination of one variable in an inductive argument. Repeating that consideration, we at last arrive in the base case $(2, 2d)$. This is a Hilbert case and therefore fully understood. It thus remains to investigate the situation of the first $\tau + 1$ cones

$$\Sigma_{n+1,2d} = C_0 \subseteq \ldots \subseteq C_\tau. \tag{3}$$

Indeed, putting (2) and (3) together recovers the initial filtration (1).

In (3), an immediate application of the main result from Blekherman et al. (2016) allows us to conclude that the SOS cone always coincides with C_1. Furthermore, a slight variation of this result ensures $\Sigma_{n+1,2d} = C_i$ for any $i \in \{1, \ldots, n\}$. Thus,

$$\Sigma_{n+1,2d} = C_0 = \ldots = C_n. \tag{4}$$

After that, for inclusions of the type $C_i \subseteq C_{i+1}$ with $i \in \{n, \ldots, \tau - 1\}$, the situation is more evolved and other methods have to be applied.

For example, in the basic non Hilbert case $(4, 4)$, exactly two strictly separating intermediate cone in (3) are identifiable. Indeed, the famous *Robinson form*

$$R(X_0, X_1, X_2, X_3) := X_0^2(X_0 - X_3)^2 + X_1^2(X_1 - X_3)^2 + X_2^2(X_2 - X_3)^2 + 2X_0X_1X_2(X_0 + X_1 + X_2 - 2X_3)$$

and the *Choi-Lam form*

$$W(X_0, X_1, X_2, X_3) := X_0^2X_1^2 + X_0^2X_2^2 + X_1^2X_2^2 + X_3^4 - 4X_0X_1X_2X_3$$

both certify the proper containment $\Sigma_{4,4} \subsetneq \mathcal{P}_{4,4}$ (see Robinson (1969) and Choi and Lam (1977a,b)). In particular, the Robinson form was alongside the *Motzkin form* (see Motzkin (1967)) one of the first forms found separating the SOS and PSD cone in a basic non Hilbert case. Both were firstly mentioned roughly nine decades after Hilbert's original abstract proof from 1888 in the late 1960's. The Choi-Lam form followed in 1977.
Now, a deeper reaching investigation of the Robinson form, the Choi-Lam form and a variation of the Choi-Lam form under permuation of variables reveals

$$C_3 \subsetneq C_4 \subsetneq C_5 \subsetneq C_6 \tag{5}$$

in the basic non Hilbert case of quaternary quartics. Furthermore,

$$\Sigma_{4,4} = C_0 = C_1 = C_2 = C_3$$

by (4) and $C_6 \subseteq \ldots \subseteq C_{10} = \mathcal{P}_{4,4}$ corresponds to (2) and with that to the $(3, 4)$ case by our inductive argument. The ternary quartics describe a Hilbert case and, consequently, the latter subfiltration collapses to

$$C_6 = \ldots = C_{10} = \mathcal{P}_{4,4}.$$

Putting it all together, we thus fully understand the situation in the basic non Hilbert case of quaternary quartics.
In particular, we strengthen Hilbert's original observation from 1888 in the quaternary quartics case by testifying the existence of two distinct strictly separating intermediate cones between the SOS and the PSD cone.

Abstract: This paper concerns an optimal control problem on the space of probability measures over a compact Riemannian manifold. The motivation behind it is to model certain situations where the central planner of a deterministic controlled system has only a probabilistic knowledge of the initial condition. The lack of information here is very specific. In particular, we show that the value function verifies a dynamic programming principle and we prove that it is the unique viscosity solution to a suitable Hamilton Jacobi Bellman equation. The notion of viscosity is defined using test functions that are directionally differentiable in the the space of probability measures.

Keywords: Optimal Control, Viscosity solutions, Hamilton Jacobi Bellman equation, Wasserstein spaces, Multi-agent systems.

1. INTRODUCTION

The study of optimal control problems and viscosity theory in the space of probability measures has been an active area of research in the mathematical community in the last years, in particular because of its potential real-world applications in the modeling of multi-agent systems. The potential applications include crowd dynamics modeling, opinion formation process modeling, herd analysis, social network analysis, autonomous multi-vehicle navigation and the modeling of uncertainties on the initial state of a deterministic controlled system.

At the individual level, the behavior of each agent is dictated not only by local interactions but also by the *non local* interactions that depend on the distribution of all agents. When the number of agents is assumed to be very large, the complexity of the system grows extremely fast. A suitable way to modelize this problem is through a macroscopic approach, where the discrete collection of agents is replaced by a spatial density that evolves in time. If we assume further that the total number of agents remains constant at all times during the evolution of the system, then one can normalize the density of the agents and assume that its total mass is equal to 1.

Hence, the evolution of the multi-agent system, seen as normalized spatial density in a given base space X (typically the Euclidean space or a Riemannian manifold), is described by a curve $t \mapsto \mu_t \in \mathcal{P}(X)$, where $\mathcal{P}(X)$ is the space of Borel probability measures over X, and μ_t represents the spatial density of the multi-agent system at a given time $t \geq 0$. The conservation of the mass along the trajectory $t \mapsto \mu_t$ is described by the following continuity equation

$$\partial_t \mu_t + div(v_t \mu_t) = 0,$$

where $v_t(.)$ is a time-dependent Borel vector field, and the equation is understood in the sense of distributions.

In this paper, we take the base space $X = M$ to be a compact Riemannian manifold without boundary. We propose to study a simple model of multi-agent systems, where the non local interactions between the agents are not considered. This problem can be interpreted as a deterministic control system with imperfect information on the initial condition, i.e. the initial condition is not known precisely by the controller, but they only know that the initial condition follows a probability distribution $\mu_0 \in \mathcal{P}(M)$. More precisely, consider the following controlled equation:

$$\begin{cases} \dot{Y}(t) = f(Y(t), u(t)), \quad t \in [t_0, T], \\ Y(t_0) = x_0, \quad u(t) \in U, \end{cases} \tag{1}$$

where $f : M \times U \to TM$ is the dynamics, assumed to be Lipschitz with respect to the first variable and continuous with respect to the second variable, $x_0 \in M$ and $t_0 \in [0, T]$. The set U is the set of admissible control values which is assumed to be a compact subset of some metric space. the control function $u(.) \in U$ is a Borel measurable function $u : [t_0, T] \to U$. The main feature of this problem is that the initial position x_0 is not perfectly known, but rather distributed along the probability measure μ_0. Notice that, since $f(., u(t))$ is Lipschitz continuous and bounded, the evolution curve of the uncertainty, $t \mapsto \mu_t$ starting from μ_0, is the unique solution to the equation

$$\begin{cases} \partial_t \mu_t + div(f(., u(t))\mu_t) = 0, \ t \in (t_0, T), \\ \mu_{t_0} = \mu_0, \end{cases}$$

in the distributional sense. The measures μ_t are obtained by the pushforward of μ_0 by the flow at time t of the controlled equation (1).
The controller aims at minimizing the following final cost:

$$L(\mu) = \int l(y)d\mu(y),$$

where $l : M \to \mathbb{R}$ is a Lipschitz function. An immediate consequence of this assumption is that the function $L : \mathcal{P}(M) \to \mathbb{R}$ inherits the Lipschitz property from l as well. The quantity $L(\mu_T)$ represents the expectation of the deterministic final cost with respect to the measure μ_T.

To this optimal control problem, we associate the following value function:

$$\vartheta(t_0, \mu_0) = \inf_{u(.)\in U} L(\mu_T).$$

The first main goal of this paper is to study the properties and the regularity of the value function. In particular we will show that the value function is Lipschitz continuous with respect to both variables and that it verifies the dynamic programming principle. The second goal of the paper is to prove that value function can be characterized as the unique viscosity solution of a suitable Hamilton Jacobi Bellman equation (HJB in short) of the form

$$\begin{cases} \partial_t v + H(\mu, D_\mu v) = 0, \quad (t,\mu) \in [0,T) \times \mathcal{P}_2(M), \\ v(T,\mu) = L(\mu), \end{cases}$$

in the space of probability measures $\mathcal{P}(M)$. We aim at transposing the viscosity theory techniques that are used in the classical theory (Crandall et al. (1992)) to the space of Borel probability measures $\mathcal{P}_2(M)$. In particular, we define a suitable notion of viscosity using a class of real valued functions that admit *directional derivatives* at all points $\mu \in \mathcal{P}(M)$. We then prove a local comparison principle between any bounded upper semicontinuous subsolution and any lower semicontinuous supersolution. Finally, we prove that the value function is the unique viscosity solution to the above HJB equation by using the dynamic programming principle verified by the value function.
This paper is expository. All the results asserted in here are proven in Jean et al. (2022). The paper is structured as follows. In Section 2, we recall some classical notions of optimal transport theory and the geometry of the space of probability measures. In Section 3, we formulate the Mayer problem in the space of probability measures and we give the main properties of the value functions. Section 4 is devoted to the study of a suitable HJB equation that characterizes the value function. In particular, we define the Hamiltonian we are going to work with, then we define a notion of viscosity using a class of test functions that are directionally differentiable, we show the comparison principle and we show that the value function is the unique viscosity of the HJB equation.

2. PRELIMINARIES

In this section, we recall some facts about optimal transport and the geometry of Wasserstein spaces. Let $(M, \langle ., . \rangle)$ be a finite dimensional, compact and connected Riemannian manifold without boundary. We denote by $|\,.\,|$ the associated norm on the tangent bundle TM, and by $d(.,.)$ its Riemannian distance on M. The metric space (M, d), is a complete, separable and compact space and its topology is equivalent to the topology of the differentiable manifold M. The tangent bundle TM is itself a complete and separable Riemannian manifold when endowed with the Sasaki metric (Sasaki (1962)). We denote by $d_{TM}(.,.)$ the Riemannian distance on TM associated with the Sasaki metric.

2.1 The Wasserstein space $\mathcal{P}_2(M)$

We denote by $\mathcal{P}(M)$ the set of Borel probability measures over M and $\mathcal{P}_2(M)$ the set of Borel probability measures with bounded second moments:

$$\mathcal{P}_2(M) := \{\mu \in \mathcal{P}(M) : \int d^2(x, x_0)d\mu(x) < \infty, \ \forall x_0 \in M\}$$

Actually, since M is compact, we have $\mathcal{P}_2(M) = \mathcal{P}(M)$ but we will keep using the notation $\mathcal{P}_2(M)$. Recall that for any two topological spaces X and Y, any Borel probability measure μ on X and any Borel function $g : X \to Y$, the pushforward measure $g\sharp\mu$ on Y is defined by

$$g\sharp\mu(A) = \mu(g^{-1}(A)) \quad \forall A \subset Y, \text{ a Borel set},$$

or equivalently, for all $h : Y \to \mathbb{R}$, a Borel measurable and bounded function, we have:

$$\int h \, dg\sharp\mu = \int h \circ g \, d\mu.$$

We define the Wasserstein distance $W_2(.,.)$ over $\mathcal{P}_2(M)$ by

$$W_2(\mu,\nu) := \sqrt{\inf\Big\{ \int d^2(x,y)d\gamma(x,y) \Big\}},$$

where the infimum is taken over all Borel probability measures of $M \times M$ that have marginals μ and ν, i.e. for all $A, B,$ Borel sets of M, we have

$$\gamma(A \times M) = \mu(A) \quad \text{and} \quad \gamma(M \times B) = \nu(B).$$

The metric space $(\mathcal{P}_2(M), W_2)$ is complete and separable. Furthermore, it is a geodesic space, i.e. any two points of $\mathcal{P}_2(M)$ can be joined by at least one geodesic. We recall that a curve $\alpha : [0,1] \to \mathcal{P}_2$ is a geodesic if

$$W_2(\alpha_t, \alpha_s) \leq |t-s| W_2(\alpha_0, \alpha_1), \ \forall t, s \in [0,1].$$

2.2 The tangent space $T_\mu(\mathcal{P}_2(M))$

In this subsection, we will adopt a purely metric perspective to define the tangent space of $(\mathcal{P}_2(M), W_2)$ at a given point μ. First, Let $\mathcal{P}(TM)$ be the set of Borel probability measures over TM. Since (TM, d_{TM}) is a complete geodesic space, we can define the Wasserstein space over TM as the set of all $\eta \in \mathcal{P}(TM)$ such that

$$\int d^2_{TM}\Big((x,v),(x_0,v_0)\Big)d\eta(x,v) < \infty,$$

for all $(x_0, v_0) \in TM$. We denote it by $\mathcal{P}_2(M)$. We endow it with the usual Wasserstein distance for any $\eta, \gamma \in \mathcal{P}_2(TM)$:

$$W_2(\gamma,\eta) := \sqrt{\inf\Big\{ \int d^2_{TM}(x,y)d\beta(x,y) \Big\}},$$

the infinimum is taken over all admissible plans β with marginals γ and η. We are now able to define the tangent space at a point $\mu \in \mathcal{P}_2(M)$.

Definition 1. (Tangent space). Let $\mu \in \mathcal{P}_2(M)$. The tangent space $T_\mu(\mathcal{P}_2(M)) \subset \mathcal{P}_2(TM)$, is the set of plans $\gamma \in \mathcal{P}_2(TM)$ such that $\pi^M\sharp\gamma = \mu$, where $\pi^M : TM \to M$ is the canonical projection onto M.

The tangent space at a point μ has a geometric meaning. In fact, it encodes all the information about geodesics emanating from μ as we describe hereafter.
Let $\exp : TM \to M$ be the exponential map of $(M, \langle ., . \rangle)$. The exponential $\mathbf{exp}_\mu(\gamma)$ of a plan $\gamma \in T_\mu(\mathcal{P}_2(M))$ is defined by

$$\mathbf{exp}_\mu(\gamma) := \exp \sharp \gamma \in \mathcal{P}_2(M).$$

We define the map $\mathbf{exp}_\mu^{-1} : \mathcal{P}_2(M) \to T_\mu(\mathcal{P}_2(M))$ by

$$\mathbf{exp}_\mu^{-1}(\nu) := \{ \gamma \in T_\mu(\mathcal{P}_2(M)) \ : \ \mathbf{exp}_\mu(\gamma) = \nu \text{ and } \int |v|^2 \, \mathrm{d}\gamma(x,v) = (d_W(\mu,\nu))^2 \},$$

or in other words, the set of plans $\gamma \in \mathcal{P}_2(TM)$ such that $(\pi^M, \exp)\sharp\gamma$ is an optimal plan from μ to ν and $\int |v|^2 \, \mathrm{d}\gamma(x,v) = (d_W(\mu,\nu))^2$. We introduce the following notation

$$\Delta_t(x,v) = (x, tv), \quad \forall t \in \mathbb{R}, \ (x,v) \in TM.$$

Remark 2. The map $\mathbf{exp}_\mu^{-1}$ is not really an inverse map to $\mathbf{exp}_\mu$ since only optimal plans in the inverse image of ν are considered. While this might seem confusing, the map $\mathbf{exp}_\mu^{-1}$ is defined this way so that for all $\gamma \in \mathbf{exp}_\mu^{-1}(\nu)$, the curve $t \to \exp(\Delta_t)\sharp\gamma$ is a geodesic connecting μ and ν, see the theorem below.

Theorem 3. (Gigli, 2011, Theorem 1.11) Let $\mu, \nu \in \mathcal{P}_2(M)$. A curve $(\mu_t) : [0,1] \to \mathcal{P}_2(M)$ is a geodesic connecting μ to ν if and only if there exists a plan $\gamma \in \mathbf{exp}_\mu^{-1}(\nu)$ such that

$$\mu_t := \exp \circ \Delta_t \sharp \gamma, \quad \forall \, t \in [0,1]. \tag{2}$$

The plan γ is uniquely identified by the geodesic. Moreover, for any $t \in (0,1)$ there exists a unique optimal plan from μ to μ_t. Finally, if there exist two different geodesics connecting μ to ν, they do not intersect in intermediate times (i.e. on $(0,1)$).

Introducing the following rescaling of a plan:

$$t \cdot \gamma = \Delta_t \sharp \gamma, \quad \forall t \in \mathbb{R}, \ \gamma \in \mathcal{P}_2(TM),$$

equation (2) can be rewritten in a more elegant way as

$$\mu_t = \exp \circ \Delta_t \sharp \gamma = \mathbf{exp}_\mu(t \cdot \gamma), \quad \forall t \in [0,1].$$

With the characterization of geodesics in Theorem 3, notice that for any $\mu \in \mathcal{P}_2(M)$, all plans $\gamma \in T_\mu(\mathcal{P}_2(M))$ that produce geodesics, i.e. such that

$$t \mapsto \mathbf{exp}_\mu(t \cdot \gamma), \tag{3}$$

is a geodesic defined in some right neighborhood of 0, say $[0, \varepsilon]$, can be seen as *initial velocities* of these geodesics. We mention that not all curves of this form are necessarily geodesics but all geodesics are of this form.
Moreover, using this characterization of geodesics, we can define a class of real valued functions $f : \mathcal{P}_2(M) \to \mathbb{R}$ that are *directionally differentiable* along all geodesics. In particular, the squared Wasserstein distance function

$$\mu \mapsto W^2(\mu, \sigma),$$

with $\sigma \in \mathcal{P}_2(M)$ fixed, is directionally differentiable along all geodesics. In fact, a much more general result holds: the squared Wasserstein distance is directionally differentiable along all curves of the form (3) even though they are not geodesics. For more details on this, we refer to Gigli (2011). We will only give the following result for the squared Wasserstein distance, which we will need in order to define test functions for viscosity notion in Section 4.

Theorem 4. (Gigli, 2011, Theorem 4.2) Let $\mu, \sigma \in \mathcal{P}_2(M)$, and $g : M \to TM$ be a squared integrable vector field with respect to μ. Let $\gamma = g\sharp\mu \in T_\mu(\mathcal{P}_2(M))$ and $t \mapsto \mathbf{exp}_\mu(t \cdot \gamma)$ be a curve starting from μ, *not necessarily a geodesic*. Then it holds

$$\frac{d}{dt}\Big|_{t=0} W_2^2(\mathbf{exp}_\mu(t \cdot \gamma), \sigma)^2 = -2 \sup \int \langle g(x), v \rangle d\zeta(x,v),$$

where the supremum is taken over all $\zeta \in \mathbf{exp}_\mu^{-1}(\sigma)$. We denote it by

$$D_\mu W_2^2(., \sigma) \cdot (g\sharp\mu) := \frac{d}{dt}\Big|_{t=0} W_2^2(\mathbf{exp}_\mu(t \cdot \gamma), \sigma)^2,$$

and is understood as the *differential* of $W_2^2(., \sigma)$ along $g\sharp\mu$.

3. OPTIMAL CONTROL PROBLEM IN $\mathcal{P}_2(M)$

Let $T > 0$ and U be a compact subset of a metric space. Consider the dynamics, defined for $T > t_0 \geq 0$ and $x_0 \in M$, as

$$\begin{cases} \dot{Y}(t) = f(Y(t), u(t)), & t \in [t_0, T], \\ Y(t_0) = x_0, u(t) \in U, \end{cases} \tag{4}$$

where $f : M \times U \to TM$ satisfies the following assumptions:

$$\textbf{(H)} \begin{cases} f : M \times U \to TM \text{ is continuous and Lipschitz} \\ \text{ continuous with respect to the state, i.e.} \\ \exists k > 0 : d_{TM}(f(x,u), f(y,u)) \leq k \, d(x,y), \\ \forall u \in U, \ (x,y) \in M \times M. \end{cases}$$

$\textbf{(H)}_{co}$: for all $x \in M$, the set
$f(x,U) := \{f(x,u) \ : \ u \in U\}$ is convex.

We define the set of open-loop controls by

$$\mathcal{U} := \{u : [0,T] \to U \ : \ u(.) \text{ is measurable}\}.$$

The control problem aims at minimizing the final cost

$$\int l(Y_T^{t_0,x_0,u}) \, d\mu_0(x_0),$$

over all trajectories that are solutions of the dynamics (4) with the initial condition $x_0 \in M$, distributed along the measure $\mu_0 \in \mathcal{P}_2(M)$. We consider the following assumption:

$\textbf{(H}_\textbf{l}\textbf{)}$ $l : M \to \mathbb{R}$ is Lipschitz continuous with constant $Lip(l)$.

When μ_0 is equal to the Dirac mass δ_{x_0}, the resulting system corresponds to the classical case without uncertainties on the initial condition. This problem is thoroughly studied in the literature. When μ_0 is any probability measure of $\mathcal{P}_2(M)$, it is better to see this problem as an optimal control problem defined on the space of Borel probability measures $\mathcal{P}_2(M)$. First we rewrite the final cost the following way

$$\int l(Y_T^{t_0,x_0,u}) \, d\mu_0(x_0) = \int l(y) \, dY_T^{t_0,.,u}\sharp\mu_0 \, (y),$$

and we minimize this cost over the set of trajectories $t \mapsto \mu_T^{t_0,\mu_0,u}$ of the space $\mathcal{P}_2(M)$ that verify

$$\begin{cases} \mu_t^{t_0,\mu_0,u} = Y_t^{t_0,.,u}\sharp\mu_0, \quad t \in [t_0,T], \text{ and } x \mapsto Y_t^{t_0,x,u} \\ \text{is the flow of (4)}, \\ \mu_{t_0} = \mu_0. \end{cases}$$

Since $x \mapsto Y_t^{t_0,x,u} \in M$ and $\mu_0 \in \mathcal{P}_2(M)$, then $t \mapsto Y_t^{t_0,.,u}\sharp\mu_0 \in \mathcal{P}_2(M)$ for all $t \in [t_0,T]$. It is a known

fact, Ambrosio et al. (2008); Bernard (2008), that each trajectory $t \mapsto \mu_t^{\mu_0,u}$ is the unique solution to the following continuity equation

$$\begin{cases} \partial_t \mu_t^{t_0,\mu_0,u} + div(f(.,u(t))\mu_t^{t_0,\mu_0,u}) = 0,\ t \in (t_0,T) \\ \mu_{t_0}^{\mu_0,u} = \mu_0. \end{cases} \tag{5}$$

In the distributional sense. Hence the optimal control problem can be rewritten in the following way:

$$\begin{cases} \min\limits_{u(.)\in U} \int l(y) d\mu_T^{t_0,\mu_0,u}(y) = L(\mu_T^{t_0,\mu_0,u}), \\ \text{such that } \begin{cases} \partial_t \mu_t^{t_0,\mu_0,u} + div(f(.,u(t))\mu_t^{t_0,\mu_0,u}) = 0, \\ \mu_{t_0}^{\mu_0,u} = \mu_0,\ t \in (t_0,T). \end{cases} \end{cases} \tag{6}$$

The associated *value function* to the above optimal control problem is defined as

$$\vartheta(t_0,\mu_0) := \inf_{u(.)\in\mathcal{U}} \int l(y)\, d\mu_T^{t_0,\mu_0,u}(y) = L(\mu_T^{t_0,\mu_0,u}).$$

Under hypotheses $(\boldsymbol{H})$, $(\boldsymbol{H_l})$ and $(\mathbf{H})_{co}$, we have the following two properties of the value function.

Proposition 5. (Jean et al. (2022)). Assume $(\boldsymbol{H})$, $(\boldsymbol{H_l})$ and $(\mathbf{H})_{co}$. Then, the value function ϑ is Lipschitz continuous on $[0,T] \times \mathcal{P}_2(M)$. In particular, ϑ is bounded.

Theorem 6. (Jean et al. (2022)). Let $\mu \in \mathcal{P}_2(M)$, $t \in [0,T]$ and $h \in [t, T-t]$. Then it holds

$$\vartheta(t,\mu) = \inf_{u\in\mathcal{U}} \vartheta(t+h, \mu_{t+h}^{t,\mu,u}).$$

4. HJB EQUATION IN $\mathcal{P}_2(M)$

The Hamiltonian we will work with has the following expression:

$$H(\mu, D_\mu v) = \inf_{u\in U} D_\mu v \cdot \Big(f(.,u)\sharp\mu\Big), \tag{7}$$

with $v : \mathbb{R} \times \mathcal{P}_2(M) \to \mathbb{R}$ is a real valued function that admits directional derivatives along the time variable and the measure variable. The function v represents a test function that has the following form:

$$\forall (t,\mu) \in [0,T) \times \mathcal{P}_2(M),\ v(t,\mu) = \psi(t) + a\, W_2^2(\mu,\sigma),$$

with $a \in \mathbb{R}$ and $\sigma \in \mathcal{P}_2(M)$ fixed and $\psi : [0,T) \to \mathbb{R}$ is a continuously differentiable function, $\mu \mapsto W_2^2(\mu,\sigma)$ is directionally differentiable in the sense of Theorem 4. We consider the following Hamilton Jacobi Bellman equation:

$$\begin{cases} \partial_t v + H(\mu, D_\mu v) = 0, \quad (t,\mu) \in [0,T) \times \mathcal{P}_2(M), \\ v(T,\mu) = L(\mu). \end{cases} \tag{8}$$

Next, we define the test functions that we are going to use to define the notion of viscosity solutions.

Definition 7. (Test functions).
Let $\mathcal{TEST}_1$ be the set defined as:

$$\mathcal{TEST}_1 := \{(t,\mu) \to \psi(t) + a(\,(d_W(\mu,\sigma))^2\,) : a \in \mathbb{R}^+, \sigma \in \mathcal{P}_2(M)\},$$

where $\psi : [0,T) \to \mathbb{R}$ is a C^1 function.
We set $\mathcal{TEST}_2 = -\mathcal{TEST}_1 := \{-\phi : \phi \in \mathcal{TEST}_1\}$.

Definition 8. (Viscosity solutions).

- We say that a function $v : [0,T) \times \mathcal{P}_2(M) \to \mathbb{R}$ satisfies the inequality
$$\partial_t v + H(\mu, D_\mu v) \geq 0,$$
at $(t,\mu) \in [0,T) \times \mathcal{P}_2(M)$ in the viscosity sense if v is upper semicontinuous and for all $\mathcal{TEST}_1$ functions $\phi : [0,T) \times \mathcal{P}_2(M) \to \mathbb{R}$ such that $v - \phi$ attains a maximum at (t,μ), we have
$$\partial_t \phi + H(\mu, D_\mu \phi) \geq 0.$$
A function v satisfying $\partial_t v + H(\mu, D_\mu v) \geq 0$ on $[0,T) \times \mathcal{P}_2(M)$ in the viscosity sense is called a *viscosity subsolution* of (8).
- Similarly, we say that a function $v : [0,T) \times \mathcal{P}_2(M) \to \mathbb{R}$ satisfies the inequality
$$\partial_t v + H(\mu, D_\mu v) \leq 0,$$
at $(t,\mu) \in [0,T) \times \mathcal{P}_2(M)$ in the viscosity sense if v is lower semicontinuous and for all $\mathcal{TEST}_2$ functions $\phi : [0,T) \times \mathcal{P}_2(M) \to \mathbb{R}$ such that $v - \phi$ attains a minimum at (t,μ), then
$$\partial_t \phi + H(\mu, D_\mu \phi) \leq 0.$$
A function v satisfying $\partial_t v + H(\mu, D_\mu v) \leq 0$ on $[0,T) \times \mathcal{P}_2(M)$ in the viscosity sense is called a *viscosity supersolution* of (8).
- We say that a continuous function $v : [0,T] \times \mathcal{P}_2(M) \to \mathbb{R}$ is a *viscosity solution* of (8) if it is both a supersolution and a subsolution on $[0,T) \times \mathcal{P}_2(M)$ and verifies
$$v(T,\mu) = L(\mu).$$

Theorem 9. (Jean et al. (2022)). Assume $(\boldsymbol{H})$ and $(\boldsymbol{H_l})$. Let $u, v : [0,T] \times \mathcal{P}_2(M) \to \mathbb{R}$ be respectively bounded upper semicontinuous subsolution and lower semicontinuous supersolution on $[0,T] \times \mathcal{P}_2(M)$. Then it holds:

$$\sup_{[0,T]\times\mathcal{P}_2(M)} (v-w)_+ \leq \sup_{\{T\}\times\mathcal{P}_2(M)} (v-w)_+,$$

where $(a)_+ = max(a,0)$.

Theorem 10. (Jean et al. (2022)). Assume $(\boldsymbol{H})$, $(\boldsymbol{H_l})$ and $(\boldsymbol{H_{co}})$. Then the value function ϑ is the unique continuous viscosity solution to (8).

Abstract: Differential algebra-based theory and software have been widely used to study the *a priori* structural identifiability of nonlinear systems. This technique however fails to provide definitive answers for complex reaction networks which involve several reactions and species. In this work, for reaction systems following mass action kinetics, using the theory of reaction extents, we show that identifiability can be ascertained by determining the rank of a matrix. Further, we show that for systems involving most bi-molecular reactions, the parameters are guaranteed to be identifiable, if R (where R = number of independent reactions) species that satisfy a rank condition are measured.

Keywords: Parameter Identifiability, Ritts Pseudo–Division Algorithm, Extent Domain, Complex Reaction Networks, Systems Biology

1. INTRODUCTION

It is important to identify reliable and accurate models of reaction systems for use in model-based analysis tasks such as simulation, control, and optimisation. In practice, the identification of models is an iterative process involving: (i) experimental data generation using carefully planned experiments, and (ii) fitting a proposed model (or a set of proposed models) to generated data (van Riel, 2006). It is important to investigate whether the unknown parameters can be uniquely estimated from observed data before investing resources, time and effort in performing actual experiments (Chis et al., 2011).

A priori structural identifiability addresses the issue of whether it is possible to recover the unknown parameters uniquely from a proposed model structure from error-free data (Ljung and Glad, 1994). The problem of structural rate identifiability in reaction systems involves determining the actual parameters appearing in the kinetic rate laws. This has been studied in the larger context of parameter identifiability of ODE models and different methods based on the Taylor series, generating functions, differential algebra, implicit function theorem, etc. have been proposed in the existing literature and have been compared by Chis et al. (2011). Differential algebra-based methods involve two steps. In the first step, a set of differential polynomials called the characteristics set that relates the inputs, outputs, and their derivatives is derived. This is followed by testing for the injectivity of the coefficient maps of the differential polynomials. A user-friendly software tool, DAISY (Differential Algebra for Identifiability of SYstems) (Bellu et al., 2007; Saccomani et al., 2003) to check identifiability in a specific class of nonlinear systems that contain polynomial or rational functions has been developed. Systems described by non-rational functions can be approximated by rational functions and we have shown that the differential-algebraic methods can provide a partial answer to the question of structural identifiability (Jain et al., 2019). Although the algorithms are guaranteed to converge, the worst-case time complexity is very large. Hence, methods based on DAISY may fail to provide a definitive result in reasonable time (Saccomani et al., 2010; Varghese et al., 2018). Moreover, the methods do not exploit the underlying structure of the system, e.g., reaction networks which is the focus of this work.

In the previous work, we applied the theory of reaction variants and in-variants (Amrhein et al., 2010) to simplify the problem of determining structural rate identifiability in reaction systems [1] (Varghese et al., 2018). For a class of reaction systems, an appropriate extent of reaction was used to develop an alternate, but equivalent state-space model with significantly lower dimensions. The advantages of the method were demonstrated in situations where the use of conventional methods and software e.g., DAISY failed. This was also extended to the situation when the number of participating reactions is more than the number of independent reactions, and hence applicable to complex reaction networks which involve a large number of reactions and species.

In this work, for reaction systems following mass-action kinetics, we show that the characteristic set is readily

[1] In the interest of brevity, we refer to structural rate identifiability as parameter identifiability or simply identifiability

obtained by solving a set of linear equations alone. Identifiability can be ascertained by determining the rank of a matrix. Further, we show that for systems involving most bimolecular reactions, the parameters are guaranteed to be identifiable, if R (R = number of independent reactions) species that satisfy a rank condition are measured. This is significant because in many cases, this is possible by inspection alone. Hence, the need to perform computer algebra (or symbolic computation) required for differential-algebra methods and software such as DAISY can be avoided.

2. PRELIMINARIES

2.1 Differential Algebra approach to identifiability

Consider a nonlinear system:

$$\begin{aligned} \dot{\mathbf{x}}(t) &= \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{p}), \qquad \mathbf{x}(0) = \mathbf{x}_0, \\ \mathbf{y} &= \mathbf{g}(\mathbf{x}, \mathbf{u}, \mathbf{p}) \end{aligned} \tag{1}$$

where $\mathbf{x}(t) \in \mathbb{R}^S$ is the state vector, $\mathbf{u} \in \mathbb{R}^\upsilon$ is the input vector, $\mathbf{y} \in \mathbb{R}^m$ is the output vector, and $\mathbf{p} \in \mathbb{R}^p$ is the parameter vector. It is assumed that $\mathbf{f}(\cdot) : \mathbb{R}^S \to \mathbb{R}^S$ and $\mathbf{g}(\cdot) : \mathbb{R}^S \to \mathbb{R}^m$ are Lipschitz continuous with respect to $\mathbf{x}$, and $\mathbf{u}$. When the nonlinear functions in Eq. (1) are rational or polynomial, identifiability of the parameters can be determined as follows. A set of m differential polynomials in terms of input variables $\mathbf{u}$, output variables $\mathbf{y}$, derivatives of inputs, outputs and parameters $\mathbf{p}$ are determined and denoted as input-output relations or characteristic set of the system (1). This set of input-output relations is determined from (1) using the Ritt's pseudo–division algorithm (Ritt, 1950; Saccomani et al., 2003). Let $\mathbf{h}(\mathbf{p})$ denote the vector of coefficients in the input output map. Then, we can check the injectivity of the coefficients map $\mathbf{h}(\mathbf{p})$ of the m differential polynomials for determining a priori parameter identifiability by evaluating $\mathbf{h}(\mathbf{p})$ for an arbitrary $\mathbf{p}^*$. The Büchberger algorithm is usually employed to obtain the Gröbner basis for this set of equations $\mathbf{h}(\mathbf{p}) = \mathbf{h}(\mathbf{p}^*)$. Depending on the nature of solutions of $\mathbf{h}(\mathbf{p}) = \mathbf{h}(\mathbf{p}^*)$, we can classify the system as follows.

Definition 1. (Globally Identifiable). The model (1) is globally identifiable from the input-output data if and only if for any arbitrary $\mathbf{p}^*$, $\mathbf{h}(\mathbf{p}) = \mathbf{h}(\mathbf{p}^*)$ has a unique solution $\mathbf{p} = \mathbf{p}^*$.

Definition 2. (Locally Identifiable). If there exists multiple but finite number of distinct solutions for $\mathbf{h}(\mathbf{p}) = \mathbf{h}(\mathbf{p}^*)$ then the model (1) is locally identifiable.

Definition 3. (Unidentifiable). If there are infinite number of solutions for $\mathbf{h}(\mathbf{p}) = \mathbf{h}(\mathbf{p}^*)$ then the model (1) is unidentifiable.

2.2 Models of Reaction Systems

We consider an isothermal constant volume (V_0) batch reaction system with S species and R reactions. $\mathbf{N}$ is the $R \times S$-dimensional stoichiometric matrix and $\mathbf{r}(\mathbf{c}(t), \boldsymbol{\theta})$ is the R-dimensional vector of reaction rates, and $\boldsymbol{\theta}$ is the p-dimensional vector of parameters. A reaction rate is typically a nonlinear function of the concentrations $\mathbf{c}$ and the parameter vector $\boldsymbol{\theta}$. The independent reactions can be defined as follows (Bhatt, 2011):

Definition 4. (Independent reactions). R reactions are said to be independent if (i) the rows of $\mathbf{N}$ (stoichiometries) are linearly independent, i.e., rank $(\mathbf{N}) = R$, and (ii) there exists some finite time interval for which the reaction rate profiles $\mathbf{r}(t)$ are linearly independent, i.e., $\boldsymbol{\beta}^{\mathrm{T}}\mathbf{r}(t) = 0 \Leftrightarrow \boldsymbol{\beta} = \mathbf{0}_R$.

Without loss of generality, we assume that the reactions are independent. The mole balance equations for this system can be written as:

$$\begin{aligned} \dot{\mathbf{n}}(t) &= V_0\mathbf{N}^{\mathrm{T}}\mathbf{r}(\mathbf{c}(t), \boldsymbol{\theta}), \quad \mathbf{n}(0) = \mathbf{n}_0 \\ \mathbf{c}(t) &= \frac{\mathbf{n}(t)}{V_0} \end{aligned} \tag{2}$$

where $\mathbf{n}$ and $\mathbf{c}$ are the S-dimensional vectors of the number of moles, and concentrations, respectively. Without loss of generality, it is assumed that the initial concentrations ($\mathbf{c}_0$) are known. The model (2) can be written in terms of the concentrations as follows:

$$\dot{\mathbf{c}}(t) = \mathbf{N}^{\mathrm{T}}\mathbf{r}(\mathbf{c}(t), \boldsymbol{\theta}), \quad \mathbf{c}(0) = \mathbf{c}_0 \tag{3}$$

In practice, only a subset of concentrations are measured. Let $\mathbf{c}$ be partitioned as: $\mathbf{c}^{\mathrm{T}} = [\mathbf{c}_m^{\mathrm{T}}\ \mathbf{c}_u^{\mathrm{T}}]$, where $\mathbf{c}_m$ and $\mathbf{c}_u$ denote the measured and unmeasured species concentration respectively. Then, the above model can be expressed in conventional state space form as follows

$$\begin{aligned} \dot{\mathbf{c}}(t) &= \mathbf{N}^{\mathrm{T}}\mathbf{r}(\mathbf{c}(t), \boldsymbol{\theta}) \\ \mathbf{c}_m &= [\mathbf{I}_m\ \mathbf{0}]\,\mathbf{c} \end{aligned} \tag{4}$$

Definition 5. (Reaction variant, and invariant). Any set of R linearly independent variables that evolves with time and depends on reaction rates constitutes a reaction variant set. Any set of $(S - R)$ linearly independent variables that do not change with time constitutes a reaction invariant set. A linear transformation of the concentrations in (4) can be defined as follows:

$$\begin{bmatrix} \mathbf{x}_r \\ \mathbf{x}_{iv} \end{bmatrix} = \begin{bmatrix} \mathbf{N}^{T\dagger} \\ \mathbf{Q}^{\mathrm{T}} \end{bmatrix} (\mathbf{c} - \mathbf{c}_0) \tag{5}$$

where $\mathbf{x}_r$ is the $R-$dimensional vector of the extents of reaction, and $\mathbf{x}_{iv}$ is $(S - R)-$dimensional vector of invariant states. The invariant states do not change with time. '$\dagger$' denotes the Moore-Penrose pseudo–inverse of the matrix. $\mathbf{Q}$ is an $S \times S - R$-dimensional matrix such that $\mathbf{NQ} = \mathbf{0}$. The concentrations can be related to the extents of reaction as follows:

$$\mathbf{c}(t) = \mathbf{N}^{\mathrm{T}}\mathbf{x}_r + \mathbf{c}_0 \tag{6}$$

Typically, not all species are measured. Given a subset of measurements, under certain conditions, the reaction extents and unmeasured concentrations can be reconstructed using the following proposition.

Proposition 6. Let the matrix $\mathbf{N}$, and the initial conditions $\mathbf{c}_0$ be known and, without loss of generality, let $\mathbf{N}$ and $\mathbf{c}$ be partitioned as: $\mathbf{N} = [\mathbf{N}_m\ \mathbf{N}_u]$ and $\mathbf{c}^{\mathrm{T}} = [\mathbf{c}_m^{\mathrm{T}}\ \mathbf{c}_u^{\mathrm{T}}]$. Furthermore, let $\mathbf{c}_m(t)$ be measured without errors. If (i) rank $(\mathbf{N}_m) = R$, then the unmeasured concentrations $\mathbf{c}_u(t)$ can be reconstructed from the available $\mathbf{c}_m(t)$ in two steps as follows: (i) computation of the extents of reaction, $\mathbf{x}_r(t) = (\mathbf{N}_m^{\mathrm{T}})^\dagger(\mathbf{c}_m(t) - \mathbf{c}_{0,m})$, and (ii) reconstruction of the unmeasured concentrations $\mathbf{c}_u(t)$: $\mathbf{c}_u(t) = \mathbf{N}_u^{\mathrm{T}}\mathbf{x}_r(t) + \mathbf{c}_{0,u}$ (See Proof in (Bhatt, 2011))

Thus, the system can be defined in terms of a lower dimensional state space, viz., the R-dimensional space of

reaction variants or extents as follows:

$$\begin{aligned} \dot{\mathbf{x}}_r &= \mathbf{r}(\mathbf{x}, \boldsymbol{\theta}), & \mathbf{x}_r(0) &= \mathbf{0}, \\ \dot{\mathbf{x}}_{iv} &= \mathbf{0}, & \mathbf{x}_{iv}(0) &= \mathbf{0}, \\ \mathbf{c}_m &= \mathbf{N}_m^{\mathrm{T}} \mathbf{x}_r + \mathbf{c}_{0,m} \end{aligned} \tag{7}$$

Models (4) and (7) can be expressed in terms of the standard state-space equation form (1). Table 1 summarizes the two representations in the standard state-space form. Table 1 shows that the measurement function $\mathbf{g}(\cdot)$ is a linear function of the states.

Table 1. State space representations of batch reaction systems

Standard form	Model (4) Concentration domain	Model (7) Extent domain
$\mathbf{x}$	$\mathbf{c}$	$\mathbf{x}_r$
$\mathbf{y}$	$\mathbf{c}_m$	$\mathbf{c}_m$
$\mathbf{f}$	$\mathbf{N}^{\mathrm{T}}\mathbf{r}$	$\mathbf{r}$
$\mathbf{g}$	$\left[\mathbf{I}_m \;\; \mathbf{0}\right] \mathbf{c}$	$\mathbf{N}_m^{\mathrm{T}}\mathbf{x}_r + \mathbf{c}_{0,m}$
Number of states	S	R

3. IDENTIFIABILITY ANALYSIS OF REACTION NETWORKS

In this section, we demonstrate how the use of reaction variants or extents allows us to readily generate the characteristic set that significantly reduces the effort in deciding parameter identifiability in reaction systems.

In contrast to the conventional representation of reaction systems in the concentration domain, the same system is represented by a lower-dimensional subspace ($R-$dimensional) in the extent domain. Hence, the representation in terms of the extent reduces the complexity of the reaction system models when the differential-algebraic approach is applied to the model in the extent domain. Further, in the DAISY-based techniques, the Ritt's pseudo-division algorithm has to be applied to obtain the characteristic set of equations using symbolic computational techniques. In the extend-based approach, the characteristic equations can be obtained by solving a set of linear equations. This indeed reduces the computational efforts. These observations can be generalized as follows.

Proposition 7. (Varghese et al., 2018) Consider a reaction system with S species and R independent reactions. The reaction system can be represented by either the model (4) or the model (7). Let $\mathbf{y} = \mathbf{c}_m$ be the m-dimensional vector of the measured concentrations with $m \geq R$. Let $\mathbf{N}$ and $\mathbf{c}$ be partitioned as: $\mathbf{N} = [\mathbf{N}_m \;\; \mathbf{N}_u]$ and $\mathbf{c}^{\mathrm{T}} = [\mathbf{c}_m^{\mathrm{T}} \;\; \mathbf{c}_u^{\mathrm{T}}]$. If $\operatorname{rank}(\mathbf{N}_m) = R$, then the characteristic set can be given by the following equations:

$$(\mathbf{N}_m^T)^{\dagger} \dot{\mathbf{y}} = \mathbf{r}(\mathbf{y}, \boldsymbol{\theta}, \mathbf{c}_0) \tag{8}$$

Proposition 7 is used to determine the characteristic set without performing the Ritt's algorithm. for parameter identifiability in reaction systems. The result has been extended to systems with dependent reactions Varghese et al. (2018).

3.1 Mass action kinetics

A reaction is said to follow mass action kinetics if the rate law can be expressed as follows:

$$r = \prod_{i=1}^{S} k_f c_i^{|\nu_i|} - \prod_{j=1}^{S} k_b c_j^{|\nu_j|} \tag{9}$$

where ν_i and ν_j are the stoichiometric coefficients of the ith reactant and jth product in the reaction, and k_f and k_b are the forward and backward reaction constants. Consider a reaction system with S species and R independent reactions occurring in a constant volume batch reactor (for ease of exposition) which can be described by S differential equations:

$$\dot{\mathbf{c}}(t) = \mathbf{N}^{\mathrm{T}} \mathbf{r}(\mathbf{c}(t), \boldsymbol{\theta}), \quad \mathbf{c}(0) = \mathbf{c}_0 \tag{10}$$

where the rate laws follow mass action kinetics and $\boldsymbol{\theta} \in \mathbb{R}^p$ is a vector of parameters to be determined. It is assumed that R species are measured such that conditions of proposition 7 are satisfied. From Proposition 7, we have

$$\dot{\mathbf{c}}_m = \mathbf{f}(\boldsymbol{\theta}, \mathbf{c}_m) \tag{11}$$

where $\mathbf{c}_m$ is the vector of measured concentrations. Clearly, the right hand side is a polynomial function of $\mathbf{c}_m$ and linear function of parameters θ. We collect the different monomials of the form $c_1^{i_1} c_2^{i_2} \dots c_{S_m}^{i_{S_m}}$ and examine the first row of $\mathbf{f}$ as follows:

$$\mathbf{f}(\boldsymbol{\theta}, \mathbf{c}_m)_1 = \left[(c_1^{i_1} \dots c_{S_m}^{i_{S_m}}) \dots (c_1^{l_1} \dots c_{S_m}^{l_{S_m}}) \right] \begin{bmatrix} \sum \alpha_{mi} \theta_i \\ \vdots \\ \sum \alpha_{li} \theta_i \end{bmatrix} \tag{12}$$

Let A_1 be defined as follows:

$$\begin{bmatrix} \sum \alpha_{mi} \theta_i \\ \vdots \\ \sum \alpha_{li} \theta_i \end{bmatrix} = \underbrace{\begin{bmatrix} \alpha_{i1} & \alpha_{i2} & \dots & \alpha_{ip} \\ \vdots & \vdots & \vdots & \vdots \\ \alpha_{l1} & \alpha_{m2} & \dots & \alpha_{lp} \end{bmatrix}}_{A_1} \begin{bmatrix} \theta_1 \\ \vdots \\ \theta_p \end{bmatrix} = A_1 \begin{bmatrix} \theta_1 \\ \vdots \\ \theta_p \end{bmatrix} \tag{13}$$

For every row of $\mathbf{f}_i$, $i = 1, \dots, R$, we collect the matrices A_i and form a matrix

$$\mathbf{h} = \begin{bmatrix} A_1 \\ \vdots \\ A_R \end{bmatrix}$$

Let us assume that in addition to measuring the concentrations $c_1, \dots, c_{S_m}$ at times $t_1, t_2, \dots, t_N$, the derivatives are also available at these times. Hence, we can form the following set of equations:

$$\begin{bmatrix} \dot{\mathbf{c}}(t_1) \\ \dot{\mathbf{c}}(t_2) \\ \vdots \\ \dot{\mathbf{c}}(t_N) \end{bmatrix} = \begin{bmatrix} \vdots & & \vdots \\ (c_1^{i_1} c_2^{i_2} \dots c_{S_m}^{i_{S_m}})(t_1) & \dots & (c_1^{l_1} c_2^{l_2} \dots c_{S_m}^{l_{S_m}})(t_1) \\ \vdots & & \vdots \\ (c_1^{i_1} c_2^{i_2} \dots c_{S_m}^{i_{S_m}})(t_2) & \dots & (c_1^{l_1} c_2^{l_2} \dots c_{S_m}^{l_{S_m}})(t_2) \\ \vdots & & \vdots \\ (c_1^{i_1} c_2^{i_2} \dots c_{S_m}^{i_{S_m}})(t_N) & \dots & (c_1^{l_1} c_2^{l_2} \dots c_{S_m}^{l_{S_m}})(t_N) \end{bmatrix} \mathbf{h}\boldsymbol{\theta} \tag{14}$$

Proposition 8. In reaction systems with mass action kinetics, the parameters are generically identifiable if matrix $\mathbf{h}$ in (14) is full rank, i.e., rank $(\mathbf{h}) = p$.

Proof In the interest of brevity, only an outline is presented. Clearly, Eq. (14) is a set of linear equations in $\boldsymbol{\theta}$ and over-determined, i.e., there are more equations than unknowns. The data matrix, i.e., the matrix of concentrations (or rather monomials) is of full column rank with high probability. Hence, if $\mathbf{h}$ is full rank (i.e., p), there exists a unique solution to the above equations, and parameters are identifiable. □

Consider an isothermal and constant density reaction system having $\mathbf{S}$ species and $\mathbf{R}$ independent reactions. Let this reaction network consist only of uni- or bimolecular reactions alone, i.e., reactions with a maximum of two reactants and two products. The general form of the ith reaction in such a network is given by:

$$R_i : R1_i + R2_i \leftrightarrow P1_i + P2_i$$

The rate of this ith reaction can be expressed in mass action kinetics as

$$r_i = k_{f,i} c_{R1,i}^{\alpha_i} c_{R2,i}^{\beta_i} - k_{b,i} c_{P1,i}^{\gamma_i} c_{P2,i}^{\theta_i} \tag{15}$$

Given this class of systems, we can show that the above system is identifiable if R measurements satisfying a rank condition are chosen.

Theorem 9. Consider a uni-/bi-molecular reaction system with S species and R independent reactions. Let $\mathbf{y} = \mathbf{c}_m$ be the R-dimensional vector of the measured concentrations. Let $\mathbf{N}$ and $\mathbf{c}$ be partitioned as: $\mathbf{N} = [\mathbf{N}_m \ \mathbf{N}_u]$ and $\mathbf{c} = [\mathbf{c}_m \ \mathbf{c}_u]^T$. If rank $(\mathbf{N}_m) = R$, $\mathbf{r}(\mathbf{y}; \mathbf{p}; \mathbf{c}_0) = 0$, and each reaction rate follows mass-action kinetics, then, the reaction system is globally identifiable. Alternatively, this result can be interpreted in the following manner. To guarantee parameter identifiability of uni-/bi-molecular reaction networks with mass-action kinetics, the minimum number of measurements for identifiability are R.

Proof In the interest of brevity, only an outline is presented. From Proposition 6, we have

$$\begin{aligned} \dot{x}_{r,i} &= r_i(\mathbf{x}_r, \boldsymbol{\theta}) \\ (\mathbf{N}_m^{-T})_i \dot{\mathbf{y}} &= \mathbf{r}(\mathbf{N}_m^{-T}(\mathbf{y} - \mathbf{c}_{m,0}), \boldsymbol{\theta}) \\ r_i &= k_{f,i} c_i^{\alpha_i} c_{R2,i}^{\beta_i} - k_{b,i} c_{P1,i}^{\gamma_i} c_{P2,i}^{\theta_i} \end{aligned} \tag{16}$$

We note that as all reactions are independent, k_{f_i} and k_{b_i} will only appear in the characteristic differential equation for the ith reaction. Hence, the identifiability of each set of k_{f_i} and k_{b_i} can be judged on the basis of whether or not the coefficients of the variables of a single equation in the characteristic set are alone globally identifiable or not. In the event all the species in a reaction are measured, we directly know that the coefficients are k_{f_i} and k_{b_i}, whose the Grobner basis will also simply be k_{f_i} and k_{b_i}, making them globally(uniquely) identifiable. A situation where all species in a reaction are unmeasured will not arise as this will violate our initial condition for measurement that rank$(\mathbf{N}_m)$=R. As the number of unmeasured species in any reaction in the network might vary, we still need to consider the following remaining cases:
(a) Three of the four species in a reaction are measured
(b) Two of the four species in a reaction are measured
(c) Only one species in a reaction is measured.
By analyzing each of these cases and following algebraic manipulations and simplifications, it is shown that the parameters in the ith reaction. Hence, the entire system is identifiable if R independent measurements are chosen. □

4. CONCLUSIONS

In this work, we showed that identifiability in reaction systems following mass action kinetics can be ascertained by examining the rank of a matrix thus obviating the need to determine the characteristic set using the differential algebraic methods. Furthermore, in order to guarantee parameter identifiability of uni-/bi-molecular reaction networks with mass-action kinetics, the minimum number of concentration measurements required for identifiability is R. This result can be used for designing experiments for kinetic model identification.

Abstract: We develop a new algorithm named TTRISK to solve high-dimensional risk-averse optimization problems governed by differential equations (ODEs and/or PDEs) under uncertainty. As an example, we focus on the so-called Conditional Value at Risk (CVaR), but the approach is equally applicable to other coherent risk measures. Both the full and reduced space formulations are considered. The algorithm is based on low rank tensor approximations of random fields discretized using stochastic collocation. To avoid non-smoothness of the objective function underpinning the CVaR, we propose an adaptive strategy to select the width parameter of the smoothed CVaR to balance the smoothing and tensor approximation errors. Moreover, unbiased Monte Carlo CVaR estimate can be computed by using the smoothed CVaR as a control variate. To accelerate the computations, we introduce an efficient preconditioner for the KKT system in the full space formulation.The numerical experiments demonstrate that the proposed method enables accurate CVaR optimization constrained by large-scale discretized systems. In particular, the first example consists of an elliptic PDE with random coefficients as constraints. The second example is motivated by a realistic application to devise a lockdown plan for United Kingdom under COVID-19. The results indicate that the risk-averse framework is feasible with the tensor approximations under tens of random variables.
This is an extended abstract for a talk based on https://arxiv.org/abs/2111.05180

Keywords: risk measures, tensor decompositions, function approximations, reduced space, preconditioning
MSC: 93E20, 65D15, 15A69

The control or design optimization problems constrained by stochastic systems must produce controls or optimal designs which are resilient to the uncertainty due to stochasticity. To tackle this, risk-averse optimization frameworks targeting engineering applications were created. This talk will introduce a new algorithm TTRISK which uses a Tensor Train (TT) decomposition to solve risk averse optimization problems constrained by differential equations (ODEs and/or PDEs).

Let $(\Omega, \mathcal{A}, \mathbb{P})$ be a complete probability space. Let U, Y be real reflexive Banach spaces, and let Z be a real Banach space. Here Y denotes the deterministic state space, U is the space of optimization variables (control or designs etc.) and Z is the differential equation residual space. Let $U_{ad} \subseteq U$ be a closed convex subset and let $c : Y \times U_{ad} \times \Omega \to Z$ denote, e.g., a PDE in a weak form, then consider the equality constraint

$$c(y, u; \omega) = 0, \quad \text{in } Z, \quad \text{a.a. } \omega \in \Omega$$

where a.a. indicates "almost all" with respect to a probability measure $\mathbb{P}$.

For practical computations we make the *finite dimensional noise assumption* on the equality constraint (Kouri and Surowiec (2016)). More precisely, the constraint $c(y, u; \omega) = 0$ is represented by a finite random vector $\xi : \Omega \to \Xi$, where $\Xi := \xi(\Omega) \subset \mathbb{R}^d$ with $d \in \mathbb{N}$. This allows us to redefine the probability space to (Ξ, Σ, ρ), where $\Sigma = \xi(\mathcal{A})$ is the σ-algebra of regions, and $\rho(\xi)$ is the continuous probability density function such that $\mathbb{E}[X] = \int_\Xi X(\xi)\rho(\xi)d\xi$. The random variable $X(\xi)$ can be considered as a function of the random vector $\xi = (\xi^{(1)}, \ldots, \xi^{(d)})$, belonging to the Hilbert space $\mathcal{F} = \{X(\xi) : \|X\| < \infty\}$, equipped with the inner product $\langle X, Y\rangle = \int_\Xi X(\xi)Y(\xi)\rho(\xi)d\xi$ and the Euclidean norm $\|X\| = \sqrt{\langle X, X\rangle}$.

Now we consider optimization problems of the form

$$\min_{u \in U_{ad}} \mathcal{R}[\mathcal{J}(y, u; \xi)] + \alpha\mathcal{P}(u) \tag{1}$$

SD is thankful for the support from Engineering and Physical Sciences Research Council (EPSRC) New Investigator Award EP/T031255/1 and New Horizons grant EP/V04771X/1.

subject to $c(y,u;\xi)=0$, where $u\in U_{ad}$ is the deterministic control and $y\in Y$ is the state, $\mathcal{P}$ is the cost of the control, $\alpha\geq 0$ is the regularization parameter, $\mathcal{J}$ is the uncertain variable objective function and $\mathcal{R}$ is the *risk-measure* functional which maps random variables to extended real numbers.

We assume that $\mathcal{R}$ is based on expectation, i.e.,

$$\mathcal{R}[X]=\inf_{t\in\mathcal{T}}\mathcal{R}_t[X],\quad \text{where}\quad \mathcal{R}_t[X]:=\mathbb{E}[f(X,t)],\quad (2)$$

$f:\mathbb{R}\times\mathbb{R}^N\to\mathbb{R}$ and $\mathcal{T}\subseteq\mathbb{R}^N$, with $N\in\mathbb{N}$, is a closed convex set. A typical example of a risk measure $\mathcal{R}$ is the conditional value-at-risk (CVaR_β), where f in (2) is given by

$$f(X,t)=t+(1-\beta)^{-1}(X-t)_+,\quad (3)$$

with $\mathcal{T}=\mathbb{R}$, $\beta\in(0,1)$ is the confidence level and $(x)_+=\max\{x,0\}$. CVaR_β is also known as expected shortfall. It's origin lies in financial mathematics (Rockafellar and Uryasev (2000)), but owing to Kouri and Surowiec (2016), it is now being widely used in engineering applications. Our work in particular, focuses on minimization problems (1) with $\mathcal{R}$ given by CVaR_β but it can be extended to other coherent risk measures, such as buffered probability of exceedence (BPOE), of type (2).

Notice that, since risk measures, such as CVaR_β, focus on the upper tail events, the traditional sampling techniques to solve these stochastic PDE-constrained optimization problems are often computationally expensive. More precisely, CVaR_β captures the cost associated with rare events, but it requires more samples in order to be accurately approximated, which leads to many differential equation solves. Moreover, the presence of the non-smooth function $(\cdot)_+$ in CVaR_β poses several challenges, including, nondifferentiable cost functional, wasted Monte Carlo samples outside of the support of $(\cdot)_+=\max\{\cdot,0\}$, or slowly converging polynomial and other function approximation methods.

To tackle nonsmoothness in CVaR_β, Kouri and Surowiec (2016) has proposed a smoothing of $(\cdot)_+$ which requires solving a sequence of smoothed optimization problems using Newton-based methods. The smoothing approach is aimed at approximating a non-differentiable function $(\cdot)_+$ in CVaR_β by a smooth function $g_\varepsilon:\mathbb{R}\to\mathbb{R}$, which depends on some $\varepsilon>0$. In particular, we consider the following C^∞-smoothing function

$$g_\varepsilon(x)=\varepsilon\log(1+\exp(x/\varepsilon)).\quad (4)$$

Thus, the optimization problem for smooth $\text{CVaR}_\beta^\varepsilon$ is given by

$$\begin{cases}\min\limits_{(u,t)\in U_{ad}\times\mathbb{R}}\mathcal{R}^\varepsilon_{t,\beta}[\mathcal{J}(y,u;\xi)]+\alpha\mathcal{P}(u)\\ \text{subject to}\\ c(y,u;\xi)=0,\quad \text{in } Z,\quad \text{a.a. } \xi\in\Xi,\end{cases}\quad (5)$$

where

$$\mathcal{R}^\varepsilon_{t,\beta}[\mathcal{J}(y,u;\xi)]:=t+\frac{1}{1-\beta}\mathbb{E}[g_\varepsilon(\mathcal{J}(y,u;\xi)-t)].\quad (6)$$

We consider two formulations of (5). The first one is the *reduced-space* approach where we remove the equality constraint $c(y,u;\omega)=0$ via a control to solution map $u\mapsto y$. The second case is the full space approach, where we directly tackle the full problem (5) using the Lagrangian formulation. The latter formulation appears to be new in the context of risk-averse optimization. Numerical experiments demonstrate that the full formulation converges more reliably for extreme parameters, e.g. large β and small α.

To introduce the reduced-space formulation, we assume that $c(y,u;\xi)=0$ is uniquely solvable, i.e., for each $u\in U_{ad}$ there exists a unique solution mapping $y(u;\cdot):\Xi\to Y$ for almost all $\xi\in\Xi$. Moreover, we can approximate the exact expectation in (6) by a quadrature with some N points, $\mathbb{E}_N[f]\approx\mathbb{E}[f]$. The resulting optimization problem (5) only depends on u and is given by

$$\min_{(u,t)\in\mathcal{U}_{ad}\times\mathbb{R}}\left\{\mathfrak{J}_N(u,t):=\mathcal{R}^\varepsilon_{t,\beta,N}[j(u;\xi)]+\alpha\mathcal{P}(u)\right\},\quad (7)$$

where $j(u;\xi):=\mathcal{J}(y(u;\xi),u;\xi)$, and

$$\mathcal{R}^\varepsilon_{t,\beta,N}[j(u;\xi)]:=t+\frac{1}{(1-\beta)}\mathbb{E}_N[g_\varepsilon(j(u;\xi)-t)].$$

Computing first and second derivatives of $\mathfrak{J}_N(u,t)$, which exist in the classical sense for $\varepsilon>0$, we can formulate the Newton method.

In the full-space formulation, we introduce a Lagrange multiplier $p\in Z^*$, and a Lagrangian

$$\begin{aligned}\mathcal{L}_N(y,u,p,t)=t+(1-\beta)^{-1}\mathbb{E}_N\left[g_\varepsilon(\mathcal{J}(y,u,\xi)-t)\right]\\ +\alpha\mathcal{P}(u)+\mathbb{E}_N\langle p,c(y,u,\xi)\rangle,\end{aligned}\quad (8)$$

which is again differentiable for $\varepsilon>0$, so we can find a KKT point using the Newton method.

The dimension d of the random vector ξ can be arbitrarily high. For instance, ξ may be a tuple of tens of model tuning parameters, or it can be a vector of coefficients of a Karhunen-Loeve (KL) approximation of an infinite-dimensional continuous random field. In this case expectations as in (6) become high-dimensional integrals. Instead of a direct Monte Carlo average (which may converge too slowly), we introduce a high-order quadrature rule (e.g. Gauss-Legendre) with $n_\xi\in\mathbb{N}$ points in each of the components $\xi^{(1)},\dots,\xi^{(d)}$ independently. For this, we assume that each $\xi^{(k)}$ has a probability density function $\rho^{(k)}(\xi^{(k)})$, and that the space of functions $f(\xi)\in\mathcal{F}$ is isomorphic to a Cartesian product of spaces of univariate functions, $\mathcal{F}=\mathcal{F}^{(1)}\otimes\cdots\otimes\mathcal{F}^{(d)}$, where $\mathcal{F}^{(k)}=\{f^{(k)}(\xi^{(k)}):\|f^{(k)}\|<\infty\}$, $\|f^{(k)}\|=\sqrt{\langle f^{(k)},f^{(k)}\rangle}$, $\langle f^{(k)},g^{(k)}\rangle=\int_{\mathbb{R}}f^{(k)}(\xi^{(k)})g^{(k)}(\xi^{(k)})\rho^{(k)}(\xi^{(k)})d\xi^{(k)}$, $k=1,\dots,d$. However, the exponential total number of quadrature points in all variables n_ξ^d becomes intractable even for moderate dimensions.

To tackle this curse of dimensionality, we build on tensor decomposition methods, which emerged in the past two decades (Hackbusch (2012)) as an efficient approximation of multi-index arrays, in particular when those contain expansion coefficients of high-dimensional functions (Gorodetsky et al. (2019)).

Definition. A square-integrable function $f(\xi)$ is said to be approximated by a *(functional) TT decomposition* (Gorodetsky et al. (2019)) with a relative approximation error ϵ if there exist univariate functions $F^{(k)}(\cdot):\xi^{(k)}\in\mathbb{R}\to\mathbb{R}^{r_{k-1}\times r_k}$, $k=1,\dots,d$, such that

$$\tilde{f}(\xi) := \sum_{s_0,\dots,s_d=1}^{r_0,\dots,r_d} F^{(1)}_{s_0,s_1}(\xi^{(1)}) F^{(2)}_{s_1,s_2}(\xi^{(2)}) \cdots F^{(d)}_{s_{d-1},s_d}(\xi^{(d)}), \tag{9}$$

where the subscripts s_{k-1}, s_k denote elements of a matrix, and $\|f - \tilde{f}\| = \epsilon \|f\|$. The factors $F^{(k)}$ are called *TT cores*, and their image dimensions $r_0, \dots, r_d \in \mathbb{N}$ are called *TT ranks*.

Without loss of generality we can let $r_0 = r_d = 1$, but the other TT ranks $r_1, \dots, r_{d-1}$ can vary depending on the approximation error. The simplest example is a bi-variate truncated Fourier series $\tilde{f}(\xi^{(1)}, \xi^{(2)}) = \sum_{s=-r}^{r} f_s(\xi^{(1)}) \exp(\mathrm{i} s \xi^{(2)})$.

From (9), we notice that the expectation of $\tilde{f}$ factorizes into univariate integrations,

$$\mathbb{E}_N[f] = \mathbb{E}[\tilde{f}] = \sum_{s_0,\dots,s_d=1}^{r_0,\dots,r_d} (\mathbb{E}F^{(1)}_{s_0,s_1})(\mathbb{E}F^{(2)}_{s_1,s_2}) \cdots (\mathbb{E}F^{(d)}_{s_{d-1},s_d}).$$

For practical computations with (9) we introduce univariate bases $\{\ell_i(\xi^{(k)})\}_{i=1}^{n_\xi}$, and the multivariate basis constructed from a Cartesian product,

$$L_{i_1,\dots,i_d}(\xi) := \ell_{i_1}(\xi^{(1)}) \cdots \ell_{i_d}(\xi^{(d)}).$$

Now we can collect the expansion coefficients of $\tilde{f}$ into a tensor $\mathbf{F} \in \mathbb{R}^{n_\xi \times \cdots \times n_\xi}$,

$$\tilde{f}(\xi) = \sum_{i_1,\dots,i_d=1}^{n_\xi} \mathbf{F}(i_1, \dots, i_d) L_{i_1,\dots,i_d}(\xi). \tag{10}$$

Similarly, TT cores in (9) can be written using three-dimensional tensors $\mathbf{F}^{(k)} \in \mathbb{R}^{r_{k-1} \times n_\xi \times r_k}$,

$$F^{(k)}_{s_{k-1},s_k}(\xi^{(k)}) = \sum_{i=1}^{n_\xi} \mathbf{F}^{(k)}(s_{k-1}, i, s_k) \ell_i(\xi^{(k)}), \tag{11}$$

$k = 1, \dots, d$. The original (discrete) TT decomposition (Oseledets and Tyrtyshnikov (2010)) was introduced to decompose a high-dimensional tensor like $\mathbf{F}$ into a product of smaller tensors like $\mathbf{F}^{(k)}$. Note that $\mathbf{F}$ contains n_ξ^d elements, whereas storing $\mathbf{F}^{(1)}, \dots, \mathbf{F}^{(d)}$ needs only $\sum_k r_{k-1} n_\xi r_k$ elements. For brevity we can define the maximal TT rank $r := \max_k r_k$, which gives us a linear storage complexity of the TT decomposition, $\mathcal{O}(d n_\xi r^2)$.

In practice, TT cores are computed by solving an approximation or optimization problem in an alternating direction-type iteration. For example, the *TT-Cross* method by Oseledets and Tyrtyshnikov (2010) can approximate potentially any function $\tilde{f}(\xi) \approx f(\xi)$, using $\mathcal{O}(d n_\xi r^2)$ samples from the function $f(\xi)$ and $\mathcal{O}(d n_\xi r^3)$ further floating point operations. Similarly, linear algebra on functions can be recast to linear algebra on their TT cores with a linear complexity in the dimension.

However, irregular functions, such as the $(\cdot)_+$ function in (3), may lack an efficient TT decomposition. This is another reason for switching to the smoothed CVaR formulation, since smooth functions do admit convergent TT approximation. Nevertheless, this convergence can still be slow, and for practically feasible smoothness parameters, the solution of the smoothed problem can be biased. To obtain an unbiased, asymptotically exact solution, we propose a version of Multilevel Monte Carlo methods (Giles (2015)), namely, we use a smoothed solution as a control variate.

The TTRISK algorithm is a combination of the Newton method for (7) or (8) with TT approximations (9) for the computation of expectations (with optional Monte Carlo correction), and an adaptive selection of ε which is driven to zero geometrically as the iteration converges.

The numerical experiments demonstrate that the stochastic risk-averse control problem can be solved with a cost that depends at most polynomially on the dimension. This allows us to solve realistic risk-averse PDE and ODE control problems with up to 20 random variables.

Abstract: Extended Dynamic Mode Decomposition, embedded in the Koopman framework, is a widely-applied technique to predict the evolution of an observable along the flow of a dynamical (control) system. However, despite its popularity, the error analysis for control systems is still fragmentary. Here, we provide a complete and rigorous analysis of the approximation error for control systems. To this end, the approximation error is split up according to its two sources of error: the finite dictionary size (projection) and the finite amount of i.i.d. data used to generate the surrogate model (estimation). Then, invoking—among others—finite-elements techniques and the Chebyshev inequality, probabilistic error bounds are derived. Finally, we demonstrate the applicability of the novel error bounds in optimal control with state and control constraints.

Keywords: data-based control, eDMD, error bound, finite-data, Koopman, state constraints

While optimal and predictive control based on models derived from first principles are nowadays well established, data-driven controller design is becoming increasingly popular. A particularly successful technique to construct data-driven surrogate models is based on the extended Dynamic Mode Decomposition (eDMD), see Mezić (2005); Rowley et al. (2009) and the recent survey Brunton et al. (2021). A key advantage is the potential embedding of eDMD in the Koopman framework (Koopman, 1931) such that it has a sound theretical foundation.

This extended abstract, which is mainly a summary of the major findings presented in full detail in Schaller et al. (2022), provides a complete error analysis for the bilinear surrogate models resulting for nonlinear control-affine systems. To this end, the (overall) approximation error is split up into its two sources, i.e., projection and estimation. The projection error results from using a dictionary $D(\mathcal{L})$ consisting of only finitely many entries—the so-called observables $\psi_1, \dots, \psi_N$. The estimation error results from only taking finitely many data points $x_1, \dots, x_m$ in account while constructing the surrogate model on the subspace $\mathbb{V} = \operatorname{span}\{\{\psi_j\}_{j=1}^N\}$. Here, the dictionary includes linear finite elements on a triangulation of the domain of interest. In conclusion and to the best of the authors' knowledge, this is the first rigorous *finite-data* error estimate for the eDMD-based prediction for nonlinear control systems taking into account both sources of errors, i.e., the projection *and* the estimation error.

1. BILINEAR SURROGATE MODEL

The Koopman framework provides the theoretical foundation for data-driven approximation techniques like eDMD, see (Mauroy et al., 2020, Chapters 1 and 8): Using the Koopman operator semi-group $(\mathcal{K}^t)_{t\geq 0}$ or—equivalently—the Koopman generator $\mathcal{L}$, so-called observables φ (real- or complex-valued L^2-functions of the state, e.g., representing a coordinate function, a state constraint or another quantity of interest) can be propagated forward in time via

$$\mathcal{K}^t\varphi = \mathcal{K}^0\varphi + \mathcal{L}\int_0^t \mathcal{K}^s\varphi \,\mathrm{d}s. \tag{1}$$

The propagated observable $\mathcal{K}^t\varphi$ can be evaluated for some state x_0 instead of first calculating the solution $x(t;x_0)$ of the underlying Ordinary Differential Equation (ODE) and then evaluating the observable as depicted in Figure 1.

The convergence of $(\tilde{\mathcal{K}}^t)_{t\geq 0}$, i.e., the eDMD-based surrogate model of an autonomous dynamical system, to the Koopman semi-group $(\mathcal{K}^t)_{t\geq 0}$ in the infinite-data limit, i.e., for N and m tending to infinity, was shown in Korda and Mezić (2018b). However, error estimates for the estimation step explicitly depending on the dictionary size N and the amount of data points m for the ODE case were only recently established in (Zhang and Zuazua, 2021) and (Nüske et al., 2021) assuming identically and independently distributed (i.i.d.) data. While the former reference

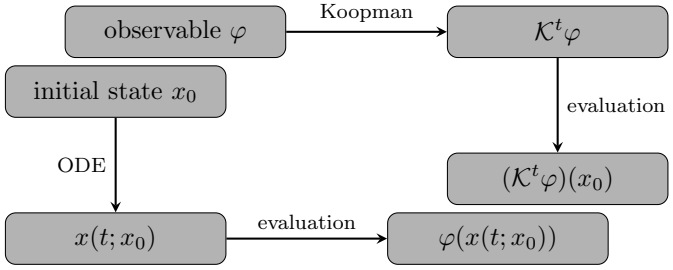

Fig. 1. Schematic sketch of the Koopman framework.

also covers the projection error in a rigorous manner, the latter one extends the analysis of the estimation error to stochastic differential equations and ergodic sampling.

We consider dynamics governed by the nonlinear control-affine differential equation

$$\dot{x}(t) = g_0(x(t)) + \sum_{i=1}^{n_c} g_i(x(t))u_i(t) \tag{2}$$

with initial condition $x(0) = x_0$ and locally Lipschitz-continuous vector fields $g_0, g_1, \ldots, g_{n_c} : \mathbb{R}^{n_x} \to \mathbb{R}^{n_x}$. Further, we impose the control constraints $u(t) \in \mathbb{U}$ for some compact, convex, and nonempty set $\mathbb{U} \subset \mathbb{R}^{n_c}$ and define the set of admissible control functions by

$$\mathcal{U}_T(x_0) \triangleq \left\{ u : [0,T] \to \mathbb{R}^{n_c} \;\middle|\; \begin{array}{l} u \text{ measurable} \\ \exists!\, x(\,\cdot\,;x_0,u) \\ u(t) \in \mathbb{U}, t \in [0,T] \end{array} \right\}, \tag{3}$$

where $x(t;x_0,u)$ denotes the unique solution at time $t \geq 0$. In the following, we assume that $\mathcal{U}_T(x_0)$ is nonempty whenever the set of initial values $\mathbb{X} \subset \mathbb{R}^{n_x}$ is suitably chosen.

In order to predict control systems by means of the Koopman framework, Proctor et al. (2016) as well as Korda and Mezić (2018a) proposed to augment the state by the control variable and, then, to generate a linear surrogate model depending on the extended state by using eDMD, see (Mauroy et al., 2020, Chapter 1) for details. In this work, however, we use the bilinear approach, exploiting the control-affine structure of (2) as suggested, e.g., in Williams et al. (2016); Surana (2016), see also (Mauroy et al., 2020, Section 4), for which estimation error bounds were first derived in Nüske et al. (2021). The advantages of this approach are twofold. First, one can observe a superior performance when considering bilinear systems where the control is coupled to the state. Second, as the state dimension is not augmented, the data-requirements are less demanding.

We briefly describe the bilinear approach for surrogate modeling of control systems. In this case, for a given control $u \in L^\infty(0,T;\mathbb{U})$, the generator inherits the control-affine structure, i.e.,

$$\mathcal{L}^u(t) = \mathcal{L}^0 + \sum_{i=1}^{n_c} u_i(t)\left(\mathcal{L}^{e_i} - \mathcal{L}^0\right), \tag{4}$$

with $\mathcal{L}^{e_i}$, $i = 0, \ldots, n_c$, being the Koopman generator for the autonomous system with constant control $\bar{u} = e_i$, where $e_0 := 0$ and e_j denotes the j-th standard basis vector, see, e.g., Peitz et al. (2020). Thus, the time evolution of an observable function $\varphi \in L^2(\mathbb{X})$ along the flow of the control system (2) can be predicted via the bilinear system

$$\dot{z}(t;u) = \mathcal{L}^u(t)z(t;u), \qquad z(0;u) = \varphi. \tag{5}$$

This propagated observable function can, then, be evaluated for an initial state $x_0 \in \mathbb{X}$ to evaluate the observable along a particular trajectory, i.e.,

$$z(t;u)(x_0) = \varphi(x(t;x_0,u)),$$

cf. Figure 1 for an illustration.

Each of the individual generators $\mathcal{L}^{e_i}$, $i \in \{0, \ldots, n_c\}$ can be approximated by means of eDMD. The orthogonal projection onto $\mathbb{V}$ and the Galerkin projection of the Koopman generator are denoted by $P_\mathbb{V}$ and $\mathcal{L}^{e_i}_\mathbb{V} := P_\mathbb{V}\mathcal{L}^{e_i}_{|\mathbb{V}}$, respectively. Along the lines of Klus et al. (2020), we have the representation $\mathcal{L}^{e_i}_\mathbb{V} = C^{-1}A$ with $C, A \in \mathbb{R}^{N\times N}$ given by

$$C_{i,j} = \langle \psi_i, \psi_j \rangle_{L^2(\mathbb{X})} \quad \text{and} \quad A_{i,j} = \langle \psi_i, \mathcal{L}^{e_i}\psi_j \rangle_{L^2(\mathbb{X})}.$$

Consider i.i.d. data points $x_1, \ldots, x_m \in \mathbb{X}$ and the matrices

$$\Psi(X) := \left(\begin{pmatrix} \psi_1(x_1) \\ \vdots \\ \psi_N(x_1) \end{pmatrix} \middle| \ldots \middle| \begin{pmatrix} \psi_1(x_m) \\ \vdots \\ \psi_N(x_m) \end{pmatrix} \right)$$

$$\mathcal{L}^{e_i}\Psi(X) := \left(\begin{pmatrix} (\mathcal{L}^{e_i}\psi_1)(x_1) \\ \vdots \\ (\mathcal{L}^{e_i}\psi_N)(x_1) \end{pmatrix} \middle| \ldots \middle| \begin{pmatrix} (\mathcal{L}^{e_i}\psi_1)(x_m) \\ \vdots \\ (\mathcal{L}^{e_i}\psi_N)(x_m) \end{pmatrix} \right).$$

Then, defining $\tilde{C}_m, \tilde{A}_m \in \mathbb{R}^{N\times N}$ by

$$\tilde{C}_m = \tfrac{1}{m}\Psi(X)\Psi(X)^\top \quad \text{and} \quad \tilde{A}_m = \tfrac{1}{m}\Psi(X)\mathcal{L}^{e_i}\Psi(X)^\top,$$

an empirical, i.e., purely data-based estimator for the Galerkin projection $\mathcal{L}_\mathbb{V}$ is given by $\tilde{\mathcal{L}}_m = \tilde{C}_m^{-1}\tilde{A}_m$. Hence, the projection of (4) onto the finite dictionary $\mathbb{V}$ is given by

$$\mathcal{L}^u_\mathbb{V}(t) := \mathcal{L}^0_\mathbb{V} + \sum_{i=1}^{n_c} u_i(t)\big(\mathcal{L}^{e_i}_\mathbb{V} - \mathcal{L}^0_\mathbb{V}\big). \tag{6}$$

In conclusion, the propagation of observable functions $\varphi \in L^2(\mathbb{X})$ projected onto the dictionary $\mathbb{V}$ is given by

$$\dot{z}_\mathbb{V}(t;u) = \mathcal{L}^u_\mathbb{V}(t)z_\mathbb{V}(t;u), \qquad z(0;u) = \mathbb{P}_\mathbb{V}\varphi. \tag{7}$$

The corresponding approximation by means of eDMD using m data points is defined analogously via

$$\tilde{\mathcal{L}}^u_m(t) := \tilde{\mathcal{L}}^0_m + \sum_{i=1}^{n_c} u_i(t)\big(\tilde{\mathcal{L}}^{e_i}_m - \tilde{\mathcal{L}}^0_m\big), \tag{8}$$

where for $i = 1, \ldots, n_c$, $\tilde{\mathcal{L}}^{e_i}_m$ are eDMD-based approximations of $\mathcal{L}^{e_i}_\mathbb{V}$. The corresponding data-based surrogate prediction dynamics read

$$\dot{\tilde{z}}_m(t;u) = \tilde{\mathcal{L}}^u_m(t)\tilde{z}_m(t;u) \qquad \tilde{z}_m(0;u) = \mathbb{P}_\mathbb{V}\varphi. \tag{9}$$

2. UNIFORM FINITE-DATA ERROR BOUND

In this section, we present error bounds when using a dictionary $\mathbb{V}$ consisting of finite elements, i.e., $\psi_i, i = 1, \ldots, N$, are the usual piecewise linear hat functions defined on a regular uniform triangulation of the compact set $\mathbb{X}$ with meshsize $\Delta x > 0$ (e.g., the maximal incircle diameter of the cells) and nodes $\hat{x}_j \subset \mathbb{X}$, $j = 1, \ldots, N$ such that for $i, j \in \{1, \ldots, N\}$, $\psi_i(\hat{x}_j) = 1$ if $i = j$ and zero otherwise.

We now state the main theorem considering the approximation error.

Theorem 1. Let a probabilistic tolerance $\varepsilon > 0$ and confidence level $1 - \delta \in (0,1)$ be given. Then, for an observable $\varphi \in \mathcal{C}^2(\mathbb{X},\mathbb{R})$, $\mathbb{X} \subset \mathbb{R}^n$ compact and time $T > 0$, there exist

constants c_{dict}, c_{data} such that the probabilistic bound on the approximation error

$$\mathbb{P}\left(\|\varphi(x(t;x_0,u)) - \tilde{z}_m(t;u)(x_0)\| \leq \varepsilon\right) \geq 1-\delta$$

holds for all $x_0 \in \mathbb{X}$, $u \in \mathcal{U}_T(x_0)$ and all $t \in [0,T]$ provided that $\{x(t;x_0,u) : t \in [0,T]\} \subset \mathbb{X}$ for the bilinear surrogate model (9) if the mesh size Δx of the finite-elements observables and the number of i.i.d. data points satisfy the data-requirement conditions

$$\Delta x \leq c_{\text{dict}}\varepsilon, \qquad m \geq c_{\text{data}} \frac{1}{\varepsilon^2 \delta} \left(\tfrac{1}{\Delta x^d}\right)^2 \tag{10}$$

Sketch of the proof. The proof follows the same argumentation as (Schaller et al., 2022, Proof of Theorem 5). The main idea is sketched in Figure 2: One first fixes a (small enough) finite element mesh size Δx, and hence the dictionary, such that the projection error is small enough. This can be done using standard finite element estimates. Then, having fixed the dictionary size, using the Chebyshev inequality, one chooses a (high enough) number of data points such that also the estimation error on this dictionary is small enough. Due to the randomness in the data points, this can only be obtained with a given desired confidence, leading to the probabilistic estimate in the statement.

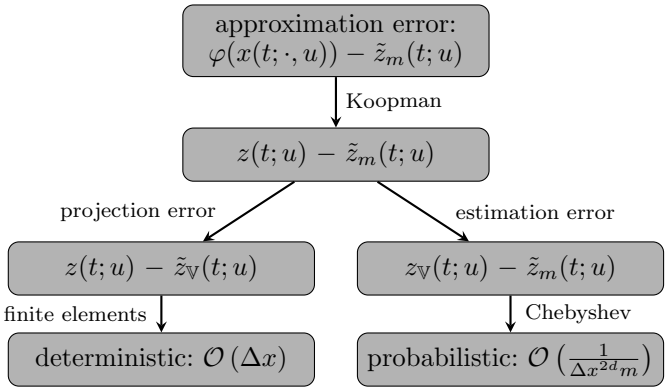

Fig. 2. Splitting of full error into projection and estimation error.

3. UNIFORM ERROR BOUNDS IN OPTIMAL CONTROL

We consider the Optimal Control Problem

$$\text{Minimize}_{u \in \mathcal{U}_T(x_0)} \int_0^T \ell(x(t;x_0,u)) + \|u(t)\|_2^2 \,\mathrm{d}t \quad \text{(OCP)}$$

subject to the initial condition $x(0) = x_0$, the control affine system dynamics (2), and the state constraints

$$h_j(x(t;x_0,u)) \leq 0 \qquad \forall\, j \in \{1,2,\dots,p\}. \tag{11}$$

The key challenge is to properly predict the performance index of (OCP) and satisfaction of the state constraints (11). Both quantities are evaluated along the state dynamcis (2), i.e., the stage cost ℓ and the constraint functions h_j, $j = 1,2,\dots,p$. Instead of propagating the state dynamics and then evaluating these *observables*, we employ the derived eDMD-based surrogate model to obtain the equality

$$(\mathcal{K}_u^t \varphi)(x_0) = \varphi(x(t;x_0,u)) \qquad \forall\, t \in [0,T] \tag{12}$$

for the observables $\varphi = h_j$, $j \in \{1,\dots,p\}$, and $\varphi = \ell$. Then, suitably applying Theorem 1 yields the error bounds, see (Schaller et al., 2022, Proposition 7).

Proposition 2. Suppose that ℓ, $h_i \in C^2(\mathbb{X},\mathbb{R})$, $i \in \{1,2,\dots,p\}$, hold. Then, for every probabilistic tolerance $\varepsilon > 0$ and every confidence level $1-\delta \in (0,1)$, every initial value $x_0 \in \mathbb{X}$ such that $x(t;x_0,u) \in \mathbb{X}$ for the solution of (2) contained in $\mathbb{X}$,

1) the probabilistic *performance bound*
$$\mathbb{P}\left(\|\ell(x(t;x_0,u)) - \tilde{\ell}_m(t;x_0,u)\| \leq \varepsilon\right) \geq 1-\delta$$
2) and the probabilistic state-constraint satisfaction, i.e.,
$$\mathbb{P}(h_i(x(t,x_0;u)) \leq 0) \geq 1-\delta,$$
is satisfied provided that $\tilde{h}_{i,m}(t;x_0,u) \leq -\varepsilon$ holds,

where $\tilde{\ell}_{1,m}$, $\tilde{h}_{i,m}$, $i \in \{1,2,\dots,p\}$, are predicted along the bilinear surrogate dynamics (9) with initial states $\tilde{\ell}_{1,m}(0;x_0,u) = P_{\mathbb{V}}\ell_1$, $\tilde{h}_{i,m}(0;x_0,u) = P_{\mathbb{V}}h_i$ if the requirements (10) for dictionary and data are met.

The result of Proposition 2 is two-fold. The first statement 1) yields a bound on the stage cost. This can be utilized to estimate the degree of suboptimality of the surrogate OCP's optimal control in view of the original problem. The second statement 2) allows us to deduce a chance constraint satisfaction of the original problem, provided we satisfy tightened constraints along the surrogate model.

4. SUMMARY AND OUTLOOK

We provided a complete and an rigorous analysis of the approximation error for eDMD-based prediction of control systems in the Koopman framework. To this end, we split the error into its two sources of error, a projection error vanishing in the dictionary size and an estimation error decreasing in the number of data points. Last, we applied the error bound to particular observables in optimal control, namely the stage cost and the constraint functions, to derive probabilistic error bounds on the performance index and the satisfaction of state constraints.

In future work, we want to apply the derived results, cf. Proposition 2, within data-driven predictive control. In particular, we aim at showing recursive feasibility and deriving suboptimality estimates in data-based predictive control.

Abstract: In this extended abstract we show, on the one dimensional (1D) heat equation example, how Boundary Controlled Irreversible Port Hamiltonian Systems (BC-IPHS) formulations and systems thermodynamic fundamental properties can be used for control design purposes.

Keywords: Irreversible port Hamiltonian systems, Boundary control systems, Heat equation.

1. INTRODUCTION

Boundary controlled port Hamiltonian formulations [4, 2] have shown to be very useful for the analysis and control of distributed parameter systems described by skew symmetric differential operators. For this class of systems, an efficient control design technique has been established using control by interconnection, structural invariants and energy shaping [5]. These formulations have been recently extended to irreversible systems [6], *i.e.* systems for which the thermal domain plays a central role, as it is the case for the heat equation or for reaction-diffusion systems. Boundary Controlled Irreversible Port Hamiltonian Systems (BC-IPHS) formulations allow to encompass the two laws of Thermodynamics, conservation of the total energy and irreversible entropy creation. In this extended abstract we show on the one dimensional (1D) heat equation example how these fundamental properties can be used for control design purpose.

2. BOUNDARY CONTROLLED IPHS FORMULATION OF THE HEAT EQUATION:

Alternatively to the classical formulation of the heat equation defined on a one dimensional spatial domain, with $\zeta \in [0, L]$,

$$c_v \partial_t T = \partial_\zeta \left(k \partial_\zeta T \right), \tag{1}$$

where $T = T(\zeta, t)$ is the temperature, c_v the heat capacitance of the medium and k the heat conduction coefficient, one can use the entropy density $s = s(\zeta, t)$ as state variable. Using the expression of the entropy flux $q_s = \frac{q}{T}$ with $q = -k\partial_\zeta T$ and Gibbs relation $du = Tds$, (1) can be written

$$\partial_t s = -\partial_\zeta q_s - \left(\frac{q_s}{T} \right) \partial_\zeta T, \tag{2}$$

that leads after integration by parts, according to [6], to the BC-IPHS

$$\begin{aligned} \partial_t s =& r_s \partial_\zeta e_s + \partial_\zeta \left(r_s e_s \right) \\ \mathbf{u} =& W_B e_s = \begin{bmatrix} -q_s|_L \\ -q_s|_0 \end{bmatrix}, \\ \mathbf{y} =& W_C e_s = \begin{bmatrix} T|_L \\ -T|_0 \end{bmatrix} \end{aligned} \tag{3}$$

with [1] $r_s = \gamma_s \{\mathcal{S}|\mathcal{H}\}$, $\gamma_s = \frac{k}{T^2}$, $e_s = \delta_s \mathcal{H} = T$ and

$$W_B = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \qquad W_C = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

The total energy and total entropy are given by $\mathcal{H} = \int_0^L u(\zeta, t) \mathrm{d}\zeta$ and $\mathcal{S} = \int_0^L s(\zeta, t) \mathrm{d}\zeta$ respectively, such that $\delta_s \mathcal{H} = \partial_s u = T$ and $\delta_s \mathcal{S} = 1$. The BC-IPHS (3) expresses explicitly the first and second laws of Thermodynamics. Indeed, the term $r_s \partial_\zeta e_s = \gamma_s \{\mathcal{S}|\mathcal{H}\}^2 \geq 0$ describes the density of entropy produced by the heat flux and the term $\partial_\zeta \left(r_s e_s \right) = -\partial_\zeta q_s$ describes the entropy diffusion, so the total entropy and total energy balance are

$$\dot{\mathcal{S}} = \int_0^L \partial_t s \mathrm{d}\zeta = \underbrace{\int_0^L \gamma_s \{\mathcal{S}|\mathcal{H}\}^2 \mathrm{d}\zeta}_{\geq 0} + [1 \ -1] \, \mathbf{u} \tag{4}$$

and

$$\begin{aligned} \dot{\mathcal{H}} &= \int_0^L e_s \partial_t s \mathrm{d}\zeta = \int_0^L \left(e_s r_s \partial_\zeta \left(e_s \right) + \delta_s \mathcal{H} \partial_\zeta \left(r_s e_s \right) \right) \mathrm{d}\zeta \\ &= \left(e_s r_s e_s \right)|_0^L = \mathbf{y}^\top \mathbf{u} \end{aligned} \tag{5}$$

[1] Defining the pseudo bracket

$$\{\mathcal{Z}|\mathcal{W}\} = \delta_s \mathcal{Z} \partial_\zeta \left(\delta_s \mathcal{W} \right)$$

for some smooth functionals $\mathcal{Z}$ and $\mathcal{W}$.

which shows that the BC-IPHS (3) is conservative and satisfies the first and second laws of Thermodynamics. From the isotropic assumption (*i.e.* k constant) the heat equation admits as equilibrium profiles [3] $T^* \in \mathcal{T}^*$ where

$$\mathcal{T}^* = \{T = m\zeta + b, \zeta \in [0, L], (m, b) \in \mathbb{R}\}$$

is the space of temperature equilibrium profiles satisfying $\partial_\zeta (k\partial_\zeta T^*) = 0$.

3. BOUNDARY CONTROL BY INTERCONNECTION

In this section we consider control by interconnection, *i.e.* the system is interconnected at the boundary of its spatial domain to a dynamic controller in a power preserving way as in Figure 1.

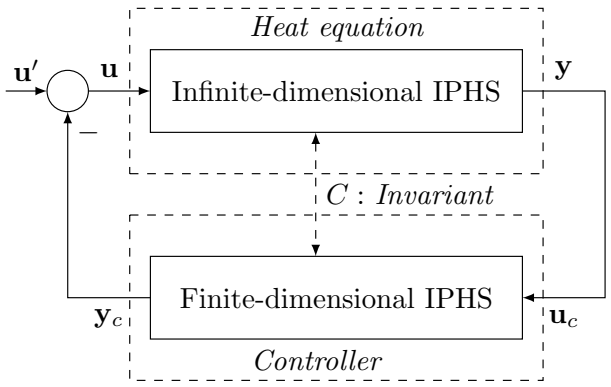

Fig. 1. CbI of the heat equation

Inspired by the classical *Control by Interconnection* method the dynamic controller is looked for under the non linear formulation

$$\dot{x}_c = G_c(x_c, \mathbf{u}_c)\mathbf{u}_c, \qquad \mathbf{y}_c = G_c^\top(x_c, \mathbf{u}_c)e_c, \tag{6}$$

where $e_c = \partial_{x_c} H_c$ and H_c a smooth function of x_c. This interconnection leads to the coupled PDE-ODE system

$$\begin{aligned} \underbrace{\begin{bmatrix} \partial_t s \\ \dot{x}_c \end{bmatrix}}_{\dot{\mathbf{x}}_{cl}} &= \underbrace{\begin{bmatrix} r_s\partial_\zeta(\cdot) + \partial_\zeta(r_s\cdot) & 0 \\ G_c(x_c, \mathbf{u}_c)W_C & 0 \end{bmatrix}}_{\mathcal{J}_{cl}} \underbrace{\begin{bmatrix} e_s \\ e_c \end{bmatrix}}_{\mathbf{e}_{cl}} \\ \mathbf{u}' &= \underbrace{\begin{bmatrix} W_B & G_c^\top(x_c, \mathbf{u}_c) \end{bmatrix}}_{W_{B_{cl}}} \mathbf{e}_{cl} \end{aligned} \tag{7}$$

where $\mathbf{e}_{cl} \in \mathcal{E}_{cl}$ denotes the vector of co-states of the closed-loop system.

Definition 1. [7, 5] Consider the boundary control system of Figure 1 with $\mathbf{u}' = 0$. A function $C : L^2([0, L], \mathbb{R}) \times \mathbb{R} \to \mathbb{R}$ is a system's invariant if $\dot{C} = 0$ along the closed loop trajectories. C is a structural invariant if $\dot{C} = 0$ along the closed loop trajectories for any $\mathbf{e}_{cl}$.

In this study we consider the following assumption.

Assumption 1. The function $C(s, x_c)$ is of the form

$$C(s, x_c) = \Gamma x_c + \int_0^L f(s(\zeta))\mathrm{d}\zeta = \kappa \tag{8}$$

where κ is a constant and $f(s) \in H^1([0, L], \mathbb{R})$ is a continuous function.

Proposition 1. Consider the BC system of Figure 1 with $\mathbf{u}' = 0$. Then (8) is a closed loop invariant if

$$\langle \mathcal{J}_{cl}\boldsymbol{\epsilon}, \mathbf{e}_{cl} \rangle = 0 \tag{9}$$

$$\begin{bmatrix} W_B & G_c^\top(x_c, \mathbf{u}_c) \end{bmatrix} \boldsymbol{\epsilon} = 0 \tag{10}$$

where

$$\boldsymbol{\epsilon} = \begin{bmatrix} \epsilon_s \\ \epsilon_c \end{bmatrix} = \begin{bmatrix} \delta_s C \\ \partial_{x_c} C \end{bmatrix} = \begin{bmatrix} \partial_s f(s) \\ \Gamma \end{bmatrix} \tag{11}$$

In the case of the heat equation Proposition 1 leads to Proposition 2.

Proposition 2. The function C satisfies Proposition 1 if $f(s) = \alpha u(s) + c_1$ where c_1 is a function that does not depend on s. The state of the control system (6) is then given by the state feedback

$$x_c = -\frac{\alpha}{\Gamma}\int_0^L u(s)\mathrm{d}\zeta + \bar{k}/\Gamma = -\frac{\alpha}{\Gamma}\mathcal{H}(s) + \bar{k}/\Gamma \tag{12}$$

with $\bar{k} = \left(k + \int_0^L c_1 \mathrm{d}\zeta\right)$ and the controller energy function is

$$H_c = \frac{\Gamma}{\alpha}x_c + k_c = -\mathcal{H}(s) + k' \tag{13}$$

where $k' = \frac{\bar{k}}{\alpha} + k_c$, with k_c a constant. In accordance with the first principle of Thermodynamics the closed loop energy function is then constant and equal to k'.

4. ENTROPY ASSIGNMENT

In the previous section we have shown that control by interconnection with a dynamic controller of the form (6) with x_c satisfying (12) allows to preserve the closed loop energy function satisfying the first principle of Thermodynamics. In the case of the heat equation, the only physical domain that is considered is the thermal domain. In this case the internal energy is then preserved and one can use the irreversible entropy creation for control design, leading to Proposition 3.

Proposition 3. The boundary controller (6) with

$$G_c^\top = \frac{\alpha}{\Gamma}\left(\begin{bmatrix} -\frac{km^*}{T|_L} \\ -\frac{km^*}{T|_0} \end{bmatrix} + \frac{1}{c_v}\Phi(x_c)\begin{bmatrix} T(T - T^*)|_L \\ -T(T - T^*)|_0 \end{bmatrix}\right) \tag{14}$$

where $\Phi(x_c) = \Phi(x_c)^\top \geq 0$, exponentially stabilizes (3) to the desired equilibrium profile T^*.

In Proposition 3 a classical Lyapunov function of the form

$$\mathcal{V}(T, T^*) = \int_0^L \frac{1}{2}(T - T^*)^2 \mathrm{d}\zeta. \tag{15}$$

is used to design the dynamic controller (6). One can show that

$$\dot{\mathcal{V}} = -(\sigma + \mathbf{y}^\top \Xi\Phi\Xi^\top \mathbf{y}) < 0, \tag{16}$$

with $\Xi = \frac{1}{c_v}\begin{bmatrix} (T - T^*)|_L & 0 \\ 0 & (T - T^*)|_0 \end{bmatrix}$, $\Phi > 0$, $\forall T \neq T^*$ and $\dot{\mathcal{V}} = 0$ when $T = T^*$. The choice of Φ allows to shape the irreversible entropy creation in the direction of the desired equilibrium.

5. SIMULATIONS

We consider a copper bar of length $L = 0.1m$ and cross-sectional area of $10^{-4}\mathrm{m}^2$. Copper material properties can be found in [1]. We choose the following constitutive relation for the temperature $T(\zeta, t) = C_0 e^{s(\zeta,t)/c_v}$, where

C_0 is a constant such that the initial temperature profile is

$$T_0 = T(\zeta, 0) = 303.15°\text{K}, \quad \forall \zeta \in [0, 0.1]$$

Similarly, the desired temperature equilibrium profile is defined by the slope $m^* = 150°\text{K/m}$ and bias $b^* = 313.15°\text{K}$, i.e.,

$$T^* = 150\zeta + 313.15, \quad \zeta \in [0, 0.1]$$

We choose $\Phi(x_c)$ in Proposition 3 as

$$\Phi(x_c) = c_v \begin{bmatrix} \frac{a|x_c|+\phi^*}{T^2|_L} & 0 \\ 0 & \frac{a|x_c|+\phi^*}{T^2|_0} \end{bmatrix} > 0 \tag{17}$$

where $a > 0$ and $\phi^* > 0$ are constant, leading to the following control law

$$\mathbf{u} = -\frac{\Gamma}{\alpha} G_c^\top(x_c) = \begin{bmatrix} \frac{km^*}{T|_L} - \frac{T-T^*}{T}\Big|_L (a|x_c| + \phi^*) \\ \frac{km^*}{T|_0} + \frac{T-T^*}{T}\Big|_0 (a|x_c| + \phi^*) \end{bmatrix} \tag{18}$$

or equivalently by using (12) with $\alpha = -1$, $\Gamma = 1$ and $\bar{k} = -\mathcal{H}_0$

$$\mathbf{u} = \begin{bmatrix} \frac{km^*}{T|_L} - \frac{T-T^*}{T}\Big|_L \left(a \left|\int_0^L (u(\zeta,t) - u_0)\mathrm{d}\zeta\right| + \phi^*\right) \\ \frac{km^*}{T|_0} + \frac{T-T^*}{T}\Big|_0 \left(a \left|\int_0^L (u(\zeta,t) - u_0)\mathrm{d}\zeta\right| + \phi^*\right) \end{bmatrix} \tag{19}$$

The closed loop performances are shown in Figure 2 and Figure 3.

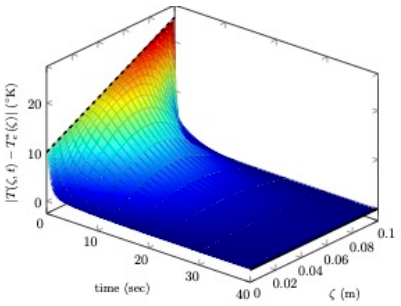

Fig. 2. Response with $\phi^* = 2$ and $a = 0.3$. Left: Absolute error $|T - T^*|$.

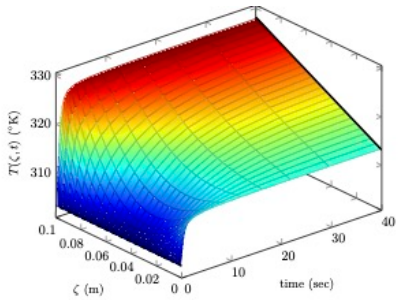

Fig. 3. Response with $\phi^* = 2$ and $a = 0.3$. Temperature trajectories.

We can see that using (19) the closed loop system is exponentially stable and reaches the desired equilibrium profile. The controller parameters can be used to modify the closed loop performances.

6. CONCLUSION

In this extended abstract we have shown how BC-IPHS formulations can be used for control design in the case of the heat equation. The main advantage of using such formulation is the physical interpretation of the closed loop system, and the design of an appropriate Lyapunov function for control design. Even if the considered case is rather simple as it corresponds to a fully actuated heat equation, it paves the way to more complex scenarios where the control is applied to only one boundary, the other being subject to a reflective condition, or unstable heat equation with distributed source terms. It should also allow to derive alternative Lyapunov functions leading to other control design with lower control efforts.

On the Computational Complexity of the Moment-SOS Hierarchy for Polynomial Optimization

Sander Gribling * **Sven Polak** ** **Lucas Slot** **

* *Université de Paris, CNRS, IRIF, F-75013, Paris, France*
** *Centrum Wiskunde & Informatica (CWI). Amsterdam, The Netherlands*

Abstract: The moment-sum-of-squares (moment-sos) hierarchy is one of the most celebrated and widely applied methods for approximating the minimum of an n-variate polynomial over a feasible region defined by polynomial (in)equalities. A key feature of the hierarchy is that it can be formulated as a semidefinite program of size polynomial in the number of variables n. Although this suggests that it may therefore be computed in polynomial time, this is not necessarily the case. Indeed, as O'Donnell [9] and later Raghavendra & Weitz [12] show, there exist examples where the sos-representations used in the hierarchy have exponential bit-complexity. We study the computational complexity of the sos-hierarchy, complementing and expanding upon earlier work of Raghavendra & Weitz [12]. In particular, we establish algebraic and geometric conditions under which polynomial-time computation is possible. As this work is still ongoing, our results should be treated as preliminary.

Keywords: polynomial optimization; sum-of-squares hierarchy; computational complexity.

1. INTRODUCTION

Consider the polynomial optimization problem:

$$\begin{aligned} f_{\min} := \min\ & f(\mathbf{x}) \\ \text{s.t. } & g_i(\mathbf{x}) \geq 0 \quad (1 \leq i \leq m), \\ & h_j(\mathbf{x}) = 0 \quad (1 \leq j \leq \ell), \\ & \mathbf{x} \in \mathbb{R}^n, \end{aligned} \tag{POP}$$

where $f, g_i, h_j \in \mathbb{R}[\mathbf{x}]$ are given n-variate polynomials. The feasible region of (POP) is a basic *semialgebraic* set, which we denote by:

$$S(\mathbf{g}, \mathbf{h}) := \{\mathbf{x} \in \mathbb{R}^n : g_i(\mathbf{x}) \geq 0,\ h_j(\mathbf{x}) = 0\}.$$

Problems of the form (POP) are generally hard and non-convex. They naturally capture several classical combinatorial problems, and have applications in finance, energy optimization, machine learning, optimal control and quantum computing. As they are often intractable, several techniques have been proposed to approximate them. Perhaps the most well-known and studied among these techniques is the so-called *moment-sum-of-squares (moment-sos) hierarchy*, due to Lasserre [5] and Parillo [10]. The main idea behind the hierarchy is that one can certify the nonnegativity of a polynomial $p \in \mathbb{R}[\mathbf{x}]$ on $S(\mathbf{g}, \mathbf{h})$ by representing it as a *weighted sum of squares*:

$$p(\mathbf{x}) = \sum_{i=0}^{m} g_i(\mathbf{x})\sigma_i(\mathbf{x}) + \sum_{j=1}^{\ell} h_j(\mathbf{x})p_j(\mathbf{x}), \tag{1}$$

where $\sigma_i \in \Sigma[\mathbf{x}]$ are sums of squares, $p_j \in \mathbb{R}[\mathbf{x}]$ and we set $g_0(\mathbf{x}) = 1$ for convenience. We say that a representation (1) is of degree t if $\deg(g_i\sigma_i) \leq t$ and $\deg(h_jp_j) \leq t$ for all i, j. For $t \in \mathbb{N}$, one then obtains a lower bound $\mathrm{sos}(f)_t \leq f_{\min}$ on the minimum of f by:

$$\mathrm{sos}(f)_t := \sup_{\lambda \in \mathbb{R}} \left\{ \lambda : \begin{array}{l} f - \lambda \text{ has a represen-} \\ \text{tation (1) of degree } 2t \end{array} \right\}. \tag{SOS}$$

Under a minor assumption on $S(\mathbf{g}, \mathbf{h})$ (see Definition 1 below), the bounds $\mathrm{sos}(f)_t$ converge to $f_{\min}$ as $t \to \infty$. The *rate* of this convergence has been the subject of some study, see, e.g., [1], [6], [7], [8], [13], [14].

For fixed level t, the lower bound $\mathrm{sos}(f)_t$ may be computed by solving a semidefinite program (SDP) involving matrices of size polynomial in n. It is often claimed that one may therefore (approximately) compute $\mathrm{sos}(f)_t$ in polynomial time, for instance by applying the ellipsoid algorithm. As was noted by O'Donnell [9] and later by Raghavendra & Weitz [12], this is not necessarily the case. Indeed, polynomial runtime of the ellipsoid algorithm is only guaranteed when the feasible region of the SDP contains an *inner ball* which is not too small, and is contained in an *outer ball* which is not too large. Informally, this means that it is possible to choose the coefficients of the multipliers σ_i, p_j in the representation (1) so that their *bit-complexity* is polynomial in n. We call such a representation *compact*.

We will consider below sets $S(\mathbf{g}, \mathbf{h})$ with the following minor algebraic boundedness condition. It is slightly stronger than the usual *Archimedean condition*, but it is more convenient to work with for our purposes.

Definition 1. We say that (POP) is *explicitly bounded* if there exists a constant $R > 0$ such that:

$$g_1(\mathbf{x}) = R - \|\mathbf{x}\|_2^2.$$

Roughly speaking, if we accept small additive errors in the solution, the condition above guarantees the existence of the inner ball (see [12]).

The remaining question, then, is whether an outer ball always exists. O'Donnell [9] shows that in fact, it does not; he constructs an example where every representation (1) of $f(\mathbf{x}) - \mathrm{sos}(f)_2$ necessarily involves multipliers σ_i, h_j whose coefficients are doubly-exponentially large in n. Raghavendra & Weitz [12] subsequently show that it is possible to construct such an example even when the equalities $\mathbf{h}$ include the boolean constraints $\mathbf{x}_i - \mathbf{x}_i^2 = 0$, negatively answering a question posed by O'Donnell. On the positive side, they show conditions under which existence of a compact representation (1) is guaranteed. These conditions are met for the reformulation of several well-known combinatorial problems as a (POP), as well as for optimization over the unit hypersphere. In order for their result to make sense, we must make the natural assumption that the coefficients of the objective function f and the polynomials g_i, h_j defining the feasible region $S(\mathbf{g}, \mathbf{h})$ of (POP) have polynomial bit-complexity.

Assumption 1. Throughout, we assume that the coefficients of the polynomials f, g_i, h_j in (POP) have polynomial bitsize in n and their degree is independent of n.

Theorem 2. (Main positive result of [12], paraphrased). Let $S(\mathbf{g}, \mathbf{h})$ be a semialgebraic set and let $t \in \mathbb{N}$ be fixed. Suppose that the following conditions are satisfied:

(1) The set $S(\mathbf{g}, \mathbf{h})$ is explicitly bounded: $g_1(\mathbf{x}) = R - \sum_{i=1}^n \mathbf{x}_i^2$ for some $R \leq 2^{\mathrm{poly}(n)}$
(2) For any $p \in \mathbb{R}[\mathbf{x}]_t$ with $p(\mathbf{x}) = 0$ for all $\mathbf{x} \in S(\mathbf{g}, \mathbf{h})$, there are $p_1, p_2, \ldots, p_\ell \in \mathbb{R}[\mathbf{x}]$ such that:
$$p(\mathbf{x}) = \sum_{j=1}^{\ell} p_j(\mathbf{x}) h_j(\mathbf{x}),$$
and $\deg(p_j h_j) = O(t)$.
(3) Let μ be the uniform probability measure on $S(\mathbf{g}, \mathbf{h})$. The *moment matrix* $M(\mu)_t$ defined by:
$$\big(M(\mu)_t\big)_{\alpha,\beta} := \int_{S(\mathbf{g},\mathbf{h})} \mathbf{x}^{\alpha+\beta} d\mu(\mathbf{x}) \quad (\alpha, \beta \in \mathbb{N}^n_t)$$
has smallest non-zero eigenvalue $\geq 2^{-\mathrm{poly}(n)}$.
(4) There exists an $\eta \geq 2^{-\mathrm{poly}(n)}$ such that $g_i(\mathbf{x}) \geq \eta$ for all $\mathbf{x} \in S(\mathbf{g}, \mathbf{h})$ and $1 \leq i \leq m$.

Then the program (SOS) has an (approximately) optimum solution involving only multipliers σ_i, p_j whose coefficients are at most $2^{\mathrm{poly}(n)}$.

1.1 Our contributions

The main goal of this paper is to carefully map under what circumstances computation of the bound $\mathrm{sos}(f)_t$ and the corresponding representation (SOS) is guaranteed to be possible in polynomial time.

Our first contribution is the following theorem.

Theorem 3. Let $S(\mathbf{g}, \mathbf{h})$ be a semialgebraic set and let $t \in \mathbb{N}$ be fixed. Suppose that the following conditions are satisfied:

(1) The set $S(\mathbf{g}, \mathbf{h})$ is explicitly bounded: $g_1(\mathbf{x}) = R - \sum_{i=1}^n \mathbf{x}_i^2$ for some $R \leq 2^{\mathrm{poly}(n)}$
(2) For any $p \in \mathbb{R}[\mathbf{x}]_{2t}$ with $p(\mathbf{x}) = 0$ for all $\mathbf{x} \in S(\mathbf{g}, \mathbf{h})$, there are $p_1, p_2, \ldots, p_\ell \in \mathbb{R}[\mathbf{x}]$ such that:
$$p(\mathbf{x}) = \sum_{j=1}^{\ell} p_j(\mathbf{x}) h_j(\mathbf{x}),$$
and $\deg(p_j h_j) \leq 2t$.
(3) There exists a constant $C \neq 0$ with $|C| \leq 2^{\mathrm{poly}(n)}$ such that the moments of the uniform probability measure μ supported on $S(\mathbf{g}, \mathbf{h})$ satisfy:
$$m(\mu)_\alpha := \int_{S(\mathbf{g},\mathbf{h})} \mathbf{x}^\alpha d\mu(\mathbf{x}) \in \tfrac{1}{C} \cdot \mathbb{N}$$
for each $\alpha \in \mathbb{N}^n_{2t}$.

Then for fixed $t \in \mathbb{N}$ and $\varepsilon \geq 2^{-\mathrm{poly}(n)}$, the bound $\mathrm{sos}(f)_t$ may be computed in polynomial time in n up to an additive error of at most ε.

Theorem 3 differs from the result of Raghavendra & Weitz in two ways: First, as we see in Section 2, it applies to several natural settings where Theorem 2 may not be applied, such as optimization over the unit ball and the standard simplex. Second, its statement is stronger in the sense that it guarantees polynomial-time computation of the bound $\mathrm{sos}(f)_t$, whereas Theorem 2 only guarantees existence of a compact representation (1).

Our second contribution is an alternative, *geometric* condition on the feasible region $S(\mathbf{g}, \mathbf{h})$ of (POP) which guarantees polynomial-time computation of $\mathrm{sos}(f)_t$ in the special case where the formulation does not contain any equality constraints.

Theorem 4. Let $S(\mathbf{g}) \subseteq \mathbb{R}^n$ be a full-dimensional, semialgebraic set defined only by inequalities. Assume that the following two conditions are satisfied:

(1) $S(\mathbf{g})$ is explicitly bounded with constant $R \leq 2^{\mathrm{poly}(n)}$, i.e., $g_1(\mathbf{x}) = R - \sum_{i=1}^n \mathbf{x}_i^2$.
(2) $S(\mathbf{g})$ contains a hypercube of size $r \geq 2^{-\mathrm{poly}(n)}$, i.e., $[-r, r]^n + z \subseteq S(\mathbf{g})$ for some $z \in \mathbb{R}^n$.

Then for fixed $t \in \mathbb{N}$ and $\varepsilon \geq 2^{-\mathrm{poly}(n)}$, the bound $\mathrm{sos}(f)_t$ may be computed in polynomial time in n up to an additive error of at most ε.

A natural motivation for the assumptions of Theorem 4 is that without them, the ellipsoid method would not be guaranteed to find a feasible point in $S(\mathbf{g})$ in polynomial time, *even if it were a convex set.* As we see below in Proposition 8, it is possible to choose the constraints g_i such that second condition of Theorem 4 is not satisfied. Interestingly, the resulting semialgebraic set $S(\mathbf{g})$ does not satisfy the conditions of Theorem 2 or Theorem 3, either.

Finally, we make explicit the connection between computational aspects of the primal formulation (SOS) of the sos-hierarchy, and its dual formulation (MOM) in terms of *moments* (see below). This connection is implicitly present in the proof of Theorem 2 in [12].

Theorem 5. Let $S(\mathbf{g}, \mathbf{h})$ be a semialgebraic set and suppose that the conditions of Theorem 3 or Theorem 4 are satisfied. Then one may (approximately) compute the bound $\mathrm{sos}(f)_t$ in time polynomial in n, using either its primal formulation (SOS) or its dual formulation (MOM). In particular, there then exists a sum-of-squares representation (1) proving nonnegativity of $f - \mathrm{sos}(f)_t + \varepsilon$ on $S(\mathbf{g}, \mathbf{h})$ with low bit-complexity.

2. SOME REMARKS AND APPLICATIONS

Here, we give some small examples that illustrate the advantages and limitations of our results with respect to previous work.

Example 6. The unit ball $B^n \subseteq \mathbb{R}^n$ and the standard simplex $\Delta^n \subseteq \mathbb{R}^n$ are semialgebraic sets, defined by:

$$B^n = \{\mathbf{x} \in \mathbb{R}^n : 1 - \|\mathbf{x}\|_2^2 \geq 0\},$$
$$\Delta^n = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{x}_i \geq 0,\ 1 - \textstyle\sum_{i=1}^n \mathbf{x}_i \geq 0\}.$$

It is straightforward to see that they both satisfy the conditions of Theorem 4. They do not, however, satisfy the third condition of Theorem 2.

Remark 7. In general, our Theorem 3 and Theorem 4 are better equipped to deal with non-discrete semialgebraic sets $S(\mathbf{g}, \mathbf{h})$ than Theorem 2. The fourth condition of Theorem 2, which demands in particular that $g_i(\mathbf{x}) > 0$ for each $\mathbf{x} \in S(\mathbf{g}, \mathbf{h})$, is generally quite hard to satisfy. For instance, the unit sphere $S^{n-1} = \{x \in \mathbb{R}^n : \|\mathbf{x}\|_2^2 = 1\}$ satisfies this condition (as it is defined without using any inequalities), but it no longer does so after adding a linear constraint such as $\mathbf{x}_1 \geq 0$. On the other hand, our Theorem 3 still applies.

The next proposition shows that the second condition of Theorem 4 is not superfluous, via a simple repeated-squaring argument.

Proposition 8. There exists a full-dimensional semialgebraic set $S(\mathbf{g})$, defined only by polynomial inequalities $\mathbf{g} = (g_1, g_2, \ldots, g_m)$ whose coefficients have bit complexity polynomial in n, which does not contain a (translated) cube $[-r, r]^n$ for $r \geq 2^{-\mathrm{poly}(n)}$.

Proof. Let $S(\mathbf{g})$ be the set defined by the system of inequalities:

$$\begin{aligned} \mathbf{x}_i &\geq 0 \qquad (1 \leq i \leq n), \\ \mathbf{x}_i - \mathbf{x}_{i+1}^2 &\leq 0 \qquad (1 \leq i \leq n-1), \\ \mathbf{x}_n &\leq 1/2. \end{aligned}$$

Set $r := 2^{-2^n}$. Then $[0, r]^n \subseteq S(\mathbf{g})$ and so $S(\mathbf{g})$ is full-dimensional. But from the inequalities it follows that $0 \leq \mathbf{x}_1 \leq r$ for any $x \in S(\mathbf{g})$, meaning $S(\mathbf{g})$ cannot contain a (translated) cube of size $2^{-\mathrm{poly}(n)}$.

It is instructive to note that the set $S(\mathbf{g})$ of Proposition 8 does not satisfy the conditions of Theorem 2 and Theorem 3. Indeed, we may easily compute the moments for the uniform probability measure μ on $S(\mathbf{g})$ and observe that:

$$\int_{S(\mathbf{g})} \mathbf{x}_1^2 d\mu(\mathbf{x}) = \int_{S(\mathbf{g})} \mathbf{x}_1^2 d\mathbf{x} \Big/ \int_{S(\mathbf{g})} 1 d\mathbf{x} \leq 2^{-2^n}$$

In particular, the smallest nonzero eigenvalue of the moment matrix $M(\mu)_t$ is at most 2^{-2^n} for any $t \geq 1$.

3. OUTLINE OF THE PROOFS

It will be convenient to work with the dual formulation of (SOS), which reads (see, e.g., [2]):

$$\begin{aligned} \mathrm{mom}(f)_t := \inf\ & L(f) \\ \text{s.t. } & L(1) = 1, \\ & L(g_i p^2) \geq 0, \quad (g_i p^2 \in \mathbb{R}[\mathbf{x}]_{2t}) \\ & L(h_j \mathbf{x}^\alpha) = 0, \ \ (h_j \mathbf{x}^\alpha \in \mathbb{R}[\mathbf{x}]_{2t}) \\ & L \in \mathbb{R}[\mathbf{x}]_{2t}^*. \end{aligned} \tag{MOM}$$

Under the assumption of explicit boundedness, these formulations are actually equivalent.

Theorem 9. ([4]). If (POP) is explicitly bounded, we have strong duality between the primal and dual formulations (SOS) and (MOM) of the moment-sos hierarchy. That is, we then have:

$$\mathrm{sos}(f)_t = \mathrm{mom}(f)_t \quad \forall t \in \mathbb{N}.$$

As we alluded to in the introduction, explicit boundedness of $S(\mathbf{g}, \mathbf{h})$ also gives a bound on the feasible region of (MOM).

Lemma 10. (see, e.g., [11]). Assume that $S(\mathbf{g}, \mathbf{h})$ is explicitly bounded for some $R > 0$. Let $L \in \mathbb{R}[x]_{2t}^*$ be a feasible solution to (MOM). Then $|L(\mathbf{x}^\alpha)| \leq R^{|\alpha|}$ for all $\alpha \in \mathbb{N}_{2t}^n$.

There is a natural relation between the dual formulation (MOM) and *moments* of measures supported on $S(\mathbf{g}, \mathbf{h})$, which clarifies the assumptions made in Theorem 2 and Theorem 3. For a measure μ supported on $S(\mathbf{g}, \mathbf{h})$, the *moment* of degree $\alpha \in \mathbb{N}^n$ is defined by:

$$m(\mu)_\alpha := \int_{S(\mathbf{g},\mathbf{h})} \mathbf{x}^\alpha d\mu(\mathbf{x}).$$

For $t \in \mathbb{N}$, the (truncated) moment matrix $M(\mu)_t$ of order t for μ is then given by:

$$\big(M(\mu)_t\big)_{\alpha,\beta} = m(\mu)_{\alpha+\beta}. \tag{2}$$

Consider the linear functional $L_\mu \in \mathbb{R}[\mathbf{x}]_{2t}^*$ defined by:

$$L_\mu(p) := \int_{S(\mathbf{g},\mathbf{h})} p(\mathbf{x}) d\mu(x) \quad (p \in \mathbb{R}[\mathbf{x}]_{2t}).$$

For any constraint g_i and $p \in \mathbb{R}[\mathbf{x}]$ with $\deg(g_i p^2) \leq 2t$, we have:

$$L_\mu(g_i p^2) = \mathbf{p}^\top M(g_i \mu)_t \mathbf{p} = \int_{S(\mathbf{g},\mathbf{h})} p^2(\mathbf{x}) g_i(\mathbf{x}) d\mu(\mathbf{x}) \geq 0,$$

where $\mathbf{p}$ denotes the vector of coefficients of $p \in \mathbb{R}[\mathbf{x}]_t$ in the monomial basis. Here the (α, β)-entry of the *localizing matrix* $M(g_i\mu)_t$ is defined as $\int_{S(\mathbf{g},\mathbf{h})} g_i(\mathbf{x}) \mathbf{x}^{\alpha+\beta} d\mu(\mathbf{x})$. In particular, for each i the matrix $M(g_i\mu)_t$ is positive semidefinite. Furthermore, for any constraint h_j and $\alpha \in \mathbb{N}^n$ with $\deg(\mathbf{x}^\alpha h_j) \leq 2t$, we have:

$$L_\mu(h_j \mathbf{x}^\alpha) = \int_{S(\mathbf{g},\mathbf{h})} h_j(\mathbf{x}) \mathbf{x}^\alpha d\mu(\mathbf{x}) = 0.$$

If μ is a probability measure, we get $L_\mu(1) = 1$, and it follows that L_μ is a feasible solution to (MOM).

Remark 11. The upshot is that in order to show that the feasible region of (MOM) contains an inner ball, it is enough to exhibit a probability measure μ on $S(\mathbf{g}, \mathbf{h})$ with:

(1) The smallest non-zero eigenvalue of $M(g_i\mu)_t$ is at least $2^{-\mathrm{poly}(n)}$ for each $i = 0, 1, \ldots, m$;
(2) For any $p \in \mathbb{R}[\mathbf{x}]_t$ with $M(\mu)_t \mathbf{p} = 0$, we have that $p(\mathbf{x}) = \sum_{j=1}^\ell h_j(\mathbf{x}) p_j(\mathbf{x})$, where $\deg(h_j p_j) \leq 2t$.

One may then use a fairly standard result on SDP complexity to conclude polynomial-time (approximate) computability of $\mathrm{mom}(f)_t$, see for instance Theorem 1.1 in [3].

3.1 Proof sketch for Theorem 3

Our proof uses similar ideas to that of Theorem 2 in [12]. Let μ be the uniform probability measure on $S(\mathbf{g}, \mathbf{h})$. We show μ satisfies the properties (1) and (2) in Remark 11. For (1), note that the third condition of Theorem 3 tells us that $C \cdot M(\mu)_t$ is an integer matrix for some $C \neq 0$, $|C| \leq 2^{\text{poly}(n)}$. The eigenvalues of integer matrices can be controlled in terms of their largest entry. By Lemma 10, we have an upper bound on the entries of $C \cdot M(\mu)_t$, and this allows us to show that the smallest nonzero eigenvalue of $M(\mu)_t$ is at least $2^{-\text{poly}(n)}$. The entries of the matrices $M(g_i\mu)_t$ are *linear combinations* of the entries of $M(\mu)_t$, involving the coefficients of the constraints g_i. As these coefficients have polynomial bit-complexity, a similar argument allows us to lower bound the smallest nonzero eigenvalue of each $M(g_i\mu)_t$. For (2), note that this is implied immediately by the second condition in Theorem 3.

3.2 Proof sketch for Theorem 4

Let μ be the normalized Lebesgue measure on $S(\mathbf{g})$. If $S(\mathbf{g})$ contains a (translated) hypercube $[-r, r]^n + z$ of size $r \geq 2^{\text{poly}(n)}$, μ trivially satisfies condition (2) in Remark 11 (as $M(\mu)_t\mathbf{p} = 0 \implies \mathbf{p} = 0$). To see that it also satisfies condition (1), we proceed as follows:

- Show that we may assume w.l.o.g. that $z = 0$, using the fact that $\|z\|_2^2 \leq R \leq 2^{\text{poly}(n)}$ as $S(\mathbf{g})$ is explicitly bounded.
- Use known formulas (c.f. [2]) for the moments of the hypercube to show that there exists a $C \neq 0$, $|C| \leq 2^{\text{poly}(n)}$ such that $C \cdot M(\mu')_t$ is integer, where μ' is the restriction of μ to $[-r, r]^n$.
- Conclude that the smallest eigenvalue of $M(g_i\mu')_t$ is at least $2^{-\text{poly}(n)}$ for each i.
- Finally, use the fact that $[-r, r]^n \subseteq S(\mathbf{g})$ to conclude that $M(g_i\mu)_t \succeq M(g_i\mu')_t$ for all i, finishing the proof.

3.3 Proof sketch for Theorem 5

In our proofs of Theorem 3 and Theorem 4, we show that the dual formulation (MOM) of the sos-hierarchy may be (approximately) solved in polynomial time using (e.g.) the ellipsoid algorithm. This does not immediately imply that the same is true for the primal formulation (SOS). By considering the pairing between primal feasible solutions (i.e., representations of the form (1)) and the dual feasible solution L_μ used in our proofs, we show that the feasible region of the primal formulation is also bounded. This pairing also plays an important role in the proof of Theorem 2 in [12]. Indeed, for any representation $f(\mathbf{x}) = \sum_i g_i(\mathbf{x})\sigma_i(\mathbf{x}) + \sum_j h_j(\mathbf{x})p_j(\mathbf{x})$, we have:

$$L_\mu(\sum_i g_i\sigma_i + \sum_j h_j p_j) = L_\mu(f) \leq 2^{\text{poly}(n)}.$$

This allows us to bound $L_\mu(g_i\sigma_i)$, which in turn allows us to bound the size of the coefficients of σ_i. To bound the coefficients of the p_j one uses the second condition of Theorem 3.

Future Control Community Papers on Algorithmic Trading Should Pay More Attention to Backtesting

B. Ross Barmish

Robust Trading Solutions, LLC
Boxford, MA 01921
email: bob.barmish@gmail.com

Abstract: The takeoff point for this work is the emerging body of literature which addresses algorithmic trading in the framework of feedback control systems. In this setting, the buying and selling of equities period is governed by the action of a controller, using past history, to determine the time-varying investment level. Almost all of the papers to date begin with a underlying mathematical model structure for the stock-price dynamics and "theoretical" performance is studied. In many cases, the parameters of the price model are not assumed to be known in advance; they are estimated over time from the realized price path. In the literature, we also see many variations on this theme. For example, the investment-level controller may have no explicit reliance on an assumed price model and instead are updated by performance variable data such as account market value or gains and losses over time. Subsequently, the authors of papers along these lines demonstrate the performance of their trading algorithms using various criteria. Given this context, we draw attention to use of the word "should" in the title. This is intentional because this short paper is an opinion piece; it does not contain new results. Instead, arguments are given that the control community will be well served if future papers devote greater attention to backtesting and standardization of benchmark data sets. It is argued that this will enable the results of one researcher to more easily replicated and compared against those of another and, in turn, this will increase the impact of control-theoretic papers on researchers and practitioners outside the control field. While it is true that a number of the control-inspired papers to date already include some backtest results, the use of widely varying data sets makes evaluation of worthiness of their "controller recipes" difficult or impossible.

Keywords: financial engineering, algorithmic stock trading, stochastic systems, backtesting

1. INTRODUCTION

The basic idea of viewing stock trading in a control-theoretic setting goes back about fifty years to the finance community where optimal control concepts were brought into play in a portfolio optimization context; e.g., see [1] and [2]. Over the last two decades, we see a number of papers bringing many other aspects of modern control theory to the fore. Among the earliest of these, [3] and [4], appear in 2001 and 2002. In the ensuing twenty years, a large number of papers along these lines have followed. To keep the length of this exposition within page-limit requirement, we refer the reader to papers [5] and [6] and their bibliographies where this literature is broadly surveyed covering the period up until 2016. Beyond 2016, we see a number of new ideas being introduced into this line of research. To mention just a few examples, in [7], [8] and [9], various generalizations of the so-called SLS method are studied, in [10], the use of modulated controllers aimed at drawdown reduction are introduced, in [11], approaches to trading in a model-predictive control context are studied and in [12], trend following from an H^∞ tracking point of view is investigated.

1.1 The Basic Setup for Control-Inspired Stock Trading

The feedback control approach to stock trading is easily understood in terms of the closed-loop feedback configuration given in Figure 1. Although this setup is not explicitly given in all of the cited literature above, it is central to almost all control-inspired research on stock trading which one can imagine.

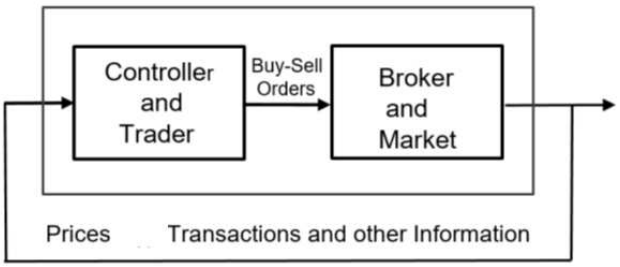

Figure 1: Feedback Loop Involving Trader and Broker

The paradigm associated with the block diagram in the figure is central to the study of a wide variety of feedback control laws which can be used to modify the time-varying investment level. In some papers, a model for future stock prices plays an important role and in other cases no stock price model is used at all and trading signals are generated based on other considerations such as the market value of the account or gains and losses over time.

1.2 This Author's Opinion of Existing Research

When looking at the existing results over the last twenty years coming from the control community, in many papers, including those of this author, there is inadequate attention being paid to "meaningful" backtesting. Too much of center stage is occupied by theoretical issues and backtest simulations which are given are of often of questionable worth. In many cases when such simulations are included, the data set is often "nonstandard" or covers too short a time duration which does not include both bull and bear markets. Simply put, it is felt that many of the backtest simulations conducted by the control field researchers are insufficient to determine whether the trading scheme being espoused will be efficacious. To illustrate the case being made in this paper, we ask the following question: Based on highly successful backtests for Tesla and Apple stock over the year 2021, can any meaningful conclusions be made about the excellence of the trading algorithm being used? Of course not. In the finance literature, the issue of "data snooping" often arises in connection with a belief that a given investment-level control algorithm is being made to look "better than deserved." In the control field, care is required to avoid cherry picking data (choice of equities, time period, etc.) and "twiddling" with parameters such as feedback gains entering into the simulation. As suggested in the sequel, the control field should adopt *standard benchmark data sets* and rules for algorithm parameter initialization and adjustment so that backtest results reported in the literature are **repeatable**and new algorithms are more easily evaluated.

2. STANDARDIZATION OF BACKTESTING

The view of this author is that the control field would be well served if papers included a credible backtest which is not easily subject to challenge. In this regard, prior to dealing with a diversified portfolio of stocks, a simulation should be carried out using some well-known benchmark such as the Dow Jones Industrial Average (DJIA) or the Standard and Poor's (S&P) 500. In addition, a sufficiently long multi-year time window should be used which includes both bull and bear markets. Finally, the performance of the algorithm over sub-windows should be also be considered. This is important because "ride quality" is very important to many traders. It does not suffice to claim that an algorithm leads to a great end result if the market value of the account undergoes large roller coaster deviations along the way. One excellent example illustrating high-quality backtesting is reference [13]. Trades are triggered based on the stock price crossing a prescribed multi-day moving average. In lieu of making the case for the "excellence" of their results based on mathematical theory on how moving averages behave, the authors provide a backtest using historical data for the DJIA covering nearly ninety years. This shifts the debate away from the quality of the mathematical justification to real-world implications such as the longstanding theory that markets are efficient and that "abnormal" rates of return, when risk-adjusted, cannot be consistently obtained.

3. FUTURE CONTROL COMMUNITY PAPERS

It is suggested that in our future papers, after the introduction and a literature review, the author provides the investment-level controller recipe and a simple backtest with as little supporting mathematical detail as possible. While it is true that some mathematical formulae will be needed to describe the controller, the theorems, proofs and price modelling can be relegated to a later section of the paper such as an appendix. Accompanying this recipe, perhaps some authors can include emphasis on the intuitive appeal of their algorithms. Then, leave it to fellow researchers to decide whether the backtest is "sufficiently impressive" to merit careful study the supporting theory. This author's opinion, controversial as it may be, is summarized as follows: *It does not suffice to provide excellent theory with weak supporting backtests. However, it does suffice to provide excellent backtests with weak supporting theory.*

Per discussion above, as in reference [13] where the Dow Jones Industrial Average is used, the view of this author, as previously mentioned, is that the chosen data set should be standard and well known to almost any possible trader. To this end, as discussed below, one very good possibility for use would be the time series for daily S&P 500 prices over a long time period. The associated Exchange Traded Fund (ETF), having ticker SPY, can be readily downloaded from Yahoo Finance. Given the high liquidity of this ETF, it is reasonable to assume in simulations that trading can be carried out with minimal friction. We also emphasize the words "long time period" above. Many types of behavior such as bull markets, bear markets and corrections should be covered.

3.1 Other Backtest Considerations

Many papers in the control literature pay little or no attention to important issues such as margin requirements and associated leverage allowed by the broker, slippage associated with the bid-ask spread and attainability of specified orders such as "market on close." When conducting backtest simulations, since one of our main objectives is to determine if promising control algorithms perform well when subjected to these practical market considerations, attention to these issues in simulation is important.

4. ON EVALUATION OF BACKTEST RESULTS

After a backtest simulation is performed, the following question arises: How do we evaluate the quality of the results? For example, if one has a 200% one-year return on some mining stock but a loss of 50% after the first six months, is this considered a good result? Some traders would be perfectly comfortable with this type of roller coaster ride but others, particularly those who are risk-averse, would not. To avoid controversy whether this result is good or bad, the suggestion in this paper is to use the method of many mutual funds to display results. That is, one begins a simulation with a fictitious $10,000 and simply provides a plot of the evolution of market value over time. For this hypothetical scenario, the 50% dip and 200% rise above will be immediately visible in the plot and each individual can judge the performance based on his or her individual utility function. While it is perfectly acceptable to report on various features of the plot such as annual returns, and highs and lows, no claims of "optimality" are appropriate. Each "examiner" of the market value plot has all the information required to make an individual judgment; see the example below for additional details.

5. EXAMPLE: TWENTY YEARS OF THE S&P 500

To make the ideas above more concrete, we imagine a control community researcher who develops a "secret" trading algorithm and conducts a 20-year backtest using price data for SPY, the ETF tracking the S&P 500. Trading begins mid-February of 1998 with the market value of the account initialized at $10,000. On day k, the trading algorithm processes the past history and determines investment level $I(k)$. Assuming short selling and use of leverage is disallowed, using $V(k)$ to denote the associated 5000+ market values of the account, the condition $0 \leq I(k) \leq V(k)$ must be satisfied. In addition, we assume that all transactions occur at the daily closing price and, for pedagogical simplicity, we neglect the small dividends which are "cast off" by the stocks comprising the index.

5.1 Evaluation: A Picture is Worth a Thousand Words

For the scenario above, in Figure 1, the black market-value plot represents the benchmark. A buy-and-hold trader sees wildly gyrating returns but ends up with about a 35% twenty-year return. On the other hand, the red plot, representing the returns on the trader's algorithm only ends up with about a 17.5% gain for the same period. Given these two plots, there is no need for the control researcher to provide an "opinion" which market-value plot is preferred; the two plots speaks for themselves. A risk-averse investor who finds the large intermediate drawdowns on the S&P 500 intolerable may give the overall market-value plot a low performance rating. The slow steady rise of the red market value associated with the algorithm only leads to a return of about 17.5% but the ride quality may result in a much higher performance rating by many more conservative traders who are unwilling to ride out a storm.

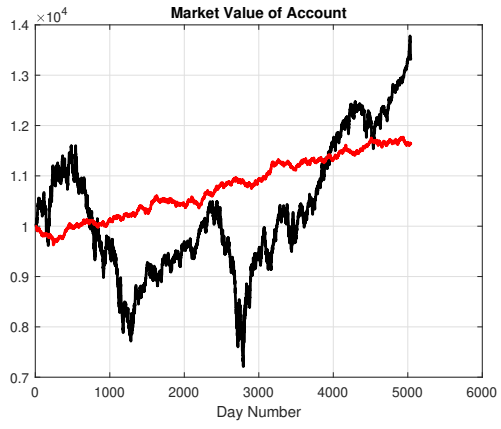

Figure 1: Growth of $10,000: Strategy Versus Benchmark

6. CONCLUSION

In this paper, it was argued that future research on algorithmic trading in the control community should pay much more attention to backtesting and use a benchmark which is simple, widely understood and covers a suitably long time period. It is the opinion of this author that the market-value plot is typically much more informative and insightful than the lengthy statistical analyses found in many papers coming from the finance community. A final point to mention is the following view held by the author: A trading algorithm which cannot be theoretically justified in a theorem-proof context, should not be disqualified from being seriously studied in a backtesting context. A backtest which is sufficiently compelling can be very important even if the trading algorithm recipe appears to be ad hoc. This includes controller recipes which may involve heuristics or use of ideas from areas such as machine learning or neural networks; e.g., see [14].

Loop Shaping with Scaled Relative Graphs

Thomas Chaffey * **Fulvio Forni** * **Rodolphe Sepulchre** *

* *University of Cambridge, Department of Engineering, Trumpington Street, Cambridge CB2 1PZ,* {tlc37, ff286, rs771}@cam.ac.uk.

Abstract: The Scaled Relative Graph (SRG) is a generalization of the Nyquist diagram that may be plotted for nonlinear operators, and allows nonlinear robustness margins to be defined graphically. This abstract explores techniques for shaping the SRG of an operator in order to maximize these robustness margins.

Keywords: Scaled Relative Graph, Nyquist, loop shaping, robustness

1. INTRODUCTION

Loop shaping is one of the earliest methods of controller design, originating in the work of Nyquist, Bode, Nichols and Horowitz on feedback amplifiers (Bode, 1960). The basic principle of loop shaping is to tune a system's closed loop performance by adjusting the open loop frequency response. Robustness is captured by the distance of the Nyquist diagram from the point -1; closed loop performance is captured by the sensitivity and related transfer functions. Loop shaping is still widely used in industry today – the graphical nature of the tool gives a clear view of the design tradeoffs between performance and robustness. Even in the age of modern optimal and robust control, loop shaping remains a core tool for the control engineer. The idea of enlarging stability margins eventually led to the Zames' formulation of H_∞ control (Zames, 1981), and some of the most successful methods of robust control combine H_∞ control with classical loop shaping ideas (Vinnicombe, 2000; McFarlane and Glover, 1992).

The Scaled Relative Graph (SRG) is a graphical representation of a nonlinear operator, recently introduced in the theory of optimization by Ryu et al. (2021). The SRG allows simple, intuitive proofs of convergence for optimization algorithms, and allows optimal convergence rates to be visualized as distances on a plot. The authors have recently connected the SRG to classical control theory, showing that it generalizes the Nyquist diagram of an LTI transfer function (Chaffey et al., 2021). A range of incremental stability results, including the Nyquist and circle criteria, small gain and passivity theorems and secant condition, can be interpreted as guaranteeing the separation of the SRGs of two systems in feedback, and this interpretation has led to new conditions for incremental stability (Chaffey, 2022). The distance between the two SRGs is an incremental disc margin, the reciprocal of which bounds the incremental gain of the closed loop. The SRG makes the design intuition afforded by the Nyquist diagram available for nonlinear systems.

This abstract describes ongoing research into the use of SRGs for loop shaping nonlinear feedback systems. It has long been observed that introducing nonlinearity can overcome fundamental limitations of LTI control – for example, the describing function of the Clegg integrator has a phase lag of only 38°, rather than the usual 90° of a linear integrator (Clegg, 1958). This motivates a better understanding of how nonlinearities may be used to shape the performance of a feedback system.

2. REVIEW OF SCALED RELATIVE GRAPHS

We begin this extended abstract with a brief review of the theory of SRGs.

2.1 Signal Spaces

We describe systems using operators, possibly multi-valued, on a Hilbert space. A Hilbert space $\mathcal{H}$ is a vector space equipped with an inner product, $\langle \cdot | \cdot \rangle : \mathcal{H} \times \mathcal{H} \to \mathbb{C}$, and the induced norm $\|x\| \coloneqq \sqrt{\langle x | x \rangle}$.

We will pay particular attention to the Lebesgue space L_2. Given $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$, $L_2^n(\mathbb{F})$ is defined as the set of signals $u : \mathbb{R}_{\geq 0} \to \mathbb{F}^n$ such that

$$\|u\| \coloneqq \left(\int_0^\infty u(t) \bar{u}(t) \, \mathrm{d}t \right)^{\frac{1}{2}} < \infty,$$

where $\bar{u}(t)$ denotes the conjugate transpose of $u(t)$. The inner product of $u, y \in L_2^n(\mathbb{F})$ is defined by

$$\langle u | y \rangle \coloneqq \int_0^\infty u(t) \bar{y}(t) \, \mathrm{d}t \, .$$

The Fourier transform of $u \in L_2^n(\mathbb{F})$ is defined as

$$\hat{u}(j\omega) \coloneqq \int_0^\infty e^{-j\omega t} u(t) \, \mathrm{d}t \, .$$

We omit the dimension and field when they are immaterial or clear from context.

2.2 Relations

An *operator*, or *system*, on a space $\mathcal{H}$, is a possibly multi-valued map $R : \mathcal{H} \to \mathcal{H}$. The identity operator, which maps

* The research leading to these results has received funding from the European Research Council under the Advanced ERC Grant Agreement Switchlet n. 670645, and from the Cambridge Philosophical Society.

$u \in \mathcal{H}$ to itself, is denoted by I. The *graph*, or *relation*, of an operator, is the set $\{u, y \mid u \in \operatorname{dom} R, y \in R(u)\} \subseteq \mathcal{H} \times \mathcal{H}$. We use the notions of an operator and its relation interchangeably, and denote them in the same way.

The usual operations on functions can be extended to relations. Let R and S be relations on an arbitrary Hilbert space. Then:

$$\begin{aligned} S^{-1} &= \{(y,u) \mid y \in S(u)\} \\ S + R &= \{(x, y+z) \mid (x,y) \in S, (x,z) \in R\} \\ SR &= \{(x,z) \mid \exists\, y \text{ s.t. } (x,y) \in R, (y,z) \in S\}. \end{aligned}$$

Note that S^{-1} always exists, but is not an inverse in the usual sense. In particular, it is in general not the case that $S^{-1}S = I$. The relational inverse plays a fundamental role in the techniques described in this abstract. Rather than directly shape the performance of a negative feedback interconnection, we will shape the performance of its inverse relation – a parallel interconnection.

These operations will also be used on sets of operators, with the meaning that the operations are applied elementwise to the sets (under the implicit assumption that the operators have compatible domains and codomains).

2.3 Scaled Relative Graphs

We define SRGs in the same way as Ryu et al. (2021), with the minor modification of allowing complex valued inner products.

Let $\mathcal{H}$ be a Hilbert space. The angle between $u, y \in \mathcal{H}$ is defined as

$$\angle(u,y) \coloneqq \operatorname{acos} \frac{\operatorname{Re}\langle u|y\rangle}{\|u\|\|y\|}.$$

Let $R : \mathcal{H} \to \mathcal{H}$ be an operator. Given $u_1, u_2 \in \mathcal{U} \subseteq \mathcal{H}$, $u_1 \neq u_2$, define the set of complex numbers $z_R(u_1,u_2)$ by

$$z_R(u_1,u_2) \coloneqq \left\{ \frac{\|y_1 - y_2\|}{\|u_1 - u_2\|} e^{\pm j \angle(u_1-u_2, y_1-y_2)} \;\middle|\; y_1 \in R(u_1), y_2 \in R(u_2) \right\}.$$

If $u_1 = u_2$ and there are corresponding outputs $y_1 \neq y_2$, then $z_R(u_1,u_2)$ is defined to be $\{\infty\}$. If R is single valued at u_1, $z_R(u_1,u_1)$ is the empty set.

The *Scaled Relative Graph* (SRG) of R over $\mathcal{U} \subseteq \mathcal{H}$ is then given by

$$\operatorname{SRG}_{\mathcal{U}}(R) \coloneqq \bigcup_{u_1,u_2 \in \mathcal{U}} z_R(u_1,u_2).$$

If $\mathcal{U} = \mathcal{H}$, we write $\operatorname{SRG}(R) \coloneqq \operatorname{SRG}_{\mathcal{H}}(R)$. The SRG of a class of operators is defined to be the union of their individual SRGs. Some examples of SRGs are shown in Figure 1, (a), (b) and (c).

2.4 Interconnections

The power of SRGs lies in the elegant interconnection theory of Ryu et al. (2021). Given the SRGs of two systems, the SRG of their interconnection can be bounded using simple graphical rules. Given two systems R and S, and subject to mild conditions, we have:

$$\begin{aligned} \operatorname{SRG}(\alpha R) = \operatorname{SRG}(R\alpha) &= \alpha \operatorname{SRG}(R) \\ \operatorname{SRG}(R+S) &\subseteq \operatorname{SRG}(R) + \operatorname{SRG}(S) \\ \operatorname{SRG}(RS) &\subseteq \operatorname{SRG}(R)\operatorname{SRG}(S) \\ \operatorname{SRG}(R^{-1}) &= \operatorname{SRG}(R)^{-1}. \end{aligned}$$

For the precise meanings of these operations, and the requisite conditions on the systems R and S, we refer the reader to (Ryu et al., 2021).

2.5 SRGs of systems

The SRGs of LTI transfer functions are closely related to the Nyquist diagram, and the SRGs of static nonlinearities are closely related to the incremental circle. These connections are explored in detail in (Chaffey et al., 2021; Pates, 2021); below we recall the two main results. The h-convex hull is the regular convex hull with straight lines replaced by arcs with centre on the real axis – for a precise treatment, we refer the reader to (Huang et al., 2020).

Theorem 1. Let $g : L_2(\mathbb{C}) \to L_2(\mathbb{C})$ be linear and time invariant, with transfer function $G(s)$. Then $\operatorname{SRG}(g) \cap \mathbb{C}_{\operatorname{Im}\geq 0}$ is the h-convex hull of Nyquist $(G) \cap \mathbb{C}_{\operatorname{Im}\geq 0}$.

Theorem 2. Suppose $S : L_2 \to L_2$ is the operator given by a SISO static nonlinearity $s : \mathbb{R} \to \mathbb{R}$, such that for all $u_1, u_2 \in \mathbb{R}$, $y_i \in s(u_i)$,

$$\mu(u_1-u_2)^2 \leq (y_1-y_2)(u_1-u_2) \leq \lambda(u_1-u_2)^2. \quad (1)$$

Then the SRG of S is contained within the disc centred at $(\mu+\lambda)/2$ with radius $(\mu-\lambda)/2$.

Theorems 1 and 2, and the SRG interconnection rules, allow us to construct bounding SRGs for arbitrary interconnections of LTI and static nonlinear components. A simple example is illustrated in Figure 1.

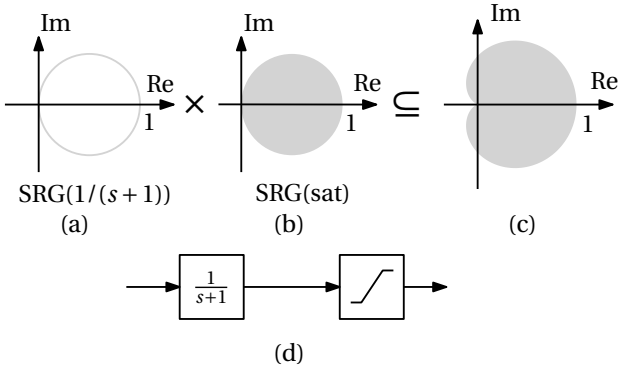

Fig. 1. Bounding SRG for the composition of a first order lag and saturation.

3. INCREMENTAL ROBUSTNESS AND SENSITIVITY

3.1 Stability and incremental gain

Given the negative feedback interconnection of Figure 2, incremental stability is guaranteed by the separation of the SRGs of P^{-1} and $-C$, and the distance between them is an incremental robustness margin, the reciprocal of which bounds the incremental gain of the feedback system. This is formalized in (Chaffey et al., 2021, Thm. 2); we recall the result here.

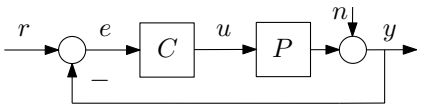

Fig. 2. Negative feedback control structure.

Let $\mathcal{H}$ be a class of operators. By $\bar{\mathcal{H}}$, we will denote a class of operators such that $\mathcal{H} \subseteq \bar{\mathcal{H}}$ and $\mathrm{SRG}(\bar{\mathcal{H}})$ satisfies the chord property: if $z_1, z_2 \in \mathrm{SRG}(\bar{\mathcal{H}})$, then $\vartheta z_1 + (1-\vartheta)z_2 \in \mathrm{SRG}(\bar{\mathcal{H}})$ for all $\vartheta \in [0,1]$.

Theorem 3. Consider the feedback interconnection shown in Figure 2 between any pair of operators $C \in \mathcal{C}$ and $P \in \mathcal{P}$, where $\mathcal{C}$ and $\mathcal{P}$ are classes of operators on L_2 with finite incremental gain. If, for all $\tau \in (0,1]$,

$$\mathrm{SRG}(\mathcal{C})^{-1} \cap -\tau\,\mathrm{SRG}(\bar{\mathcal{P}}) = \varnothing,$$

then the incremental L_2 gain from r to u is bounded by $1/r_m$, where r_m is the shortest distance between $\mathrm{SRG}(\mathcal{C}^{-1})$ and $-\mathrm{SRG}(\bar{\mathcal{P}})$.

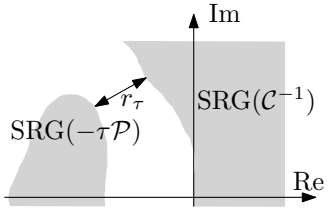

Fig. 3. Illustration of Theorem 3.

3.2 The sensitivity SRG

The operator $(I+PC)^{-1}$ maps r to e in the feedback system of Figure 2, and the operator $(I-PC(-I))^{-1}$ maps n to y. These two operators have the same SRG, which we denote by $\mathcal{S}$ – the *sensitivity SRG*.

Definition 4. The *peak incremental sensitivity* is the maximum incremental gain of the operator $(I+PC)^{-1}$.

The peak incremental sensitivity is equal to the maximum modulus of $\mathcal{S}$. The following theorem gives the peak incremental sensitivity an interpretation as a robustness margin.

Theorem 5. Let s_m be the shortest distance between $\mathrm{SRG}(PC)$ and the point -1. Then the peak incremental sensitivity is equal to $1/s_m$.

4. LOOP SHAPING

We demonstrate SRG loop shaping with two simple design examples for the control structure shown in Figure 2.

4.1 Shaping for stability and robustness

As first design example, we show how to use SRGs to ensure incremental stability of a closed loop system. Unlike traditional loop shaping, where the return ratio $L = PC$ is modified, we graphically shape the inverse of the feedback system, $(P+C^{-1})$, to improve the robustness of the closed loop. The use of SRGs makes the design close to classical Nyquist analysis, despite the nonlinearity of P.

Consider the system in Figure 4. C represents the controller, to be designed. Suppose that the process consists

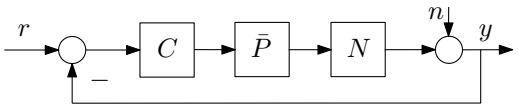

Fig. 4. Example control system. $\bar{P} = 1/(s(s+1))$, N is a nonlinear operator and C is the controller, to be designed. r is the reference input, n represents sensor noise.

of $\bar{P}$ with LTI dynamics $1/(s(s+1))$, and a nonlinear operator N, whose SRG is known to be bounded in the region illustrated in Figure 1 (c). We denote $C\bar{P}$ by L. The controller C is to be designed to stabilize the system and decrease the incremental gain.

To ensure stability, we require the SRGs of $L^{-1} = (C\bar{P})^{-1}$ and $-N$ to be separated, for all scalings of N between 0 and 1 (following Theorem 3). With $C_0 = 1$, the closed loop is unstable, as shown in Figure 5 (a). Shifting L^{-1} to the left, by designing C to give $L^{-1} = s(s+1)+1$, gives a stabilizing control. The controller reads $C_1 = s(s+1)/(1+s(s+1))$.

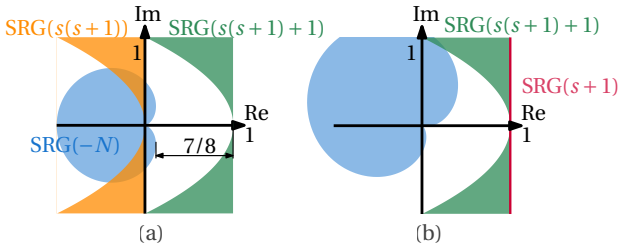

Fig. 5. (a) SRGs of $-N$, $\bar{P}^{-1}$ and $(\bar{P}C_1)^{-1}$. (b) SRGs of $(\bar{P}C_1)^{-1}$, $(\bar{P}C_2)^{-1}$ and a scaled and rotated nonlinearity, showing the improved robustness with C_2.

To improve robustness and reduce the incremental gain of the system, the separation of $\mathrm{SRG}(L^{-1})$ and $\mathrm{SRG}(-N)$ must be increased (again, following Theorem 3). For example, setting $L^{-1} = s+1$ ($C_2 = s$) gives good separation, and an incremental gain bound from r to u of $8/7 \approx 1.14$. As the incremental gain of N is bounded by 1 (the maximum modulus of its SRG), this value also bounds the incremental gain from r to y. The increased separation of the SRGs makes the system robust to uncertainties in the nonlinearity N, as illustrated in Figure 5 (b).

4.2 Shaping for performance

We now focus on graphical methods for improving performance, and explore how the sensitivity SRG can be shaped over particular sets of signals. We consider a new system, again of the form of Figure 2, with $C = 1/(ks+1)$, where k is a scalar to be designed, and P is a unit saturation. The SRGs of C and P are shown in Figure 1 (a) and (b).

Tracking performance and noise rejection are both characterized by the sensitivity SRG. Suppose that we would like this SRG to have a low modulus (corresponding to incremental gain) for signals with a bandwidth of $\omega_0 = 10$ rad/s and a maximum amplitude of 2. The aim is to limit the maximum amplification of $(I+PC)^{-1}$ over this range of signals.

A heuristic method is to maximize the distance between $\mathrm{SRG}(PC)$ and -1 over the frequency range $[-\omega_0, \omega_0]$

and amplitude range $[-2, 2]$, following Theorem 5. This corresponds to maximizing the minimum incremental gain of the inverse of the sensitivity operator over this range of signals.

SRG (PC) is bounded by the Minkowski product of SRG (P) and SRG (C). Plotting the SRG of the saturation P over the amplitude range $[-2, 2]$ gives the half-disc shown in Figure 6 (b). The SRG of C over $[-\omega_0, \omega_0]$ is described by

$$\left(\frac{1}{1+k^2\omega^2}, j\frac{-k\omega}{1+k^2\omega^2}\right)$$

for $\omega \in [-\omega_0, \omega_0]$. As a first design, we can set k so that the bandlimited SRG of C is half the circle (Figure 6 (a)) – this is achieved by setting $k = 0.01$. This gives the bound on SRG (PC) shown in Figure 6 (c). The minimum distance to the point -1 is $s_m = \sqrt{3}$.

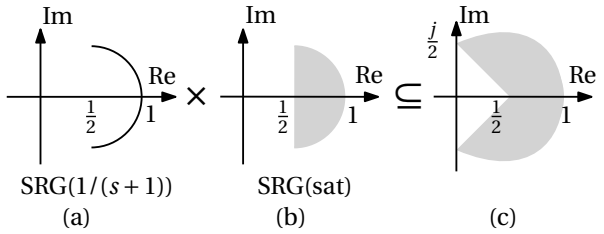

Fig. 6. Left: SRG of $1/(ks+1)$ over signals with bandwidth $[-1/k, 1/k]$. Right: SRG of saturation over signals with maximum amplitude 2.

This method is, however, only a heuristic. The saturation introduces higher harmonics, so the assumption that signals have a bounded spectrum is invalidated when the loop is closed. However, given the lowpass properties of the system, the approximation is reasonable. The higher order harmonics of the output of the saturation have low magnitude, and the unit lag has a lowpass behavior. The stability of the closed loop guarantees that these high frequencies are indeed attenuated by the feedback system. This assumption is similar to the lowpass assumption of describing function analysis Slotine and Li (1991). The method here differs from describing function analysis, however, in that arbitrary differences of bandlimited inputs are considered, not just pure sinusoids.

5. OTHER TYPES OF SYSTEMS

A significant advantage of the SRG is being able to place disparate system types on an equal footing. Like continuous time LTI systems, finite dimensional linear operators described by matrices lend themselves well to shaping. Pates (2021) has shown that the SRG of a matrix is equal to the numerical range of a closely related, transformed matrix. In the case of normal matrices, the SRG is the h-convex hull of the spectrum (Huang et al., 2020). These results pave the way for shaping a matrix's SRG by matrix multiplication and addition.

In cases where the analytic SRG is not available, the SRG can be sampled over the signals of interest, and loop shaping methods can then be applied using the sampled SRG. For example, Figure 7 shows a sampled SRG of the potassium conductance of the Hodgkin-Huxley model of a neuron (Hodgkin and Huxley, 1952).

Evaluation Subspace Codes and Convolutional Codes

Joachim Rosenthal

Institute of Mathematics, University of Zurich, Winterthurerstrasse 190, 8057 Zurich
(e-mail: rosenthal@math.uzh.ch)

Abstract: A constant dimension subspace code can be viewed geometrically as a subset of the Grassmann variety defined over a finite field.
There exist few algebraic constructions for constant dimension subspace codes. A major technique is the 'lifting technique' of a rank metric code with a good distance. For rank metric codes exist several good algebraic constructions. First and for most one should mention the technique of constructing Gabidulin codes which can be seen as the image of a linear space of linearized functions under an evaluation map. The technique of constructing Gabidulin codes naturally generalizes the construction of AG-codes such as Reed-Solomon codes and more general geometric Goppa codes.
In this talk we present a new idea on how one can construct excellent subspace codes by evaluating points on a rational curve in the Grassmannian.

Keywords: Subspace codes, rank metric codes, evaluation codes.

1. INTRODUCTION TO SUBSPACE CODES

Constant dimensional subspace codes appeared probably first in the seminal paper by Kötter and Kschischang (2008) on random network coding.

From a mathematical point of view we can view a constant dimensional subspace code simply as a subset of the finite Grassmann variety $\text{Grass}(k, \mathbb{F}_q^n)$ defined over some finite field $\mathbb{F}_q$.

One has a natural distance function on the Grassmannian. For this assume $\mathcal{U}, \mathcal{V} \subseteq \mathbb{F}_q^n$ are two subspaces. Then one defines their distance through:

$$d_S(\mathcal{U}, \mathcal{V}) := \dim(\mathcal{U} + \mathcal{V}) - \dim(\mathcal{U} \cap \mathcal{V}). \tag{1}$$

Once the distance for code elements is defined one gets a natural notion of distance for a subspace code by simply defining it as the minimal distance between two elements.

As in the classical theory of linear block codes it is a major design problem to come up with algebraic construction of constant dimension subspace codes whose distance is optimal or near optimal.

A survey on the construction of constant dimensional subspace codes is given in Horlemann-Trautmann and Rosenthal (2018).

As in the classical literature on coding theory one defines the distance $\text{dist}(\mathcal{C})$ of a code $\mathcal{C}$ as the minimal distance of two different code elements. The goal is once more the construction of subspace codes with large distance and many code elements.

⋆ Research supported by Swiss National Science Foundation under grant no. 188430

2. SOME KNOWN ALGEBRAIC CONSTRUCTIONS OF CONSTANT DIMENSION SUBSPACE CODES

Different from the theory of linear block codes there exist relatively few algebraic constructions of constant dimension subspace codes.

A major idea was already introduced by Kötter and Kschischang (2008) who showed that good rank metric codes give raise to good subspace codes by embedding the rank metric code into the 'thick open cell' of the Grassmann variety. The distance of the subspace code is then bounded by the distance of the underlying rank metric code.

In terms of matrices this lifting construction can be seen in the following way: Let

$$\{M_i \in \text{Mat}_{k\times m} \mid i = 1, \ldots, N\}$$

be a rank metric code defined over some finite field $\mathbb{F}_q$ and having N elements and minimum distance δ. Then the subspace code

$$\left\{\text{rowspace}_{\mathbb{F}_q}[I_k\ M_i] \in Grass(k, \mathbb{F}_q^{k+m}) \mid i = 1, \ldots, N\right\}$$

has also N elements and distance 2δ as one readily verifies.

Another major idea is to study group actions on the Grassmannian and to consider the orbit under this group actions. This then leads to the concept of 'Orbit codes' Trautmann et al. (2010) and the concept of 'cyclic orbit codes' Trautmann et al. (2013).

Beyond above construction techniques there exist several constructions techniques using geometric and combinatorial designs. The interested reader will find a survey in Horlemann-Trautmann and Rosenthal (2018).

It would certainly be desirable to have also construction techniques for constant dimension subspace codes which are based on some algebraic evaluation technique as this is done very successfully for Algebraic Geometric Goppa codes.

In this talk we will show how the associated Hermann Martin curve to a linear system (or a convolutional code) can be used to construct subspace codes via evaluation in some possible extension field. In the next section we will describe this technique. To our knowledge no similar constructions of subspace codes using evaluation maps is known.

3. THE ASSOCIATED HERMANN-MARTIN CURVE TO A LINEAR SYSTEM

It was an important contribution of Martin and Hermann (1978) that every linear system defines in a natural way a curve of genus zero in a Grassmann variety. One often calls the resulting curve the Hermann-Martin curve induced by the linear system. To make this concept a little more precise let $\mathbb{K}$ be an arbitrary field and consider a $k \times m$ transfer function $G(s)$.

Definition 1. Let $G(s)$ be a $k \times m$ transfer function and consider the map

$$h: \ \mathbb{K} \longrightarrow \mathrm{Grass}(k, \mathbb{K}^{k+m}), \ s \mapsto \mathrm{rowspace}_{\mathbb{K}}[I_k \ G(s)]. \quad (2)$$

Then h is called the *Hermann-Martin map* associated to the transfer function $G(s)$.

As this map is a rational map all the poles are removable. In order to see this in term of matrices consider a minimal left coprime factorization of the transfer function $G(s) = D^{-1}(s)N(s)$. Then h is equivalently described through:

$$h: \ \mathbb{K} \longrightarrow \mathrm{Grass}(k, \mathbb{K}^{p+m}), \ s \mapsto \mathrm{rowspace}_{\mathbb{K}}[D(s) \ N(s)]. \quad (3)$$

Note also that by the properties of a minimal left coprime factorization one has that $\mathrm{rowspace}_{\mathbb{K}}[D(\alpha) \ N(\alpha)]$ has full row rank for all elements α in the algebraic closure of $\mathbb{K}$ and the map can even be extended to the whole projective line $\mathbb{P}^1_{\mathbb{K}}$.

The identification by Martin and Hermann (1978) goes actually further as the McMillan degree of the transfer function corresponds to the degree of the Hermann-Martin curve and the observability indices of the linear system correspond to the Grothendick indices of an associated bundle over the projective line. (The pull back of the tautological bundle using the Hermann-Martin map). In the convolutional codes literature the observabilities indices are also often referred to as the Forney indices Forney, Jr. (1975) of the convolutional code and the concepts also naturally translate here.

The interested reader will find more material on these intriguing connections in Rosenthal (2005) and material on convolutional codes can be found in the recent survey article Lieb et al. (2021).

In the next section we will show how it is possible to construct excellent subspace codes startinng from a linear system (or convolutional code) and using evaluation of the the Hermann-Martin map.

4. A CONSTRUCTION OF SUBSPACE CODES USING THE HERMANN MARTIN MAP

In the sequel assume that the base field is the finite field $\mathbb{F}_q$. If $G(s)$ is a transfer function having the left coprime factorization $G(s) = D^{-1}(s)N(s)$ then we know from systems theory that $\mathrm{rowspace}_{\mathbb{K}}[D(\alpha) \ N(\alpha)]$ has full row rank for all elements α in any extension field of $\mathbb{F}_q$.

Based on this observation one can define a subspace code through:

$$\{\mathrm{rowspace}_{\mathbb{K}}[D(\alpha) \ N(\alpha)] \mid \alpha \in \mathbb{K}\}, \quad (4)$$

where $\mathbb{K} = \mathbb{F}_{q^k}$ is a finite extension field of $\mathbb{F}_q$.

Of course note that the resulting subspace code is a subspace code in the Grassmannian $\mathrm{Grass}(k, \mathbb{K}^n)$ defined over the extension field. It is also not clear how good the codes can be if one does such an evaluation.

In the sequel we will show how one can overcome the difficulties with the extension field and how it is possible to come up with excellent constant dimension subspace codes.

For simplicity we will consider only one input, one output transfer functions

$$G(s) := \frac{n(s)}{d(s)} \in \mathbb{F}_q(s).$$

Here $n(s), d(s)$ are simply elements of the polynomial ring $\mathbb{F}_q[s]$.

In order to present our main result we first have to make a definition:

Definition 2. A rational function $\frac{n(s)}{d(s)} \in \mathbb{F}_q(s)$ is called a permuation rational function over the extension field $\mathbb{K} = \mathbb{F}_{q^k}$ if the map

$$\varphi: \ \mathbb{K} \longrightarrow \mathbb{K}, \ s \mapsto \frac{n(s)}{d(s)} \quad (5)$$

describes a permutation of the extension field $\mathbb{K}$.

Note that if the denominator polynomial $d(s)$ is a constant then a permutation rational function is simply a permutation polynomial for $\mathbb{K} = \mathbb{F}_{q^k}$ this remark also shows that permutation rational functions are plentiful.

As it is well known one can identify elements of the extension field $\mathbb{K} = \mathbb{F}_{q^k}$ with the $\mathbb{F}_q$ algebra $\mathbb{F}_q[M]$ where M is a $k \times k$ matrix defined over $\mathbb{F}_q$ whose characteristic polynomial is irreducible.

A main result which hopefully justifies the outlined construction technique is then:

Theorem 3. Assume $\frac{n(s)}{d(s)} \in \mathbb{F}_q(s)$ is a permutation rational function over some extension field $\mathbb{K} = \mathbb{F}_{q^k}$ which is also non-proper, i.e. numerator degree is larger than the denominator degree. Identify elements of $\mathbb{K}$ with elements of the $\mathbb{F}_q$ algebra $\mathbb{F}_q[M]$. Then the evaluation map:

$$\mathbb{P}^1_{\mathbb{K}} \longrightarrow \mathrm{Grass}(k, \mathbb{K}^{2k}), \ \alpha \mapsto \mathrm{rowspace}_{\mathbb{K}}[d(\alpha) \, n(\alpha)]$$

defines a so called spread code. In particular this is a subspace code having maximal possible distance $2k$ and the number of elements is $q^k + 1$, the maximal possible cardinality.

Spread codes are somehow optimal subspace codes. The proof of the theorem follows from the way spread codes were constructed in Manganiello et al. (2008).

It will be a matter of future research to investigate if other evaluation maps can lead to subspace codes with optimal or near optimal distance.

Here one should in particular also look at the evaluation map based on multidimensional convolutional codes Weiner (1998).

A Finite Lyapunov Matrix-Based Stability Criterion via Piecewise Linear Approximation ⋆

Irina V. Alexandrova *

* *St. Petersburg State University, 7/9 Universitetskaya nab., St. Petersburg, 199034, Russia (e-mail: i.v.aleksandrova@spbu.ru).*

Abstract: Recently, a number of Lyapunov matrix-based necessary and sufficient stability tests which require a finite set of operations to be verified were presented for linear time-invariant time delay systems, see Egorov et al. (2017), Gomez et al. (2019) and Bajodek et al. (2022). Motivated by those works, in this contribution we revisit the early paper Medvedeva & Zhabko (2015) and develop the idea to construct a necessary and sufficient finite stability test for a single-delay system as well. The approach relies on a simple piecewise linear approximation of the arguments of Lyapunov–Krasovskii functionals based on the Lyapunov matrix, and shows its competitiveness at least in case of small delays.

Keywords: time delay systems, linear systems, exponential stability, Lyapunov–Krasovskii functionals, Lyapunov matrices

The Lyapunov–Krasovskii functionals with prescribed derivative based on the so-called Lyapunov matrix are known to deliver the necessary and sufficient stability conditions for linear time-invariant time delay systems (Kharitonov & Zhabko, 2003). However, verification of their positive definiteness required for the stability test is challenging. Recently, a number of finite necessary and sufficient tests where such verification is reduced to positive definiteness analysis of a certain block matrix based on the Lyapunov matrix values have been appeared. In Egorov et al. (2017); Egorov & Mondié (2014); Gomez et al. (2019), this was achieved by approximating the functionals arguments by specific piecewise continuous functions based on the fundamental matrix of the system. The approach of Bajodek et al. (2022) employs a different type of approximation based on Legendre polynomials. The benefit of the first approach is that the resulting block matrix has very nice structure. Indeed, it consists solely of the Lyapunov matrix values at different points of the delay interval even for systems with multiple delays. In the second approach, the Lyapunov matrix-based integrals are involved in the matrix. However, its dimension is much smaller, which is a significant advantage.

It is important to note that both approaches rely on the key ideas of early works (Medvedeva & Zhabko, 2013, 2015) which made the construction of finite necessary and sufficient Lyapunov matrix-based stability tests possible. Those ideas include introducing a specific set of functions satisfying the condition $\|\varphi(\theta)\| \leqslant \|\varphi(0)\|$ for $\theta \in [-h, 0]$ in context of positive definiteness test; showing that the approximation error (i.e. the difference between the exact and the approximated functionals) tends towards zero when the discretization is refined; estimating the exact functional on the solution from the mentioned set in case of instability. The numerical scheme proposed in Medvedeva & Zhabko (2013, 2015) employed simply piecewise linear or piecewise cubic approximations of the functionals arguments. Here, being motivated by Egorov et al. (2017); Gomez et al. (2019) and Bajodek et al. (2022), we give a new perspective on the piecewise linear approximation scheme of Medvedeva & Zhabko (2015). The goal is to find a compromise between the resulting block matrix dimension and its simplicity as well as whole computational performance of the approach.

Note that our approach is different from those of Gu (1997) where the functionals kernels rather than arguments are approximated by piecewise linear matrix functions.

Notation: Assume that initial functions belong to the space $PC\big([-h, 0], \mathbb{R}^n\big)$ of piecewise continuous $\mathbb{R}^n$-valued functions defined on $[-h, 0]$ which is supplied with the norm $\|\varphi\|_h = \sup_{\theta\in[-h,0]} \|\varphi(\theta)\|$; $C^2\big([-h, 0], \mathbb{R}^n\big)$ stands for the space of twice continuously differentiable vector functions; $\Re(s)$ denotes the real part of a complex value s; $\lambda_{\min}(W)$ is the smallest eigenvalue of a matrix W; notation $k = \overline{n_1, n_2}$, where $n_1, n_2 \in \mathbb{Z}$, $n_1 < n_2$, means that k is an integer between n_1 and n_2; $\lceil\cdot\rceil$ denotes the ceiling function; $\mathrm{vec}(X)$ means a vectorization of the matrix X; $A \otimes B$ stands for the Kronecker product, namely,

$$A \otimes B \stackrel{\text{def}}{=} \begin{pmatrix} b_{11}A & b_{21}A & \dots & b_{n1}A \\ b_{12}A & b_{22}A & \dots & b_{n2}A \\ \vdots & \vdots & \ddots & \vdots \\ b_{1n}A & b_{2n}A & \dots & b_{nn}A \end{pmatrix},$$

where $B = \big\{b_{ij}\big\}_{i,j=1}^{n}$.

In this work, we analyze the exponential stability of a linear time delay system of the form

$$\dot{x}(t) = A_0 x(t) + A_1 x(t - h), \quad t \geqslant 0. \tag{1}$$

⋆ The work was supported by the Russian President Program for promotion of young researchers, Project MK-2301.2022.1.1.

Here, A_0, A_1 are constant $n \times n$ matrices, and $h \geqslant 0$ is a constant delay. Given a positive definite matrix W, consider a functional with the derivative prescribed along the solutions of system (1) as

$$\frac{\mathrm{d}v_0(x_t)}{\mathrm{d}t} = -x^T(t)Wx(t), \quad t \geqslant 0.$$

This functional is given by (Huang, 1989)

$$v_0(\varphi) = \varphi^T(0)U(0)\varphi(0) + 2\varphi^T(0)\int_{-h}^{0} U^T(h+\theta)A_1\varphi(\theta)\mathrm{d}\theta + \int_{-h}^{0}\int_{-h}^{0} \varphi^T(\theta_1)A_1^T U(\theta_1-\theta_2)A_1\varphi(\theta_2)\mathrm{d}\theta_2\mathrm{d}\theta_1.$$

Here, $U(\tau)$, $\tau \in [-h,h]$, is called the Lyapunov matrix of system (1) associated with W. This matrix can be computed as a matrix exponential provided that the so-called Lyapunov condition holds, see Kharitonov (2013) for the details. Now, introduce the set

$$\mathcal{S} = \Big\{\varphi \in C^2([-h,0],\mathbb{R}^n) \;\Big|\; \|\varphi\|_h = \|\varphi(0)\| = 1, \; \|\varphi^{(l)}\|_h \leqslant K^l, \; l = 1,2\Big\},$$

where $K = \|A_0\| + \|A_1\|$, and $\varphi^{(l)}$ means the l-th derivative of φ. It is shown in Medvedeva & Zhabko (2013, 2015) that system (1) is exponentially stable, if and only if there exist functional v_0 and a constant $\mu > 0$ such that

$$v_0(\varphi) \geqslant \mu\|\varphi(0)\|^2, \quad \varphi \in \mathcal{S}.$$

In other words, positive definiteness of the functional may be assessed on the set $\mathcal{S}$ only for the stability test of system (1). Moreover, if system (1) is unstable, then there exists a function $\varphi \in \mathcal{S}$ such that

$$v_0(\varphi) \leqslant -a_0 \stackrel{\text{def}}{=} -\lambda_{\min}(W)/(4\hat{\alpha}),$$

where $\hat{\alpha}$ is such that $\Re(s) \leqslant \hat{\alpha}$ with s being an eigenvalue of an unstable system (1). In particular, $\hat{\alpha} = K$ may be taken as a rough bound. The last-mentioned claim can be found in the implicit form in Alexandrova & Zhabko (2019).

Below, we revisit a piecewise linear discretization scheme of a function φ in functional v_0 proposed in Medvedeva & Zhabko (2015). First, discretize an interval $[-h,0]$ with the points $\theta_j = -j\Delta$, $j = \overline{0,N}$, and consider a piecewise linear approximation of a function φ given by

$$\varphi(s+\theta_j) = l_N(s+\theta_j) + \eta_N(s+\theta_j), \;\; s \in [-\Delta, 0], \quad (2)$$

$j = \overline{0,N-1}$, where

$$l_N(s+\theta_j) = \varphi(\theta_j)\left(1+\frac{s}{\Delta}\right) - \varphi(\theta_{j+1})\frac{s}{\Delta}. \quad (3)$$

Here, $l_N(\theta)$ and $\eta_N(\theta)$, $\theta \in [-h,0]$, stand for the approximation itself and the approximation error, respectively. Now, we substitute the approximation (2)–(3) into the functional $v_0(\varphi)$ and arrive at the expression

$$v_0(\varphi) = v_0(l_N) + \Psi_N.$$

It turns out that the approximated functional $v_0(l_N)$ represents a quadratic form with respect to the vector

$$\widehat{\varphi} = \begin{pmatrix} \varphi(0) \\ \varphi(\theta_1) \\ \vdots \\ \varphi(\theta_N) \end{pmatrix}.$$

That is,

$$v_0(l_N) = \widehat{\varphi}^T \mathcal{L}_N \widehat{\varphi},$$

where $\mathcal{L}_N = \left\{\mathcal{L}^{ij}\right\}_{i,j=0}^{N}$ consists of the blocks $\mathcal{L}^{ij}$ of dimensions $n \times n$. Further, the piecewise linear approximation error admits a bound of the form

$$\|\eta_N(s+\theta_j)\| \leqslant \frac{1}{2}K^2(-s)(s+\Delta), \quad s \in [-\Delta, 0],$$

for all $j = \overline{0,N-1}$. Hence, we derive that

$$|\Psi_N| \leqslant \delta_N \stackrel{\text{def}}{=} \frac{c_1}{N^2} + \frac{c_2}{N^4},$$

where

$$c_1 = \frac{1}{6}K^2h^3(M_1 + hM_2), \quad c_2 = \frac{1}{144}M_2K^4h^6,$$
$$M_1 = \max_{\theta\in[0,h]}\|U^T(\theta)A_1\|, \;\; M_2 = \max_{\theta\in[-h,h]}\|A_1^T U(\theta)A_1\|.$$

Clearly, the term Ψ_N approaches zero when the value of N tends to infinity. Following Gomez et al. (2019) and Bajodek et al. (2022), we introduce the next lemma which plays a key role in the presentation of the result in the form a finite criterion.

Lemma 1. Given $\varepsilon > 0$, if

$$N \geqslant \sqrt{\frac{c_1 + \sqrt{c_1^2 + 4\varepsilon c_2}}{2\varepsilon}},$$

then $|\Psi_N| \leqslant \varepsilon$.

Finally, defining the value

$$N^\star = \left\lceil \sqrt{\frac{c_1 + \sqrt{c_1^2 + 4a_0c_2}}{2a_0}} \right\rceil,$$

we are ready present the following stability criterion.

Theorem 2. System (1) is exponentially stable, if and only if the Lyapunov condition holds and

$$\min_{\substack{\|\zeta_0\|=1,\\ \|\zeta_j\|\leqslant 1,\, j=\overline{1,N^\star}}} \zeta^T\mathcal{L}_{N^\star}\zeta > 0. \quad (4)$$

Here, $\zeta = \left(\zeta_0^T, \zeta_1^T, \ldots, \zeta_{N^\star}^T\right)^T \in \mathbb{R}^{n(N^\star+1)}$.

Note that instead of (4) positive semi-definiteness of matrix $\mathcal{L}_{N^\star+1}$ may be verified. Below, we present expressions for the blocks $\mathcal{L}^{ij}$ of the matrix $\mathcal{L}_N$ for completeness:

$$\mathcal{L}^{00} = U(0) + 2\int_{-\Delta}^{0} U^T(s+N\Delta)\left(1+\frac{s}{\Delta}\right)\mathrm{d}sA_1 + A_1^T\int_{-\Delta}^{0}\int_{-\Delta}^{0}\left(1+\frac{s_1}{\Delta}\right)\left(1+\frac{s_2}{\Delta}\right) \times U(s_1-s_2)\mathrm{d}s_2\mathrm{d}s_1A_1,$$

$$\mathcal{L}^{k,k+l} = A_1^T\int_{-\Delta}^{0}\int_{-\Delta}^{0}\Big\{\Big[\Big(1+\frac{s_1}{\Delta}\Big)\Big(1+\frac{s_2}{\Delta}\Big) + \frac{s_1s_2}{\Delta^2}\Big] \times U(s_1-s_2+l\Delta) + \Big(1+\frac{s_1}{\Delta}\Big)\Big(-\frac{s_2}{\Delta}\Big) \times U(s_1-s_2+(l-1)\Delta) + \Big(-\frac{s_1}{\Delta}\Big)\Big(1+\frac{s_2}{\Delta}\Big) \times U(s_1-s_2+(l+1)\Delta)\Big\}\mathrm{d}s_2\mathrm{d}s_1A_1,$$

$$\mathcal{L}^{NN} = A_1^T\int_{-\Delta}^{0}\int_{-\Delta}^{0}\frac{s_1s_2}{\Delta^2}U(s_1-s_2)\mathrm{d}s_2\mathrm{d}s_1A_1,$$

$$\begin{aligned}
\mathcal{L}^{0k} &= \int_{-\Delta}^{0} \Big[U^T(s+(N-k)\Delta)\left(1+\frac{s}{\Delta}\right) \\
&\quad + U^T(s+(N-k+1)\Delta)\left(-\frac{s}{\Delta}\right)\Big] \mathrm{d}s A_1 \\
&\quad + A_1^T \int_{-\Delta}^{0}\int_{-\Delta}^{0} \left(1+\frac{s_1}{\Delta}\right) \\
&\quad \times \Big[\left(1+\frac{s_2}{\Delta}\right) U(s_1-s_2+k\Delta) \\
&\quad + \left(-\frac{s_2}{\Delta}\right) U(s_1-s_2+(k-1)\Delta)\Big] \mathrm{d}s_2 \mathrm{d}s_1 A_1, \\
\mathcal{L}^{0N} &= \int_{-\Delta}^{0} U^T(s+\Delta)\left(-\frac{s}{\Delta}\right) \mathrm{d}s A_1 \\
&\quad + A_1^T \int_{-\Delta}^{0}\int_{-\Delta}^{0} \left(1+\frac{s_1}{\Delta}\right)\left(-\frac{s_2}{\Delta}\right) \\
&\quad \times U(s_1-s_2+(N-1)\Delta)\mathrm{d}s_2 \mathrm{d}s_1 A_1, \\
\mathcal{L}^{kN} &= A_1^T \int_{-\Delta}^{0}\int_{-\Delta}^{0} \Big[\left(1+\frac{s_1}{\Delta}\right) \\
&\quad \times U(s_1-s_2+(N-k-1)\Delta) + \left(-\frac{s_1}{\Delta}\right) \\
&\quad \times U(s_1-s_2+(N-k)\Delta)\Big] \left(-\frac{s_2}{\Delta}\right) \mathrm{d}s_2 \mathrm{d}s_1 A_1.
\end{aligned}$$

Here, $k = \overline{1, N-1}$, $l = \overline{0, N-k-1}$, and $\mathcal{L}^{jk} = \mathcal{L}^{kj\,T}$ for other indices.

Despite the fact that the matrix $\mathcal{L}_N$ is determined by the integrals of the Lyapunov matrix, multiplied possibly by polynomials, we claim that all those integrals may be computed explicitly in a vectorized form, without performing the operation of integration in fact, provided that $\det(L) \neq 0$, where

$$L = \begin{pmatrix} I \otimes A_0 & I \otimes A_1 \\ -A_1^T \otimes I & -A_0^T \otimes I \end{pmatrix}.$$

For instance, the terms

$$J_l = \int_{-\Delta}^{0} U(s+l\Delta)\mathrm{d}s, \quad l = \overline{1, N},$$

may be computed from

$$\begin{pmatrix} a_l \\ a^\star_{N-l+1} \end{pmatrix} = L^{-1} \begin{pmatrix} u(l\Delta) - u((l-1)\Delta) \\ u^\star((N-l)\Delta) - u^\star((N-l+1)\Delta) \end{pmatrix},$$

where

$$u(\tau) = \mathrm{vec}(U(\tau)), \quad u^\star(\tau) = \mathrm{vec}(U^T(\tau)),$$
$$a_l = \mathrm{vec}(J_l), \quad a_l^\star = \mathrm{vec}(J_l^T), \quad l = \overline{1, N}.$$

This fact allows us to improve computational performance of the approach significantly, comparing to the experiments made in Medvedeva & Zhabko (2015).

Finally, we suggest to use our approach in a combination with the necessary stability conditions of Egorov & Mondié (2014), since the values $U(k\Delta)$, $k = \overline{0, N}$, involved in their matrix are calculated during the computation of $\mathcal{L}_N$ anyway.

Abstract: Signature methods represent a non-parametric way for extracting characteristic features from time series data which is essential in machine learning tasks. This explains why these techniques become more and more popular in econometrics and mathematical finance. Indeed, signature based approaches allow for data-driven and thus more robust model selection mechanisms, while first principles like no arbitrage can still be easily guaranteed.
Here we focus on financial models whose dynamics are described by linear functions of the (time-extended) signature of a primary underlying process, which can range from a (market-inferred) Brownian motion to a general multidimensional tractable stochastic process. The framework is universal in the sense that any classical model can be approximated arbitrarily well and that the model characteristics can be learned from all sources of available data by simple methods. In view of option pricing and calibration, key quantities that need to be computed in these models are the expected value or Fourier Laplace transform of the signature of the primary underlying process. Surprisingly this can be achieved via techniques from affine and polynomial processes. These formulas can then be used in the calibration procedure to option prices, while calibration to time series data just reduces to a simple regression.

Keywords: signature methods, calibration of financial models, Monte Carlo methods, linear infinite dimensional systems, affine and polynomial processes
MSC (2010) Classification: 91B70, 62P05, 65C20.

1. INTRODUCTION

In the past few years data driven models have successfully entered the area of stochastic modeling and mathematical finance. The paradigm of calibrating a few well interpretable parameters has changed to learning the model's characteristics as a whole, thereby exploiting all available sources of data. Thus highly parametric and over-parametrized models methods have gained more and more importance. On the one hand side this has opened the door to robust and more data-driven model selection mechanisms, while on the other hand model classes still have to be chosen in a way to guarantee first principles from finance like "no arbitrage". Relying on different universal approximation theorems then leads to different well-suited universal classes of dynamic processes that can serve both purposes.

One class of such financial models are so-called *neural stochastic differential equations* (SDEs) which are defined as Itô-diffusions where the drift and the volatility function are parameterized via neural networks (see e.g. Gierjatowicz et al. (2020); Cuchiero et al. (2020); Cohen et al. (2021)). Another class of models, considered in Perez-Arribas et al. (2020) and inspiring the current work, are so-called *Sig-SDEs*. These are again Itô-diffusions, however in this case the characteristics are linear functions of the *signature* (more precisely introduced below) of some driving Brownian motion and time.

We consider here a related approach, where the asset price model itself is parameterized as a linear function of the signature of a primary underlying process. This underlying process can either be a classical driving signal, e.g. a Brownian motion, but also a more general tractable stochastic model describing well observable quantities.

Before going into the details of the current model framework, let us first explain the mathematical significance of *signature*, a notion which goes back to Chen (1977, 1957) and plays a particular important role in the context of rough path theory initiated by Lyons (1998). Indeed, the signature of an $\mathbb{R}^d$-valued path serves as linear regression basis for continuous path functionals, since

- it is *point-separating*, as long as the path contains one strictly monotone component (which can always be achieved by adding time), as it then uniquely determines the underlying path;

- linear functions on the signature form an algebra that contains 1. More precisely, every polynomial on the signature may be realized as a linear function via the so-called shuffle product.

The Stone-Weierstrass theorem therefore yields a universal approximation theorem (UAT), telling that continuous (with respect to a certain variation distance) path functionals on compact sets can be uniformly approximated by a linear function of the time extended signature. Therefore signature-based methods provide a non-parametric way to extract characteristic features (linearly) from time series data, which is essential in machine learning tasks in finance. This explains why these techniques become more and more popular in econometrics and mathematical finance, see e.g., Buehler et al. (2020); Perez-Arribas et al. (2020); Lyons et al. (2020); Ni et al. (2021); Bayer et al. (2021); Akyildirim et al. (2022) and the references therein.

We consider here signature-based methods with the goal to provide a data-driven, universal, tractable and easy to calibrate model for a set of traded assets $S = (S^1, \dots, S^m)$. To achieve this the main ingredient is a primary underlying process $(\widehat{X}_t)_{t\geq 0} = (t, X_t^1, \dots, X_t^d)_{t\geq 0}$ with $d \leq m$, where X is a continuous Itô-semimartingale. We suppose here that time-series data of $\widehat{X}$ is available and that its signature denoted by $\widehat{\mathbb{X}}$ serves a linear regression basis for S.

2. NOTATION AND PRELIMINARIES ON SIGNATURE

We shall now introduce the most essential concepts in order to rigorously define signature in the current context. In particular, we shall use the following notation:

- The signature takes values in the extended tensor algebra $T((\mathbb{R}^d))$ given by
$$T((\mathbb{R}^d)) := \{(a_0, \dots, a_n, \dots) \,|\, n \geq 0,\, a_n \in (\mathbb{R}^d)^{\otimes n}\}.$$
Elements of $T((\mathbb{R}^d))$ are denoted in bold face, e.g. $\mathbf{a} = (a_0, a_1, \dots, a_n, \dots)$.
- Let $I = (i_1, \dots, i_n)$ be a multi-index with entries in $\{1, \dots, d\}$ and denote by $e_I = e_{i_1} \otimes \cdots \otimes e_{i_n}$ the basis elements of $(\mathbb{R}^d)^{\otimes n}$.
- We write $\langle e_I, \mathbf{a}\rangle$ to extract the I^{th} component from a_n. More generally we often write $\mathbf{u}(\mathbf{x}) = \langle \mathbf{u}, \mathbf{x}\rangle$ if $\sum_I |u_I x_I| < \infty$ and call this linear maps in $\mathbf{x}$ (on their domain of convergence).

The coordinate signature indexed by a multi-index $I = (i_1, \dots, i_n)$ of an $\mathbb{R}^d$-valued semimartingale $\widehat{X}$ is defined via iterated Stratonovic integrals (denoted by $\circ$)
$$\langle e_I, \widehat{\mathbb{X}}_T\rangle := \int_{0<t_1<\cdots<t_n<T} \circ d\widehat{X}_{t_1}^{i_1} \cdots \circ\, d\widehat{X}_{t_n}^{i_n}.$$
Hence, $\widehat{\mathbb{X}}_T = 1 + \sum_{n=1}^{\infty} \sum_{|I|=n} \langle e_I, \widehat{\mathbb{X}}_T\rangle e_I \in T((\mathbb{R}^d))$.

3. THE MODEL AND ITS PROPERTIES

Let us now describe the precise modeling framework. The traded assets $(S^1, \dots, S^m)$ are modeled via $S_n(\ell) = (S_n^1(\ell), \dots, S_n^m(\ell))$ where
$$S_n^j(\ell^j)_t := \ell(\mathbb{X}_t) = \ell_0^j + \sum_{0<|I|\leq n} \ell_I^j \langle e_I, \widehat{\mathbb{X}}_t\rangle, \quad \text{(Sig-model)}$$
with

- $\widehat{\mathbb{X}}$ the signature of $\widehat{X}$,
- $n \in \mathbb{N}$ is the degree of truncation,
- $\ell_0^j, \ell_I^j \in \mathbb{R}$ are the deterministic coefficients of the linear map ℓ to be found from data.

For notational simplicity we shall in the sequel set $m = 1$.

Note that since it is possible to express (Sig-model) also in terms of stochastic integrals, the class of Sig-SDEs considered in Perez-Arribas et al. (2020) can be embedded in our framework by choosing a one-dimensional Brownian motion as primary underlying process.

The attractiveness of this model class described by (Sig-model) arises from several important features that we summarize in the sequel:

Universality: Any classical model driven by Brownian motion can be arbitrarily well approximated. This is again a consequence of the Stone-Weierstrass theorem because the solution map of a stochastic differential equation is a continuous (with respect to a certain variation distance) map of the signature of the driving signal.

No arbitrage: The model can also be expressed in terms of stochastic integrals with respect to local martingales, from which conditions for no-arbitrage can be easily deduced.

Tractable option pricing formulas: By relying on the above UAT and in turn on approximations via so-called sig-payoffs of the form $\langle e_J, \widehat{\mathbb{S}}_T(\ell)\rangle$ (see also Lyons et al. (2020)), (approximate) option pricing reduces to the computation of the expected signature of $\widehat{X}$. Thus the question is for which primary underlying processes $\mathbb{E}_{\mathbb{Q}}[\widehat{\mathbb{X}}_T]$ can be easily computed. This is the case for highly generic processes of the form
$$d\widehat{X}_t = \mathbf{b}(\widehat{\mathbb{X}}_t)dt + \sqrt{\mathbf{a}(\widehat{\mathbb{X}}_t)}dB_t, \qquad (1)$$
where $\mathbf{b}$ and $\mathbf{a}$ are linear maps. Indeed, as shown in Cuchiero et al. (2022) these processes can be seen as projections of extended tensor algebra valued *affine and polynomial process* (see Duffie et al. (2003); Cuchiero et al. (2012)), which implies that the expected signature can be computed by solving a linear ODE. This ODE is usually infinite dimensional, but if $\widehat{X}$ is itself a polynomial process it becomes finite dimensional. Analogously we can rely on affine technology, i.e. solving (infinite dimensional) Riccati equations to obtain the Fourier-Laplace transform of the marginals of $\widehat{\mathbb{X}}$.

Note that similarly to polynomial approximations the approximation of vanilla call and put option via sig-payoffs is not straightforward. Nevertheless sig-payoffs can be used for variance reduction techniques and are interesting in their own right as certain path dependent options like Asian forwards fall into this class.

Calibration to time series data: The tractability of the model class becomes particularly clear in view of calibration tasks. Indeed, when the goal is to calibrate to times series data of market prices $(S_{t_i}^M)_{i=1}^N$, this task reduces to a simple linear regression.

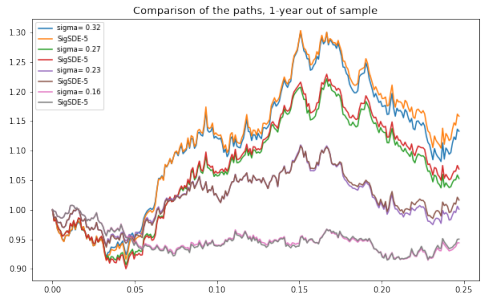

Fig. 1. Out of sample comparison between trajectories generated from a Black-Scholes model and the calibrated Sig-model.

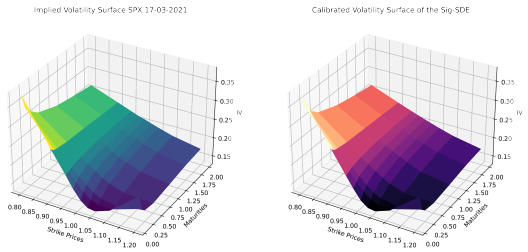

Fig. 2. Comparison of the market volatility surface (left) and the calibrated Sig-model volatility surface (right).

Calibration to options: When calibrating to the market's volatility surface, we exploit the linearity of the model by precomputing Monte-Carlo samples of $\widehat{\mathbb{X}}$ and then performing a standard optimizations to find the parameters of the linear map ℓ. By initializing the parameters of ℓ appropriately this optimization task actually becomes a convex problem, which makes it particularly tractable. On simulated and real market data (S&P 500 index) we show that a full calibration to the volatility surface, in particular when using time dependent parameters, is highly accurate and very fast.

Note that our calibration method differs from the approach proposed in Perez Arribas (2020) since we do not rely on sig-payoffs as a good approximation of vanilla call and put option via sig-payoffs uniformly over the range of possible models can hardly be achieved.

Subsequently we shall illustrate some of these model features in more detail.

3.1 Calibration to time series data

With regard to calibration to time-series data, the goal is to match N market prices $(S^M_{t_1}, \dots, S^M_{t_N})$. Due to our assumption that time series data of the primary underlying process $\widehat{X}_{t_1}, \dots, \widehat{X}_{t_N}$ (e.g. market inferred Brownian motion) is available, we can compute the path of its signature $\widehat{\mathbb{X}}$. This then serves as linear regression basis to find ℓ by matching the prices, i.e.

$$\text{argmin}_\ell \sum_{i=1}^{N} \left(\ell_0 + \sum_{0\le|I|\le n} \ell_I \langle e_I, \widehat{\mathbb{X}}_{t_i} \rangle - S^M_{t_i} \right)^2$$

Since the dimension of ℓ is typically high, introducing a regularization (Lasso, Ridge) is necessary. In the Figure 3.1 below we illustrate by means of a 4 dimensional Black-Scholes market how well out-of-sample trajectories can be learned. There we us as primary underlying process time extended (market inferred) Brownian motion up to order 5 and regress on its signature.

3.2 Calibration to option data

When calibrating to option data the goal is to match N option prices $(\pi^1, \dots, \pi^N)$ corresponding to European payoffs $F_i(S_{T_i})$ for $i = 1, \dots, N$. Typically we calibrate to call and put options with different strikes and maturities, whose prices are expressed in terms of implied volatility. To achieve this we start by computing M Monte-Carlo samples of $\widehat{\mathbb{X}}^j_{T_1}, \dots, \widehat{\mathbb{X}}^j_{T_N}$ for $j = 1, \dots M$ (under a pricing measure $\mathbb{Q}$). The calibration can then be formalized via

$$\text{argmin}_\ell \sum_{i=1}^{N} w^i \left(\frac{1}{M} \sum_{j=1}^{M} F_i(\ell(\widehat{\mathbb{X}}^j_{T_i})) - \pi_i \right)^2,$$

where w^i are weights, e.g. vega-weights known to match implied volatility well. The advantages of the Sig-model class is that all Monte-Carlo samples can be easily precomputed and re-used, so that the calibration reduces to a simple optimization task without any Monte-Carlo simulation in an optimization step. A further nice feature is that for parameters ℓ such that $\frac{1}{M}\sum_{j=1}^{M} F_i(\ell(\widehat{\mathbb{X}}^j_{T_i})) \ge \pi_i$ the optimization is convex for convex payoffs. This means that for starting values in this range and small learning rates in appropriate gradient descent methods the algorithms are likely to converge to the true minimum.

In Figure 3.2 we illustrate the calibration to an S&P 500 volatility surface (from 17-03-21) by using as primary underlying process a two dimensional time extended Brownian motion. We consider here an extension of the model with time-dependent parameters and achieve a nearly perfect fit. Indeed, with 13 parameters per maturity the absolute error is in the range of 0 to 15 basis points.

3.3 Pricing of sig-payoffs

The tractability of the model is also crucial when it comes to pricing, in particular of path-dependent options. Indeed, sig-payoffs, like Asian forwards, can be priced via the following formula. For generic payoffs these sig-payoffs can be used in an approximate manner, e.g. similarly as in Ackerer and Filipović (2020) for standard polynomial processes, or as control variates to reduce the variance in Monte-Carlo pricing.

Theorem 1. The price of a sig-payoff $\langle e_J, \widehat{\mathbb{S}}_{\mathbb{T}}(\ell) \rangle$ can be expressed as

$$\begin{aligned} \mathbb{E}_{\mathbb{Q}}[\langle e_J, \widehat{\mathbb{S}}_T(\ell) \rangle] &= \langle e(J,\ell), \mathbb{E}_{\mathbb{Q}}[\widehat{\mathbb{X}}_T] \rangle \\ &= \sum_I p_I(J,\ell) \langle e_I, \mathbb{E}_{\mathbb{Q}}[\widehat{\mathbb{X}}_T] \rangle, \end{aligned}$$

where $p_I(J,\ell)$ are polynomials in the coefficients of ℓ.

As already stated above to compute $\mathbb{E}_{\mathbb{Q}}[\widehat{\mathbb{X}}_T]$, an affine and polynomial process point view works for generic primary processes $\widehat{X}$ of form (1) (see Cuchiero et al. (2022) for details).

Code-based digital signatures: state of the art and open challenges

Marco Baldi *

* *Università Politecnica delle Marche, Ancona, Italy (e-mail: m.baldi@univpm.it).*

Abstract: The problem of decoding a random-like linear block code is recognized as one of the most important mathematical problems that apparently will remain hard even with the availability of solvers based on quantum computers. This motivates an increasing interest in code-based cryptography as a solution for the design of post-quantum cryptographic primitives. However, while several robust and efficient code-based systems exist for asymmetric encryption and key exchange, mostly stemming from the McEliece and Niederreiter original cryptosystems, devising robust and efficient code-based signature schemes is a far more challenging task. This work provides an overview of past and current approaches to the problem of designing secure and practical code-based signature schemes following two main directions: adapting the McEliece and Niederreiter schemes to the digital signature setting following the classical hash-and-sign approach or deriving digital signatures from code-based identification schemes through suitable transformations.

Keywords: Code-based cryptography, decoding problem, digital signatures, identification schemes, post-quantum cryptography.

1. INTRODUCTION

Digital signatures traditionally rely on cryptographic trapdoors, that is, functions whose solution is easy to compute for those who own some secret, known as private key, while requiring the solution of some computationally hard problem for all the others. A public key is then derived from the private key through some sort of one-way function, such that it can be publicly distributed without revealing the private key. In the case of digital signatures, the private key of a user allows computing their digital signature of a message, while the associated public key allows verifying the signature or, equivalently, ascertaining the signer's identity and the message integrity.

Cryptographic trapdoors used in widespread digital signature schemes rely on the hardness of either factoring large semiprime numbers or computing discrete logarithms. These classical hard problems have withstood cryptanalysis for about fifty years, and have enabled very fast digital signature schemes with compact signatures. However, quantum algorithms like Shor's algorithm (Shor, 1997) make the same problems solvable in polynomial time with a quantum computer, which motivates the search for alternative, quantum-resistant solutions (Moody, 2021).

The most established solutions for constructing quantum-resistant cryptographic trapdoors are those relying on lattice-based problems, code-based problems, multivariate polynomial problems, isogenies between elliptic curves and others (Chen et al., 2016). Differently from problems based on lattices, which have already been exploited for constructing both efficient asymmetric encryption and digital signature schemes, problems based on coding are more challenging to be exploited as a basis for digital signature schemes. This work provides a critical overview of current solutions for post-quantum digital signatures based on codes, focusing on challenging aspects and describing the most promising avenues for the development of efficient code-based digital signature schemes.

2. HARDNESS OF THE DECODING PROBLEM

The main hard problem derived from coding theory is the so-called decoding problem, that is, the problem of finding the nearest vector (or codeword) belonging to a k-dimensional subspace (named code) $\mathcal{C} \subset \mathbb{F}_q^n$ starting from any vector $\mathbf{x} \in \mathbb{F}_q^n$. Any $k \times n$ matrix $\mathbf{G}$ over $\mathbb{F}_q$ forming a basis for $\mathcal{C}$ is called generator matrix for the code $\mathcal{C}$, while any $(n-k) \times n$ matrix $\mathbf{H}$ over $\mathbb{F}_q$ forming a basis for its dual $\mathcal{C}^\perp$ is called a parity-check matrix for $\mathcal{C}$, such that $\mathcal{C}$ is the kernel of $\mathbf{H}$. The parity-check matrix $\mathbf{H}$ divides the space $\mathbb{F}_q^n$ into q^{n-k} cosets, that is, any vector $\mathbf{x} \in \mathbb{F}_q^n$ belongs to the coset represented by $\mathbf{H} \cdot \mathbf{x}^T$, also known as the syndrome of $\mathbf{x}$ through $\mathbf{H}$. Since any codeword belongs to the coset corresponding to the all-zero syndrome, the aforementioned decoding problem can also be formulated in terms of syndrome, that is, finding the smallest weight vector $\mathbf{e}$ belonging to the same coset of $\mathbf{x}$. In such a case, due to the code linearity, $\mathbf{x} - \mathbf{e}$ has an all-zero syndrome and thus belongs to the code, actually being the decoded codeword. This alternative formulation of the decoding problem is known as syndrome decoding problem.

If we consider the Hamming metric, that is, we define syndrome decoding as finding the vector with the smallest Hamming weight in a coset, then the problem has been proved to be NP-complete for random codes (Berlekamp et al., 1978; Barg, 1994). A number of algorithms have been developed over years for solving such a problem

(Prange, 1962; Dumer, 1989; Lee and Brickell, 1988; Leon, 1988; Stern, 1988; Becker et al., 2012; May et al., 2011; Bernstein et al., 2011), all characterized by exponential complexity, although with progressively decreasing exponential factors.

3. DIGITAL SIGNATURES BASED ON HASH-AND-SIGN

The first and traditional approach to code-based cryptography is the one introduced by McEliece in 1978 (McEliece, 1978), according to which the cleartext message is encoded into a codeword of a public code, and then corrupted with a number of intentional errors below the error correction capability of the public code. The trapdoor is constructed by providing the receiver with a secret representation of the public code which enables decoding through efficient algorithms, while the corresponding public representation of the same codes forces the use of algorithms for general decoding of random codes, which are characterized by exponential complexity. An alternative formulation of the same approach has been introduced by Niederreiter in 1986 (Niederreiter, 1986), and exploits syndromes in the place of noisy codewords.

While these approaches based on decoding work very well for asymmetric encryption, leading to robust and efficient public-key cryptosystems, their conversion into digital signature schemes is more challenging. In fact, differently from some asymmetric cryptosystems like RSA, these cryptosystems cannot be easily converted into hash-and-sign digital signature schemes. In fact, opposed to RSA, these cyptosystems have a domain and an image of the encryption function that do not coincide, which makes them difficult to be "reversed" for obtaining a hash-and-sign scheme. In fact, it is very unlikely that a random cleartext message, or its hash digest, coincides with a syndrome that is correctable through the secret code, or with a codeword of the same code affected by a limited number of errors.

Thus, some workaround needs to be used for making signatures of random messages or their digests easy to generate in the traditional code-based setting, and this normally undermines the primitive security. A well-known proposal in this sense has been made by Courtois, Finiasz, and Sendrier (Courtois et al., 2001), but it has been found exposed to some vulnerabilities that require the adoption of very costly solutions from the point of view of signature generation time and size of public keys. The use of codes characterized by sparse representations, which is a promising avenue for achieving public-key encryption schemes derived from McEliece with compact keys, has also been attempted to build signature schemes relying on the hardness of decoding (Baldi et al., 2013), but with little fortune (Phesso and Tillich, 2016).

A more recent approach is that of exploiting large-weight error vectors, instead of small-weight ones, which are also difficult to find through decoding, especially over non-binary fields. The scheme proposed in (Debris-Alazard et al., 2019), named Wave, exploits this fact, and uses codes in the $(U|U+V)$ form to enable aided versions of general decoding algorithms for signature generation. This provides a step further with respect to CFS, by achieving a public key size growing as λ^2, where λ is the security level in bits. However, a public key with size in the order of 4 megabytes is required for achieving 128 bits of classical security, which is rather large. Moreover, generating signatures requires the execution of a modified version of Prange's general decoding algorithm (Prange, 1962), with a complexity in the order of λ^3, thus resulting in a slow signature generation. Another scheme relying on the hardness of decoding of large-weight vectors has been recently introduced in (Baldi et al., 2022), with the main advantage of a fast signature generation, thanks to the possibility of generating signatures without requiring the execution of a decoding algorithm. However, secure instances have still been studied only for one-time use, and further investigations are needed to address the multiple-time use case.

All the above schemes rely on some hidden code structure, which certainly represents a delicate point and can turn into a vulnerability if the structure of the secret code is not adequately hidden. Such a hidden code structure is no longer required in code-based signature schemes derived from identification schemes, as described next.

4. DIGITAL SIGNATURES FROM IDENTIFICATION SCHEMES

An alternative approach to design digital signature schemes is the one stemming from code-based identification schemes. Classical identification protocols based on zero-knowledge proofs allow one party (the prover) to demonstrate to another party (the verifier) knowledge about a secret, without revealing the secret itself, and work as follows.

(1) The prover, owning the secret, commits to some random data that is sent to the verifier.
(2) The verifier receives the random data and generates a corresponding challenge for the prover.
(3) The prover generates a response to the challenge, without revealing anything concerning the secret.

A zero knowledge identification protocol of this type can be converted into a digital signature scheme through the Fiat-Shamir approach (Fiat and Shamir, 1986), according to which the challenge is obtained through a deterministic function applied to the message, besides committed data, and the transcript of the protocol provides the signature. The rationale of the Fiat-Shamir approach is that of replacing the prover's choices with the output of a hash-based algorithm, thus making the protocol no longer interactive and suitable for digital signatures. The verifier, owning the public key, can then use it to verify that the transcript is actually consistent with the message, thus validating the signature.

The first code-based identification scheme has been proposed by Stern in 1994 (Stern, 1994); several variants have subsequently appeared in the following years (e.g., (Véron, 1997; Gaborit and Girault, 2007; Cayrel et al., 2011; El Yousfi Alaoui et al., 2013)). The main advantage of these schemes is that they use public random-like codes without any hidden structure, which eliminates an important source of potential vulnerabilities. Hence, security is based on a pure, random instance of some (usually NP-hard) problem. These schemes are also characterized by

very compact public keys, which is another important advantage.

However, for many years, digital signature schemes derived from identification protocols have been considered not practical, because of their normally large signatures. In fact, these schemes are characterized by a usually high soundness error, which implies that an adversary can cheat on a single execution of the protocol with non-trivial probability, for example 1/2 or 2/3. This requires iterating the protocol for a significant number of times in order for the adversary to experience a sufficiently small overall cheating probability (say, not greater than $2^{-\lambda}$). As a consequence, the transcript of the protocol becomes rather long, which translates into a significant size of generated signatures, in the order of tens or even hundreds of kilobytes.

However, some recent works have described how to apply several optimizations on top of an identification scheme, in order to reduce the signature size (Gueron et al., 2022; Bettaieb et al., 2021; Bidoux et al., 2022; Becker et al., 2020; Barenghi et al., 2021; Feneuil et al., 2021). These techniques can be thought of as a clever rewriting of the straight identification protocol, with no impact on the underlying security assumptions. Some of them consist, for instance, in extracting randomness from a so-called seed tree, or emulating an imaginary multiparty computation phase. Techniques of this kind have been shown to have a great potential in reducing the signature size. For this reason, zero knowledge identification schemes are currently deemed as one of the most promising strategies to achieve secure and efficient code-based signatures. Another promising avenue to achieve compact public keys and reduced communication costs in zero-knowledge identification schemes based on codes is that of restricting the entries of the searched vector within a subset of the underlying finite field (Baldi et al., 2020).

In this context, but under the setting of lattice-based problems, an important advance is represented by the Schnorr-Lyubashevsky approach (Lyubashevsky, 2012), which indeed allows deriving compact digital signatures from identification schemes. Some attempts have been made for translating such an approach in the code-based setting (Persichetti, 2018), but the resulting schemes have been successfully exposed to cryptanalysis based on statistical approaches (Aragon et al., 2021).

4.1 Identification schemes based on code equivalence

In 2020, a new code-based zero knowledge identification scheme named LESS has been proposed (Biasse et al., 2020). Differently from classical code-based identification schemes, it comes as a three pass protocol in which the soundness error can be arbitrarily reduced by using multiple key pairs. These characteristics are intrinsically due to the fact that the scheme is constructed upon the somehow unorthodox code equivalence problem (which can be described as a transitive code-based group action). In a nutshell, the problem reads as follows: given two linear codes, find an isometry which maps one code into the other. Notably, determining whether two codes are equivalent is a standard problem in coding theory and, as such, has been studied for decades. Despite the fact that code-equivalence is not NP-hard (unless the polynomial hierarchy collapses), there exist instances (e.g., monomial equivalences or permutations of self-dual codes) for which no efficient solver is known. Interestingly, for such instances, the currently known best attack (Beullens, 2020) reduces to the problem of decoding a linear code, which is instead NP-complete, as already said. The original LESS parameters have been broken in (Beullens, 2020), but in a subsequent paper new and secure instances have been recommended (Barenghi et al., 2021), together with several optimizations to make signatures more compact.

Abstract: Port-Hamiltonian DAE systems are discussed that are the composition of a Dirac structure and a Lagrangian subspace, where the latter is generalizing the Hamiltonian function expressing energy storage. The algebraic constraints in such systems are correspondingly divided into Dirac and Lagrange algebraic constraints. The relations between different representations of the same port-Hamiltonian DAE system are discussed.

Keywords: Port-Hamiltonian systems, algebraic constraints, Dirac structures, Lagrangian subspaces, equivalence

1. PORT-HAMILTONIAN DAE SYSTEMS

Differential-algebraic equation (DAE) system models are ubiquitous in physical systems modeling. In particular, the algebraic constraints often arise from interconnection of subsystems. Port-based modeling of complex engineering systems leads to a broad, but specific, class of DAE systems, called *port-Hamiltonian DAE systems*. Analysis, simulation, and control of such systems can benefit from a closer study of the structural properties of port-Hamiltonian DAE systems.

From a port-based modeling perspective Van der Schaft (2013, 2017); Van der Schaft, Jeltsema (2014), the algebraic constraints in port-Hamiltonian systems are primarily reflected in the Dirac structure of the system. However, as was argued before, e.g. in Beattie et al. (2017, 2019); Mehrmann et al. (2018), and more explicitly in Barbero-Linan et al. (2019); Van der Schaft, Maschke (2018, 2020); Gernandt et al. (2021), algebraic constraints may also arise by replacing the Hamiltonian function in the definition of port-Hamiltonian systems by a *Lagrangian subspace* (more general than the graph of the gradient of the Hamiltonian function). The present contribution aims at taking a closer look at the representations and properties of such generalized port-Hamiltonian DAE systems. For simplicity of exposition we will concentrate on linear port-Hamiltonian DAE systems *without* energy dissipation and *without* inputs and outputs. The remaining (autonomous) port-Hamiltonian DAE systems are fully described by two geometric structures, namely a Lagrangian subspace and a Dirac structure.

Recall the definitions of such structures. A Dirac structure on an n-dimensional linear state space $\mathcal{X}$ is specified by a subspace $\mathcal{D} \subset \mathcal{X} \times \mathcal{X}^*$, which is a maximal subspace on which the symmetric canonical bilinear form on $\mathcal{X} \times \mathcal{X}^*$ represented by the $2n \times 2n$ matrix

$$\begin{bmatrix} 0 & I \\ I & 0 \end{bmatrix} \tag{1}$$

is zero. It follows that the dimension of any Dirac structure $\mathcal{D}$ is equal to $\dim \mathcal{X} = n$, and that there exist $n \times n$ matrices K and L such that

$$\mathcal{D} = \ker \begin{bmatrix} K & L \end{bmatrix} = \operatorname{im} \begin{bmatrix} L^\top \\ K^\top \end{bmatrix} \subset \mathcal{X} \times \mathcal{X}^*, \quad KL^\top + LK^\top = 0, \tag{2}$$

while conversely any such pair (K, L) defines a Dirac structure $\mathcal{D}$. Note that the property $KL^\top + LK^\top = 0$ is a generalized skew-symmetry property, and reflects the fact that $e^\top f = 0$ for any $(f, e) \in \mathcal{D}$, expressing power conservation.

Analogously, a Lagrangian subspace is a maximal subspace on which the skew-symmetric canonical symplectic form on $\mathcal{X} \times \mathcal{X}^*$ represented by the $2n \times 2n$ matrix

$$\begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix} \tag{3}$$

is zero. The dimension of any Lagrangian subspace $\mathcal{L}$ is equal to $\dim \mathcal{X} = n$, and for any $\mathcal{L}$ there exist $n \times n$ matrices P and S such that

$$\mathcal{L} = \ker \begin{bmatrix} -S^\top & P^\top \end{bmatrix} = \operatorname{im} \begin{bmatrix} P \\ S \end{bmatrix} \subset \mathcal{X} \times \mathcal{X}^*, \quad S^\top P = P^\top S, \tag{4}$$

while conversely any such pair (P, S) defines a Lagrangian subspace $\mathcal{L}$. The Lagrangian subspace corresponding to a quadratic Hamiltonian function $H(x) = \frac{1}{2} x^\top Q x$, $Q = Q^\top$, is defined by $P = I, S = Q$.

The port-Hamiltonian DAE system corresponding to a pair $(\mathcal{D}, \mathcal{L})$ of a Dirac structure and Lagrangian subspace is defined by the *composition* of $\mathcal{D}$ and $\mathcal{L}$ (over the shared variables $e \in \mathcal{X}^*$) , that is

$$\begin{aligned} \mathcal{D} \circ \mathcal{L} = \{(f, x) \in \mathcal{X} \times \mathcal{X} \mid \text{there exists } e \in \mathcal{X}^* \text{ such that} \\ (f, e) \in \mathcal{D}, (e, x) \in \mathcal{L}\} \end{aligned} \tag{5}$$

This defines the port-Hamiltonian dynamics

$$(-\dot{x}, e) \in \mathcal{D} \circ \mathcal{L} \tag{6}$$

(Note that strictly speaking $-\dot{x} = f$ is an element of the *tangent space* of $\mathcal{X}$ at $x \in \mathcal{X}$, which however can be identified with $\mathcal{X}$.) Coordinate representations of the port-Hamiltonian dynamics (6) can be obtained as follows.

1.1 The x-representation

The composition $\mathcal{D} \circ \mathcal{L} \subset \mathcal{X} \times \mathcal{X}$ can be explicitly computed as follows. First consider the 'intersection' of $\mathcal{D}$ and $\mathcal{L}$, given by the kernel of

$$\begin{bmatrix} K & L & 0 \\ 0 & -P^\top & S^\top \end{bmatrix} \tag{7}$$

Consider a maximal annihilator $[M \;\; N]$ of $\begin{bmatrix} L \\ -P^\top \end{bmatrix}$, that is

$$\ker [M \;\; N] = \operatorname{im} \begin{bmatrix} L \\ -P^\top \end{bmatrix} \tag{8}$$

and thus in particular $ML - NP^\top = 0$. Premultiply the 'intersection' with this maximal annihilator, so as to obtain

$$[M \;\; N] \begin{bmatrix} K & L & 0 \\ 0 & -P^\top & S^\top \end{bmatrix} = \begin{bmatrix} MK & 0 & NS^\top \end{bmatrix} \tag{9}$$

Then $\mathcal{D} \circ \mathcal{L} \subset \mathcal{X} \times \mathcal{X}$ is given as

$$\mathcal{D} \circ \mathcal{L} = \ker \begin{bmatrix} MK & NS^\top . \end{bmatrix} \tag{10}$$

Thus the resulting DAE system (in the original state variables x for $\mathcal{X}$) is the port-Hamiltonian DAE system

$$MK\dot{x} = NS^\top x, \quad \text{where } ML = NP^\top. \tag{11}$$

Remark 1.1. If P is invertible, then also M is invertible (and conversely). In this case we may take $M = I$ and N such that

$$\ker [I \;\; N] = \operatorname{im} \begin{bmatrix} L \\ -P^\top \end{bmatrix}, \tag{12}$$

implying $L = NP^\top$. Thus $N = LP^{-\top}$ and the DAE system takes the form

$$K\dot{x} = LP^{-\top}S^\top x = L\left(SP^{-1}\right)^\top x = LSP^{-1}x, \tag{13}$$

where the last equality follows from $S^\top P = P^\top S$. This is exactly the form of a port-Hamiltonian DAE system in case of a general Dirac subspace, and a Lagrangian subspace which is given as the graph of the symmetric matrix $Q = SP^{-1}$. If additionally K is invertible then we obtain the Poisson formulation of Hamiltonian dynamics

$$\dot{x} = \left(K^{-1}L\right)\left(SP^{-1}\right)x, \tag{14}$$

where the skew-symmetric matrix $J := K^{-1}L$ defines a Poisson structure.

Remark 1.2. If instead we assume L to be invertible, then N is invertible, and thus we can take $N = I$. In this case the equations become

$$MK\dot{x} = S^\top x, \quad ML = P^\top.$$

Substituting $M = P^\top L^{-1}$ we obtain the port-Hamiltonian DAE

$$P^\top L^{-1} K\dot{x} = S^\top x \tag{15}$$

where $\left(L^{-1}K\right)^\top = -L^{-1}K$. If additionally P is invertible, this may be rewritten as

$$\left(L^{-1}K\right)\dot{x} = \left(SP^{-1}\right)x, \tag{16}$$

which is the standard symplectic formulation of Hamiltonian dynamics in case the skew-symmetric matrix $L^{-1}K$ is invertible.

1.2 The z-representation

Another way to obtain a DAE representation of the defining pair $(\mathcal{D}, \mathcal{L})$ is to consider a *parametrization* of the Lagrangian subspace

$$\begin{bmatrix} x \\ e \end{bmatrix} = \begin{bmatrix} P \\ S \end{bmatrix} z \tag{17}$$

with $z \in \mathcal{Z}$, where $\mathcal{Z}$ is an n-dimensional parametrization space. As detailed in Van der Schaft, Maschke (2018) this yields the port-Hamiltonian DAE system

$$KP\dot{z} = LSz \tag{18}$$

Note that singularity of the matrix KP (and thus the appearance of algebraic constraints) may originate from two different sources: singularity of K (corresponding to *Dirac algebraic constraints*), as well as singularity of P (*Lagrange algebraic constraints*).

The Hamiltonian of the port-Hamiltonian DAE system (18) is given as

$$\mathcal{H}^z(z) = \frac{1}{2} z^\top S^\top P z, \tag{19}$$

and indeed $\frac{d}{dt}\mathcal{H}^z(z) = z^\top S^\top P\dot{z} = 0$ by the property $e^\top f = 0$ for any $(f, e) \in \mathcal{D}$. In case P is invertible the Hamiltonian $\mathcal{H}^x$ of the x-representation is

$$\mathcal{H}^x(x) = \frac{1}{2} x^\top SP^{-1}x \tag{20}$$

Substituting $x = Pz$ we immediately observe the following equality with $\mathcal{H}^z$:

$$\mathcal{H}^x(x) = \frac{1}{2} x^\top SP^{-1}x = \frac{1}{2} z^\top P^\top SP^{-1}Pz = \mathcal{H}^z(z). \tag{21}$$

Alternatively, starting from the x-representation we can define in case S is invertible the *co-energy* (Legendre transform)

$$\mathcal{H}_c^x(e) = \frac{1}{2} e^\top PS^{-1}e, \tag{22}$$

for which $\mathcal{H}_c^x(e) = \mathcal{H}^z(z)$ for $e = Sz$.

Note that the state vector x of the x-representation (11) is in general (especially if P is singular) *different* from the state vector of the z-representation (18); although of equal dimension. In the presentation and in the forthcoming paper Mehrmann, van der Schaft (2022) the precise notion of equivalence of these two representations will be discussed. Furthermore, we aim to address the structural properties of port-Hamiltonian DAE systems, including index analysis.

2. WHEN IS A DAE SYSTEM A PORT-HAMILTONIAN DAE SYSTEM: A GENERALIZED LYAPUNOV EQUATION

Next we study the question when a general DAE system $\Sigma \subset \mathcal{X} \times X$ given as $E\dot{x} = Ax$, $x \in \mathcal{X}$, is actually a port-Hamiltonian system; i.e., when does there exist a Dirac structure $\mathcal{D} \subset \mathcal{X} \times \mathcal{X}^*$ and a Lagrangian subspace $\mathcal{L} \subset \mathcal{X} \times \mathcal{X}^*$ such that $\Sigma = \mathcal{D} \circ \mathcal{L}$. First we identify two *necessary* conditions for the existence of $(\mathcal{D}, \mathcal{L})$.

Proposition 2.1. Consider $\Sigma \subset \mathcal{X} \times \mathcal{X}$ represented by $Ef + Ax = 0$ and the Lagrangian subspace $\mathcal{L} \subset \mathcal{X} \times \mathcal{X}^*$ represented by P, S. Then necessary conditions for the existence of a subspace $\mathcal{D}$ such that $\Sigma = \mathcal{D} \circ \mathcal{L}$ are

$$\begin{aligned} &(i)\ \ker S^\top \subset \ker A \\ &(ii) A^{-1}(\operatorname{im} E) \subset \operatorname{im} P \end{aligned} \tag{23}$$

Next step will be to develop a *Lyapunov equation* (in terms of the unknown pair (P, S) defining a Lagrange subspace). This is aimed at further generalizing the theory of Lyapunov equations for DAE systems developed in e.g. Stykel (2002); Reis et al. (2015).

Computational Methods for Uniform Ensemble Reachability ⋆

Michael Schönlein *

* *Faculty of Computer Science and Mathematics, University of Passau, Germany*

Abstract: We consider reachability properties of families of parameter-dependent linear systems, where the inputs are restricted to be independent of the parameter. If for every family of parameter-dependent target states and every neighborhood of it there is an input such that the zero state can be steered simultaneously into the given neighborhood the parameter-dependent system is called ensemble reachable. Recently, a lot of effort has been spent on the derivation of necessary and sufficient conditions for ensemble reachability. Here we tackle the subsequent question how to determine a suitable input if the target family and the neighborhood is given. We present two methods for discrete-time linear systems which are based on complex approximation theory. We will also point out that one of the polynomial techniques can also be applied to certain continuous-time systems.

Keywords: parameter-dependent systems, polynomial approximation, ensemble reachability, infinite-dimensional systems, approximation
MSC: 30E10; 93B05; 93C05

1. EXTENDED ABSTRACT

Controlling ensembles of systems is motivated by a wide range of engineering applications. In robotics and systems engineering there has recently been much interest in studying motion control problems for spatio-temporal systems and infinite platoons of vehicles, cf. Bamieh et al. (2002), where control actions and measurements take place in a spatially distributed way. Also problems arising in quantum control (NMR spectroscopy) and the control of flocks falls into the area of ensemble control, cf. (Brockett, 2012, Section 2.4).

1.1 Problem Statement

In this work we investigate families of parameter-dependent linear control systems. First, we treat the discrete-time case, i.e. we consider

$$x_{t+1}(\theta) = A(\theta)x_t(\theta) + b(\theta)u_t, \tag{1}$$

where the matrices $A(\theta) \in \mathbb{C}^{n\times n}$ and the vectors $b(\theta) \in \mathbb{C}^n$ are assumed to depend continuously on the parameter $\theta \in \mathbf{P}$ which is varying over a nonempty compact set $\mathbf{P} \subset \mathbb{C}$ with empty interior. To make things not too technical, we assume that $\mathbf{P} \subset \mathbb{R}$ is a compact interval. To express these assumptions we will shortly write $(A, b) \in C_{n,n}(\mathbf{P}) \times C_n(\mathbf{P})$ in the following. We emphasize that the input u does *not* dependent on the parameter. Since we are interested in reachability properties we set the initial condition to zero, i.e. $x_0(\theta) = 0$ for every $\theta \in \mathbf{P}$. For $T > 0$ and $u = (u_0, ..., u_{T-1}) \in \mathbb{C}^{1\times T}$, let $\varphi(T, u)(\theta)$ denote the solution to (1), i.e.

$$\varphi(T, u)(\theta) = \sum_{\tau=0}^{T-1} A(\theta)^{T-1-\tau} b(\theta)u_\tau \,. \tag{2}$$

In ensemble control, the key point is that the input u has to be independent of the system parameter $\theta \in \mathbf{P}$ and a central question is the following reachability property: A pair (A, B) is called *uniformly ensemble reachable* if for any state $f \in C_n(\mathbf{P})$ and for any $\varepsilon > 0$ the are $T > 0$ and $u \in \mathbb{C}^{1\times T}$ such that

$$\|\varphi(T, u) - f\|_\infty = \sup_{\theta\in\mathbf{P}} \|\varphi(T, u)(\theta) - f(\theta)\| < \varepsilon. \tag{3}$$

Note that, it is an immediate consequence of the assumption that the input has to be independent of the parameter that exact reachability (i.e. $\varepsilon = 0$) is never possible.

The focus of this paper is to provide methods to compute suitable inputs for uniformly ensemble reachable pairs (A, b). That is, given a family of terminal states $f \in C_n(\mathbf{P})$ and a neighborhood $B_\varepsilon(f) = \{g \in C_n(\mathbf{P}) \,|\, \|f - g\|_\infty < \varepsilon\} \subset C_n(\mathbf{P})$ find $T > 0$ and an open-loop control $u \in \mathbb{C}^{1\times T}$ such that $\varphi(T, u) \in B_\varepsilon(f)$.

1.2 Known criteria for uniform ensemble reachability

In this section we recall relevant known results that prepare the ground to derive constructive methods for the computation of suitable inputs. We start with two necessary conditions, cf. (Dirr and Schönlein, 2021, Thm. 3): If the pair (A, b) is uniformly ensemble reachable, then

(N1) the pair $(A(\theta), b(\theta))$ is reachable for every $\theta \in \mathbf{P}$.
(N2) for any pair of distinct parameters $\theta, \theta' \in \mathbf{P}$, the spectra of $A(\theta)$ and $A(\theta')$ are disjoint:

$$\sigma(A(\theta)) \cap \sigma(A(\theta')) = \emptyset.$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

For single-input linear systems the following conditions are sufficient for uniform ensemble reachability, cf. (Dirr and Schönlein, 2021, Thm. 4 & Cor. 1).

Theorem 1. Let $\boldsymbol{P}$ be a compact interval. A pair (A, b) is uniformly ensemble reachable if it satisfies (N1) and (N2) and one of the following sufficiency conditions:

(S1) The characteristic polynomials of $A(\theta)$ take the form
$$z^n - (a_{n-1}z^{n-1} + \cdots + a_1 z + a_0(\theta))$$
for some $a_{n-1}, ..., a_1 \in \mathbb{C}$ and $a_0 \in C(\mathbf{P})$.

(S2) $A(\theta)$ has simple eigenvalues for each $\theta \in \boldsymbol{P}$.

We note that due to the condition (N2) the function a_0 in (S2) is necessarily injective. Thus, $a_0 \colon \mathbf{P} \to a_0(\mathbf{P})$ is one-to-one and onto and so $a_0(\mathbf{P})$ defines a Jordan arc. In certain cases, like the controlled harmonic oscillator, it happens that the sufficiency conditions (S1) and (S2) are satisfied at the same time. Also, if $\mathbf{P}$ is compact interval, it is shown in (Dirr and Schönlein, 2021, Thm. 3) that the conditions (S2) holds necessarily for an open and dense subset of $\mathbf{P}$.

For discrete-time single input systems the solution can also be written as
$$\begin{aligned}\varphi(T,u)(\theta) &= \sum_{\tau=0}^{T-1} u_\tau \big(A(\theta)\big)^{T-1-\tau}\, b(\theta) \\ &= \big(u_{T-1}I + \cdots + u_0 A(\theta)^{T-1}\big)\, b(\theta).\end{aligned}$$
Using the polynomial
$$p(z) = u_{T-1} + u_{T-2}\, z + \cdots + u_1\, z^{T-2} + u_0\, z^{T-1}$$
and it follows that (A, b) is uniformly ensemble reachable if and only if for every $f \in C_n(\mathbf{P})$ and for every $\varepsilon > 0$ there is a polynomial p such that
$$\|p(A)b - f\|_\infty < \varepsilon.$$
Thus, the construction of suitable inputs is equivalent to the construction of a suitable polynomial. In this work, for given $f \in C_n(\mathbf{P})$ and $\varepsilon > 0$, we will present sufficient conditions and methods for the construction of suitable inputs $u = (u_0, ..., u_{T-1}) \in \mathbb{C}^{1\times T}$. Since the inputs will be given in terms of the coefficients of an appropriate polynomial, it is required to determine the degree and the coefficients of the polynomial. Indeed, the degree of the polynomial determines the number of inputs that are required and the coefficients specify the input values.

2. APPROXIMATION THEORY

This section contains results from classical approximation theory that are used in the construction methods in Section 3. We start with the results due to Weierstrass. Recall that, given a function $f \colon [a, b] \to \mathbb{R}$ the nth Bernstein polynomials is given by
$$B_{f,n}(x) := \sum_{k=0}^{n} \binom{n}{k} f(a + \tfrac{k}{n}(b-a)) \left(\tfrac{x-a}{b-a}\right)^k \left(\tfrac{b-x}{b-a}\right)^{n-k}.$$
The following version of the classical Weierstrass Approximation Theorem has been shown by Gzyl and Palacios (1997).

Theorem 2. (Weierstrass first theorem).
Let $f \colon [a, b] \to \mathbb{R}$ satisfy a Lipschitz condition. Then, for $n \geq 3$ the sequence of Bernstein polynomials satisfies
$$\|f - B_{f,n}\|_\infty \leq \left(4\, M_f + \frac{(b-a)\, L_f}{2}\right) \frac{\sqrt{\log n}}{\sqrt{n}}.$$

Associated with a continuous function $f \colon \partial\mathbb{D} \to \mathbb{C}$ we consider the trigonometric polynomials due to Fejér, defined as
$$F_{f,n}(z) := \sum_{k=-n}^{n} \frac{n+1-|k|}{n+1} \hat{f}(k)\; z^k,$$
where
$$\hat{f}(k) := \frac{1}{2\pi} \int_{-\pi}^{\pi} f(e^{is}) e^{-iks}\, \mathrm{d}s$$
denotes the kth *Fourier coefficient* of f. Similar to Gzyl and Palacios (1997) the following version of the trigonometric Weierstrass Approximation Theorem can be shown, cf. Natanson (1964).

Theorem 3. (Bernstein).
Suppose that $f \colon \partial\mathbb{D} \to \mathbb{C}$ satisfies a Lipschitz condition. Then, the sequence of trigonometric polynomials $(F_{f,n})_{n\in\mathbb{N}}$ converges uniformly to f and satisfies
$$\sup_{z\in\partial\mathbb{D}} |f(z) - F_{f,n}(z)| \leq 2\sqrt{2}\pi L_f \cdot \frac{\ln n}{n},$$
where $L_f > 0$ denotes the Lipschitz constant.

Moreover we make use of

Theorem 4. (Runge's little Theorem (1885)).
Let K be a compact subset in $\mathbb{C}$ such that $\mathbb{C} \setminus K$ is connected. If there is an open set Ω containing K such that f is holomorphic on Ω, then for every $\varepsilon > 0$ there is polynomial p such that
$$\sup_{z\in K} |f(z) - p(z)| < \varepsilon.$$

For Runge's little Theorem there are constructive procedures illustrated in the literature, cf. e.g. Remmert (1998). However, to the best of the authors knowledge, an explicit representation of the degree and the coefficients of the Runge polynomial in terms of the function f and $\varepsilon > 0$ was previously not available and is presented in Schönlein (2021).

3. COMPUTATIONAL METHODS FOR DISCRETE-TIME SYSTEMS

We take the sufficient conditions provided in Theorem 1 as a starting point and we provide for each case a constructive procedure to compute a suitable input for a given target function f and a given neighborhood $B_\varepsilon(f)$ of it. To this end, we will need the following notations. For $g \colon \Omega \subset \mathbb{C} \to \mathbb{C}$ we define
$$M_g := \max_{z\in\Omega} |g(z)|.$$
Also we say that g satisfies a Lipschitz condition, i.e. there exists a $L_g > 0$ such that
$$|g(z_1) - g(z_2)| \leq L_g\, |z_1 - z_2|$$
for all $z_1, z_2 \in \Omega$. We use $\mathrm{Lip}(\Omega)$ to denote the set of functions that satisfy a Lipschitz condition.

3.1 Method S1

The first method is based on sufficient condition (S1). Let $f \in \mathrm{C}_n(\mathbf{P})$ and $\varepsilon > 0$ be given. A suitable input is obtained by carrying out the following basic steps (details for step (A2) will be given below):

(A1) Compute the Jordan arc
$$a_0(\mathbf{P}) = \{a_0(\theta) | \, \theta \in \mathbf{P}\} \subset \mathbb{C}.$$
(A2) Compute the polynomials $p_1, ..., p_n$ such that
$$\sup_{z \in a_0(\mathbf{P})} |p_k(z) - f_k(a_0^{-1}(z))| < \varepsilon$$
for all $k = 1, ..., n$.
(A3) Set $g(z) := z^n - (a_{n-1}z^{n-1} + \cdots + a_1 z)$ and define
$$p(z) := \sum_{k=1}^{n} p_k\big(g(z)\big) z^{k-1}. \tag{4}$$

It remains to provide how to get the polynomials in step (A2). We distinguish the cases that $a_0(\mathbf{P})$ is real or complex. Also we will assume that
$$f_k \circ a_0^{-1} \in \mathrm{Lip}(a_0(\mathbf{P}))$$
for all $k = 1, ..., n$. The polynomials are determined via the constructive proofs to the approximation results stated in Section 2. More precisely:

(a1) If $a_0(\mathbf{P}) = [a, b] \subset \mathbb{R}$, then according to Theorem 2 we take p_k, $k = 1, ..., n$ as the Bernstein polynomials to the component functions $f_k \circ a_0^{-1}$ of degree n_k, where the degree $n_k \in \mathbb{N}$ is chosen such that
$$\sqrt{2}\left(4\, M_{f_k \circ a_0^{-1}} + \tfrac{(b-a)}{2}\, L_{f_k \circ a_0^{-1}}\right) \sqrt{\frac{\log n_k}{n_k}} \leq \varepsilon.$$
(a2) If $a_0(\mathbf{P}) \subset \partial\mathbb{D} = \{z \in \mathbb{C} \,|\, |z| = 1\}$, we first extend the functions $f_k \circ a_0^{-1}$ to $\partial\mathbb{D}$ by defining
$$f_k(z) := w_{k,1} + (w_{k,2} - w_{k,1}) \frac{z - z_{k,1}}{z_{k,2} - z_{k,1}}$$
for all $z \in \partial\mathbb{D} \setminus a_0(\mathbf{P})$, where $w_{k,1}$ and $w_{k,2}$ are the values of f_k at the end-points $z_{k,1}$ and $z_{k,2}$ of $a_0(\mathbf{P})$, respectively and take $p_k = F_{f_k \circ a_0^{-1}, n_k}$ with n_k such that
$$\left(2\sqrt{2}\pi L_{f_k \circ a_0^{-1}} \frac{\ln n_k}{n_k}\right) \leq \varepsilon.$$

Sufficient conditions such that Method S1 works are presented in the following result.

Theorem 5. Suppose (A, b) satisfies (N1), (N2) and (S1). Let $\varepsilon > 0$ and suppose that $f \in C_n(\mathbf{P})$ is such that $f_k \circ a_0^{-1} \in \mathrm{Lip}(a_0(\mathbf{P}))$ for all $k = 1, ..., n$ and assume that the Jordan arc $a_0(\mathbf{P})$ lies either on the real line or on the unit circle. Let
$$p(z) = p_0 + \cdots + p_k z^k$$
be the polynomial of degree k defined by (4). Then, at time $T - 1 = k \geq 3$ with inputs
$$u = (u_0, ..., u_{T-1}) = (p_k, ..., p_0)$$
one has
$$\|\varphi(T, u) - f\|_\infty < \varepsilon.$$

The construction yields that the degree of the polynomial defined in (4) is given by
$$\max_{k=1,...,n} n_k(k-1)n.$$

3.2 Method S2

The second method is based on the sufficient condition (S2). Let $f \in \mathrm{C}_n(\mathbf{P})$ and $\varepsilon > 0$ be given. After applying a change of coordinates $T(\theta)$ we consider the pair
$$T(\theta)^{-1} A(\theta) T(\theta) = \begin{pmatrix} a_1(\theta) & & \\ & \ddots & \\ & & a_n(\theta) \end{pmatrix}$$
$$T(\theta)^{-1} b(\theta) = \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix},$$
where $a_1, ..., a_n$ denote the distinct eigenvalue Jordan arcs. Let $\tilde{f}(\theta) = T(\theta)^{-1} f(\theta)$ and let $\|\cdot\|_M$ be a matrix norm that is submultiplicative to $\|\cdot\|$ and set
$$\|T\|_{M,\infty} := \sup_{\theta \in \mathbf{P}} \|T(\theta)\|_M.$$

A suitable input is obtained by carrying out the following basic steps (details for steps (B2) and (B3) will be given below):

(B1) Compute the Jordan arcs
$$a_k(\mathbf{P}) = \{a_k(\theta), | \, \theta \in \mathbf{P}\} \subset \mathbb{C}, \;\; k = 1, ..., n$$
and set $a(\mathbf{P}) = \cup_{k=1,...,n} a_k(\mathbf{P})$.
(B2) Compute the polynomials $p_1, ..., p_n$ such that
$$\sup_{z \in a_k(\mathbf{P})} |p_k(z) - \tilde{f}_k(a_k^{-1}(z))| < \tfrac{\varepsilon}{3\|T\|_{M,\infty}}$$
for all $k = 1, ..., n$.
(B3) Let $\alpha_{k,l} := \sup_{\theta \in \mathbf{P}} |p_k(a_l(\theta))|$ and define $h_k \colon a(\mathbf{P}) \to \mathbb{C}$ by
$$h_k(z) = \begin{cases} 1 & \text{if } z \in a_k(\mathbf{P}) \\ 0 & \text{if } z \in a(\mathbf{P}) \setminus a_k(\mathbf{P}) \end{cases}$$
for $k = 1, ..., n$. Compute via Runge's little Theorem the polynomials $q_1, ..., q_n$ such that
$$\sup_{z \in a(\mathbf{P})} |q_k(z) - h_k(z))| < \frac{\varepsilon}{3\|T\|_{M,\infty} \sum_{l=1}^{n} \alpha_{k,l}}$$
for all $k = 1, ..., n$.
(B4) Set
$$p(z) = \sum_{k=1}^{n} p_k(z) q_k(z). \tag{5}$$

The polynomials in step (B2) are obtained as follows. Again we distinguish the cases that the Jordan arcs are real or complex and assume that
$$\tilde{f}_k \circ a_k^{-1} \in \mathrm{Lip}(a_k(\mathbf{P})).$$

(b1) If $a_k(\mathbf{P}) = [a, b] \subset \mathbb{R}$ take p_k as the Bernstein polynomials corresponding to the component functions $\tilde{f}_k \circ a_k^{-1}$ of degree n_k, where the degree $n_k \in \mathbb{N}$ is chosen such that
$$\sqrt{2}\left(4\, M_{\tilde{f}_k \circ a_k^{-1}} + \tfrac{(b-a)}{2}\, L_{\tilde{f}_k \circ a_k^{-1}}\right) \sqrt{\tfrac{\log n_k}{n_k}} \leq \frac{\varepsilon}{3\|T\|_{M,\infty}}.$$
(b2) Let $a_k(\mathbf{P}) \subset \partial\mathbb{D} = \{z \in \mathbb{C} \,|\, |z| = 1\}$. Then, first extend the functions $\tilde{f}_k \circ a_k^{-1}$ to $\partial\mathbb{D}$ by defining
$$\tilde{f}_k(z) := w_{k,1} + (w_{k,2} - w_{k,1}) \frac{z - z_{k,1}}{z_{k,2} - z_{k,1}}$$
for all $z \in \partial\mathbb{D} \setminus a_0(\mathbf{P})$, where $w_{k,1}$ and $w_{k,2}$ are the values of $\tilde{f}_k$ at the end-points $z_{k,1}$ and $z_{k,2}$ of $a_0(\mathbf{P})$,

respectively and take $p_k = F_{\tilde{f}_k \circ a_0^{-1}, n_k}$ with n_k such that

$$\left(2\sqrt{2}\pi L_{\tilde{f}_k \circ a_0^{-1}} \frac{\ln n_k}{n_k}\right) \leq \frac{\varepsilon}{3\|T\|_{M,\infty}}.$$

The next result states sufficient conditions so that Method S2 yields an appropriate input sequence.

Theorem 6. Assume that (A, b) satisfies (N1), (N2) and (S2). Let $\varepsilon > 0$ and suppose that $f \in C_n(\mathbf{P})$ is such that $\tilde{f}_k \circ a_k^{-1} \in \mathrm{Lip}(a_k(\mathbf{P}))$ for all $k = 1, ..., n$ and assume that the Jordan arcs $a_k(\mathbf{P})$ are either on the real line or on the unit circle. Let

$$p(z) = p_0 + \cdots + p_k z^k$$

be the polynomial of degree k defined by (5). Then, at time $T - 1 = k \geq 3$ with inputs

$$u = (u_0, ..., u_{T-1}) = (p_k, ..., p_0)$$

one has

$$\|\varphi(T, u) - f\|_\infty < \varepsilon.$$

We close this section by noting that there are two ways how the Methods S1 and S2 can be extended to arbitrary Jordan arcs in the complex plane. First, using techniques from numerical conformal mapping theory together with approximation results due to Walsh, cf. Walsh (1965), Schönlein (2021). A second approach is to apply a mixture of open-loop and feedback control inputs of the form

$$u(t) + k(\theta)x_t(\theta).$$

This ansatz yields the possibility to enforce the sufficiency conditions (S1) or (S2). Indeed, due to the necessary condition (N1), the eigenvalues can be placed so that all Jordan arcs are on the real line or on the unit circle. For details we refer to Schönlein (2022).

4. CONTINUOUS-TIME SINGLE-INPUT SYSTEMS

In this section we sketch how the Method S2 can be also be applied to continuous-time single input systems

$$\frac{\partial x}{\partial t}(t, \theta) = A(\theta)x(t, \theta) + b(\theta)u(t) \tag{6}$$

that satisfy the conditions (N1), (N2) and (S2). Let $T(\theta)$ denote the change of coordinates as in Section 3.2. Then, for $u \in L^1([0, T], \mathbb{C}^m)$ the solution to (6) can be written as

$$\begin{aligned}\varphi(T, u)(\theta) &= \int_0^T \mathrm{e}^{(T-\tau)A(\theta)} b(\theta)u(\tau)\,\mathrm{d}\tau \\ &= T(\theta) \begin{pmatrix} \int_0^T u(\tau)\mathrm{e}^{(T-\tau)a_1(\theta)}\,\mathrm{d}\tau \\ \vdots \\ \int_0^T u(\tau)\mathrm{e}^{(T-\tau)a_n(\theta)}\,\mathrm{d}\tau \end{pmatrix}\end{aligned}$$

Note also that for continuous-time systems the time $T > 0$ can chosen arbitrarily, cf. (Dirr and Schönlein, 2021, Section 1). Thus, let $T > 0$ be fixed. We divide $[0, T]$ into $K \in \mathbb{N}$ intervals I_l, $l = 0, ..., K - 1$ of length $\tau > 0$ so that the mappings $\theta \mapsto \mathrm{e}^{\tau a_k(\theta)}$ are injective for all $k = 1, ..., n$. Then, we take piecewise constant input functions $u\colon [0, T] \to \mathbb{C}$ given by

$$u|_{I_l}(t) := u_l \in \mathbb{C} \tag{7}$$

for some complex numbers $u_0, ..., u_{K-1}$. The kth component of the solution is then

$$\varphi_k(T, u)(\theta) = \left(\frac{\mathrm{e}^{\tau a(\theta)} - 1}{\tau a(\theta)}\right) \sum_{l=0}^{K} \tau u_{K-l}\, \mathrm{e}^{l\tau a(\theta)}$$

Furthermore, it holds

$$\lim_{\tau \to 0} \frac{\mathrm{e}^{\tau z} - 1}{\tau z} = 1 \quad \text{for all } z \in \mathbb{C} \setminus \{0\}.$$

So, for any $\varepsilon > 0$ there is a $\tau^* > 0$ so that for any $\tau \in (0, \tau^*)$ we have

$$\left|\frac{\mathrm{e}^{\tau a_k(\theta)} - 1}{\tau a_k(\theta)} - 1\right| < \tfrac{\varepsilon}{2} \tag{8}$$

for any $a_k(\theta) \neq 0$, $k = 1, ..., n$. Let $K^* := \left\lfloor \frac{T}{\tau^*} \right\rfloor$, where $\lfloor x \rfloor = \max\{z \in \mathbb{Z} : z \leq x\}$. Thus, in terms of the polynomial

$$p(z) := \sum_{l=0}^{K} u_{K-l}\, z^l \tag{9}$$

the kth component of the solution satisfies

$$\left|\tau p(\mathrm{e}^{\tau a_k(\theta)}) - \varphi_k(1, u)(\theta)\right| < \tfrac{\varepsilon}{2} \tag{10}$$

for all $\tau \in (0, \tau^*)$ and all $k = 1, ..., n$. The significance of (10) is that it is independent of the input values $u_0, ..., u_{K-1}$. Thus, to compute suitable inputs values one can follow the steps of Method S2. For a detailed exposition we refer to Schönlein (2021).

Abstract: We study internal stability in the context of diffusively-coupled control architecture, common in multi-agent systems (e.g. the celebrated consensus protocol). We derive a condition under which the system can be stabilized by no controller from that class. The condition says effectively that diffusively-coupled controllers cannot stabilize agents that share common unstable dynamics, directions included. This class always contains a group of homogeneous unstable agents, like integrators. We argue that the underlying reason is intrinsic cancellations of unstable agent dynamics by such controllers, even static ones, where directional properties play a key role. The intrinsic lack of internal stability explains the notorious behavior of some distributed control protocols when affected by measurement noise or exogenous disturbances.

Keywords: Multi-agent systems, structural properties, stability.

1. INTRODUCTION

A multi-agent system (MAS) is a collection of independent systems (agents) coupled via pursuit of a common goal. In large-scale MASs the information exchange between agents is normally limited to a subset of the agents, known as *neighbors*. Control laws using only information from neighboring agents are called *distributed*.

This work studies a class of distributed control laws, where only *relative* measurements are exchanged between neighbors. In other words, each agent has access only to the difference between its output and that of each of its neighbours. Relative sensing appears frequently in MAS tasks where absolute measurement are hard to obtain, such as space and aerial exploration and sensor localization, see (Smith and Hadaegh, 2005; Khan et al., 2009; Zelazo and Mesbahi, 2011b) and the references therein. Distributed control laws generated by relative information are called *diffusive*, and systems controlled by such laws are called *diffusively coupled*. Diffusive coupling appear naturally in consensus and synchronization problems (Olfati-Saber et al., 2007; Wieland et al., 2011), making them common in the MAS literature. However, diffusively-coupled systems behave poorly when affected by disturbances and noise. Measurement noise rapidly deteriorates performance (Zelazo and Mesbahi, 2011a, §III.A), and even dynamic controllers can hardly attenuate disturbances (Ding, 2015). To illustrate some of these traits, consider a simple example.

1.1 Motivating example

Reaching agreement between autonomous agents is a fundamental building block in multi-agent coordination (Ren and Beard, 2008). In its simplest form, it concerns a group of integrator agents described by $\dot{x}_i(t) = u_i(t)$, which need to synchronize their states x_i in a distributed manner. Namely, it is required to attain

$$\lim_{t\to\infty}\big(x_i(t) - x_j(t)\big) = 0, \quad \forall i, j. \tag{1}$$

by an appropriate choice of control signals u_i with access only to a states of neighboring agents, denoted by the set $\mathcal{N}_i$. This problem can be solved by the celebrated consensus protocol (Olfati-Saber et al., 2007), which is a diffusive state-feedback

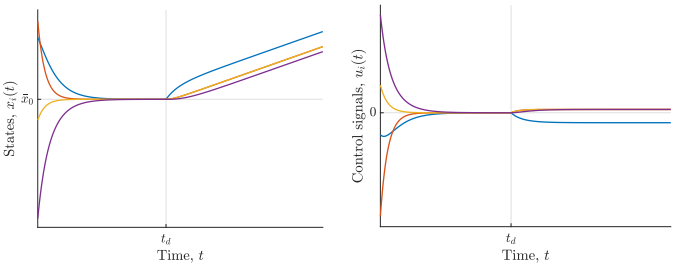
$$u_i(t) = -\sum_{j\in\mathcal{N}_i}\big(x_i(t) - x_j(t)\big). \tag{2}$$

If certain conditions on the communication topology hold, then the control law (2) drives the agents to agreement exponentially fast (Mesbahi and Egerstedt, 2010, Ch. 3).

This is no longer the case if the agent dynamics are affected also by exogenous inputs,

$$\dot{x}_i(t) = u_i(t) + d_i(t) \tag{3}$$

for some independent and unmeasurable load disturbances d_i. Fig. 1 demonstrates what happens with a group of 4 agents controlled by (2) when a unit step disturbance appears at one of them at some time instance $t = t_d$. For $t < t_d$, when the system is undisturbed, the states converge exponentially to the average



(a) states of the agents (b) control signals

Fig. 1. Consensus protocol for agents perturbed at $t = t_d$

of their initial conditions and the control signals go to zero. However, for $t > t_d$ the states x_i disagree and diverge, whereas the control signals u_i reach non-zero steady-state values.

The apparent instability of the whole system, manifested in the unboundedness of the states, can be explained by the well-known fact that the consensus protocol has a closed-loop eigenvalues at the origin (Olfati-Saber et al., 2007). Nevertheless, the boundedness of the control signals under such conditions is intriguing. The situation when some signal in the closed-loop system are bounded, whereas some other are not, may indicate unstable *pole-zero cancellations* in the feedback loop (Zhou et al., 1996, Ch. 5.3). However, controller (2) is static and thus has no zeros.

Still, the behavior like that in Fig. 1 prompts a deeper inspection of the *internal stability* property, which is the stability of all possible input/output relations in the system, see (Zhou et al., 1996; Skogestad and Postlethwaite, 2005). To the best of our knowledge, the instability phenomenon above was never explicitly connected with the lack of internal stability or unstable cancellations [1] . This is the starting point of the current study.

1.2 Contribution

In this note we show that the diffusive-coupling distributed control architecture for MASs is intrinsically internally unstable for many common agents configurations. Specifically, we prove that this is the case whenever all agents share common unstable dynamics (directions included for MIMO agents). This, for example, always happens in the group of homogeneous unstable agents, like integrator agents in (3).

We also explain the mechanism for the shown internal instability. It is indeed caused by unstable cancellations in the cascade of the block-diagonal aggregate plant and the diffusively coupled controller. Interesting is that these cancellations are caused not by controller zeros, but rather by an intrinsic spatial deficiency of the diffusive coupling configuration. They are thus independent of particular dynamics in processing relative measurements, only agents dynamics matter. It is worth mentioning that this instability mechanism is unrelated to the decentralized fixed modes (Wang and Davison, 1973).

The internal instability in the form of canceled plant poles explains then observed problems associated with the load disturbance response in some MAS applications.

Notations We extensively use standard notation from algebraic graph theory (Godsil and Royle, 2001). An undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ consists of a finite vertex set $\mathcal{V}$ and edges $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$. Denote by E the (oriented) incidence matrix of $\mathcal{G}$, defined component-wise by $[E(\mathcal{G})]_{ij} = 1$, when i is the head of edge j, $[E(\mathcal{G})]_{ij} = -1$ when i is the tail of edge j, and 0 otherwise. The matrix $L \coloneqq EE^\top$ is the combinatorial Laplacian matrix of $\mathcal{G}$. Note that $\mathbb{1} \in \ker E^\top$, thus L has an eigenvalue at the origin with $\mathbb{1}$ as its eigenvector.

The sets of real and complex numbers are denoted by $\mathbb{R}$ and $\mathbb{C}$ respectively, while the notations $\mathbb{C}_0$ and $\bar{\mathbb{C}}_0$ denote the open and closed right half complex plane, respectively. The complex-conjugate transpose of a matrix M is denoted by $M^\top$. The notation $\mathrm{diag}\{M_i\}$ stands for a block-diagonal matrix with diagonal elements M_i. The image (range) and kernel (null) spaces of a matrix M are notated $\mathrm{Im}\, M$ and $\ker M$, respectively. Given two matrices (vectors) M and N, $M \otimes N$ denotes their Kronecker product. By I_ν, or simply I, we denote the $\nu \times \nu$ identity matrix, by $\mathbb{1}_\nu$, or simply $\mathbb{1}$, the ν dimensional all-ones vector. The notation $\mathrm{spec}\, G$ refers to the set of eigenvalues if G is a matrix, or the set of poles if $G(s)$ is a proper transfer function. By H_∞ we denote the space of functions holomorphic and bounded in $\mathbb{C}_0$.

[1] Reminiscent reasoning has been mentioned in a formation control problem solved by a diffusive controller in (Fax and Murray, 2004, Sec. III.B), where the a cancelled mode was interpreted as unobservability of absolute motion.

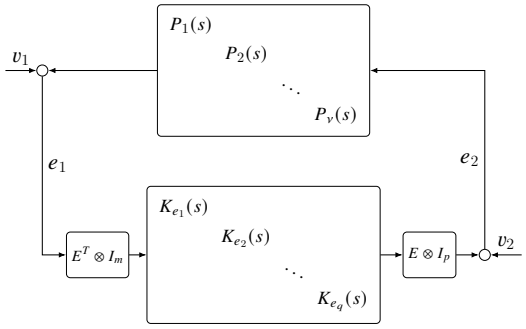

Fig. 2. Block diagram of the closed-loop

2. PROBLEM FORMULATION

Consider ν continuous-time agents P_i, each with m inputs and p outputs. Their aggregate dynamics are denoted as $P \coloneqq \mathrm{diag}\{P_i\}$, $i = 1, \ldots, \nu$. The interconnection topology of all agents is described by a graph $\mathcal{G}$ with ν nodes and q edges. Agent i and agent j are neighbors in the sense described in Section 1 if they are incident to the same edge. A dynamic controller, $K_e \coloneqq \mathrm{diag}\{K_{e,j}\}$, $j = 1, \ldots, q$, acts on the relative measurements on the edges. We assume hereafter that all P_i and K_{e_i} are linear time invariant (LTI), finite dimensional [2] , and that their transfer functions are proper.

A general diffusively-coupled architecture can be presented as the interconnection shown in Fig. 2, where the coupling matrix is the incidence matrix of $\mathcal{G}$. This representation is common in passivity-based analysis (Arcak, 2007), and sometimes called the canonical cooperative control structure (Sharf and Zelazo, 2017), (Bullo, 2022, Ch. 9). An equivalent representation can be made using the Laplacian matrix (Bullo, 2022, Ch. 8).

Note that the coupling matrices can be attached to either the plant or the controller, resulting in two distinct problems. One of them considers edge controllers stabilizing diagonal node dynamics (Bürger and De Persis, 2015), while the other a diagonal controller stabilizing the edge dynamics (Zelazo and Mesbahi, 2011a). In this note we consider the former, which includes controller

$$K \coloneqq (E \otimes I_m) K_e (E^\top \otimes I_p) \tag{4}$$

connected with a diagonal plant, as shown in Fig. 2, where v_1 and v_2 are arbitrary and bounded exogenous signals.

We say that the system in Fig. 2 is internally stable if all four closed-loop transfer functions connecting the exogenous signals v_1 and v_2 with the internal signals e_1 and e_2 are stable, i.e. belong to H_∞. The question studied in this note is under

[2] The arguments below could be extended to infinite-dimensional systems, but the involved technicalities are beyond the scope of this note.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

what conditions on the dynamics of the agents P_i there are edge controllers K_{e_j} internally stabilizing this system.

3. THE MAIN RESULT

The main result of this note provides a condition for the interconnection in Fig. 2 to be internally unstable irrespective of the choice of dynamics of K_e. As mentioned, the underlying reason is *cancellations* between poles of P and the controller K. It is well documented that poles cancelled in a cascade between a plant and controller are not truly cancelled (Anderson and Gevers, 1981). They may not appear in one I/O relation, but will still appear in a different one. For SISO systems cancellations are simple to spot and understand, they happen if and only if one system has a pole and the other a zero at the same location. When generalizing this to MIMO, poles and zeros have directional properties, see (Skogestad and Postlethwaite, 2005, §4.6.1) and (Mirkin, 2019, §3.4.2). Thus, directions, and not just locations, have to be considered.

Definition 1. Let G be an LTI system with m inputs and p outputs and (A, B, C, D) be its state space realization with realization poles at $\lambda_i \in \mathbb{C}$. The *input direction* of every λ_i is

$$\mathrm{pdir}_{\mathrm{i}}(G, \lambda_i) \coloneqq B^\top \ker([\lambda_i I - A]^\top) \subseteq \mathbb{C}^m$$

and its *output direction* is

$$\mathrm{pdir}_{\mathrm{o}}(G, \lambda_i) \coloneqq C \ker(\lambda_i I - A) \subseteq \mathbb{C}^p.$$

Pole directions span subspaces of either the input or output space. If λ_i is a hidden, i.e. uncontrollable or unobservable, mode of the realization (A, B, C, D), then both $\mathrm{pdir}_{\mathrm{i}}(G, \lambda_i) = \{0\}$ and $\mathrm{pdir}_{\mathrm{o}}(G, \lambda_i) = \{0\}$, which follows by PBH arguments. In the SISO case, $\mathrm{pdir}_{\mathrm{i}}(G, \lambda_i) = \mathrm{pdir}_{\mathrm{o}}(G, \lambda_i) = \mathbb{C}$ whenever λ_i is also a pole of the transfer function $G(s)$, i.e. every pole is excited by every input.

Cancelled poles correspond to unobservable (uncontrollable) modes in either KP or PK (Zhou et al., 1996, Thm. 5.7). The following Lemma provides conditions on pole directions of the agents in the diagram in Fig. 2 under which parts of the dynamics of agents are canceled by the controller K.

Lemma 2. Let P and K be as described in Section 2 and λ be a common pole of all agents P_i.

i) If
$$\bigcap_{i=1}^{\nu} \mathrm{pdir}_{\mathrm{o}}(P_i, \lambda) \neq \{0\},$$
then λ is an unobservable mode of KP.

ii) If
$$\bigcap_{i=1}^{\nu} \mathrm{pdir}_{\mathrm{i}}(P_i, \lambda) \neq \{0\},$$
then λ is an uncontrollable mode of PK.

The cancellation of λ in Lemma 2 is independent of the controller dynamics. In MIMO systems poles of the plant can be canceled not by zeros of the controller, but rather by a normal rank deficiency of the latter. This is exactly what happens in the diffusively-coupled interconnection in Fig. 2. Namely, the intrinsic singularity of the incidence matrix, present in every diffusive controller, might cancel plant poles. A formal condition for that is stated in Lemma 2.

Since cancelled poles remain poles of at least one closed-loop transfer function (Anderson and Gevers, 1981), the above Lemma immediately implies the main result.

Theorem 3. Let P_i, $i = 1, \ldots, \nu$, be LTI finite-dimensional agents with proper transfer functions. If $\lambda \in \bar{\mathbb{C}}_0$ is a pole of each one of them such that

$$\bigcap_{j=1}^{\nu} \mathrm{pdir}_{\mathrm{i}}(P_j, \lambda) \neq \{0\} \tag{5a}$$

or

$$\bigcap_{j=1}^{\nu} \mathrm{pdir}_{\mathrm{o}}(P_j, \lambda) \neq \{0\}, \tag{5b}$$

then the interconnection shown in Fig. 2 is internally unstable irrespective of the choice of K_e. Moreover, if this λ is not a zero of K_e, then condition (5a) implies that λ is the pole of the closed-loop transfer function from v_2 to e_1, while condition (5b) implies that λ is the pole of the closed-loop transfer function from v_1 to e_2.

Theorem 3 asserts that that any common dynamics, determined by poles and corresponding directions, are cancelled by the diffusive coupling. This has an interesting immediate corollary. If the agents are homogeneous they share their entire dynamics, both stable and unstable, thus the diffusive structure can be thought of as cancelling an *entire agent*. This not only proves the unobservability of the mode at the origin claimed in (Fax and Murray, 2004), but proves that every pole loses multiplicity in the cascade.

This may have ramifications not only about the stability of the system, but also of its maximal attainable performance. For example, it explains the observation reported in (Li et al., 2010), where the disturbance rejection performance measure of the entire system is upper bounded by that of a single, uncontrolled agent. It also generalizes the observation from (Zelazo and Mesbahi, 2011a), where it was shown that for integrator agents there is always an unobservable mode parallel to span $\mathbb{1}$. Since this direction is in the null space of the incidence matrix, noise or disturbances effecting this mode cannot be attenuated by a diffusive controller. Similarly, this cancellation explains why the cooperative disturbance rejection scheme of (Ding, 2015) cannot reject load disturbances, but only synchronize to it.

4. CONCLUDING REMARKS

We presented necessary conditions for internal stabilizability of diffusively-coupled LTI systems. In particular, we have shown that, for finite-dimensional agents, common dynamics are cancelled by the diffusive controller. The final conclusion is that in numerous multi-agent problems, one cannot simultaneously achieve a cooperative objective and guarantee internal stability using only relative measurements. Extending these results to time-varying graphs and more general systems are subject to current research.

Towards a general port-Hamiltonian descriptor formalism for multi-phase flow dynamics

Harshit Bansal * **Wil Schilders** *

Abstract: Recently, port-Hamiltonian (pH) representations have been developed for multi-phase flow models, such as the Two-Fluid Model and the zero-slip Drift Flux Model (DFM), with non-quadratic Hamiltonian functionals, by eliminating constraints and writing a partial differential-algebraic system as a system with (only) partial differential equations. However, the existing multi-phase modelling framework is not modular enough since mathematical computations have to be performed again for even a small change, say a different governing equation of state, in the model description. Furthermore, a pH representation of the general DFM still does not exist, and the complicated, non-linear models may not always be amenable to the pH model formulation as per the current state-of-the-art. To this end, we make efforts towards developing a general pH descriptor formalism for non-linear multi-phase flow dynamics.

Keywords: port-Hamiltonian, descriptor realization, multi-phase, Drift Flux Model, non-linear

1. INTRODUCTION

Port-Hamiltonian (pH) representations for fluid flow models have been developed in de Wilde (2015); Bansal et al. (2021a); Bansal (2020); Bansal et al. (2021b). In the scope of two-phase flow models, the pH formulation of the Two-Fluid Model (TFM) and the special zero-slip case of the Drift Flux Model (DFM) have recently been developed; see Bansal et al. (2021a,b). However, as mentioned in Bansal et al. (2021a), for the general DFM, for e.g., the DFM with the Zuber-Findlay slip conditions, there have been technical challenges in obtaining a pH formalism.

In Bansal et al. (2021a,b), the pH formulation of multi-phase flow models has been obtained by eliminating constraints and writing a system of partial differential-algebraic equations (PDAEs) as a system with (only) partial differential equations (PDEs). As a consequence, the exisiting pH-based multi-phase modelling framework is not modular enough since mathematical computations have to be performed again for even a small change in the model description. In order to have a modular modelling framework, it is best to resort to pH descriptor realizations. Quite some work has been done in the area of pH descriptor formalism; see Beattie et al. (2018); Mehrmann and Morandin (2019); Mehrmann and Unger (2022) for instance, but the field is still in the initial stages of theoretical development, in particular for partial differential algebraic systems with non-quadratic Hamiltonian functionals, which is a representative feature of multi-phase flow dynamical models of interest. Furthermore, despite the developments, for complex physical systems in general, re-formulating the (nonlinear, coupled) PDAEs into a pH structure is very cumbersome and almost unrealizable. Moreover, based on some theoretical observations; see Sections 2.1 and 2.2, it seems that there is a scope of having a more generalized pH descriptor realization.

In addition, one of the key hindrances in obtaining a pH formulation of a model written in terms of (non-conservative) state variables could be due to the use of the standard $\mathcal{L}^2$ inner product; see Matignon and Helie (2013), wherein the authors have shown that the formal skew-adjointness of an operator holds if it is defined with respect to a weighted inner product. It is, hence, tempting to check if the operators, which are not formally skew-adjoint with respect to the $\mathcal{L}^2$ inner product, can be shown to be formally skew-adjoint with respect to a weighted one.

The main contributions of this paper are: *(i)* we showcase the limitations of the state-of-the-art pH descriptor model formulations, *(ii)* we propose a (general) novel pH descriptor formalism based on the notion of the weighted inner product, which requires solving homogeneous Sylvester equations, and test it on a simplified model problem.

The outline of the rest of this paper is as follows: In Section 2.1 and Section 2.2, we highlight the possible issues with the current state-of-the-art pH (descriptor) formalisms. In Section 2.3, we propose a new methodology to develop pH descriptor realizations of linear or non-linear problems. Section 3 deals with conclusions and future works.

2. TOWARDS A GENERAL PORT-HAMILTONIAN DESCRIPTOR REALIZATION

2.1 One possible methodology

We first recall definition of pH descriptor systems from Mehrmann and Unger (2022), which is a slight generalization of the one by Mehrmann and Morandin (2019).

Definition 1. A pH descriptor system is a system of differential(-algebraic) equations of the form

$$\mathbf{E}(t,\mathbf{x})\dot{\mathbf{x}}+\mathbf{r}(t,\mathbf{x}) = \mathbf{A}(t,\mathbf{x})\mathbf{z}(t,\mathbf{x})+\mathbf{B}(t,\mathbf{x})\mathbf{u},$$
$$\mathbf{y} = \mathbf{B}(t,\mathbf{x})^{\mathrm{T}}\mathbf{V}(t,\mathbf{x})^{\mathrm{T}}\mathbf{z}(t,\mathbf{x}),$$

with state $\mathbf{x}(t) \in \mathbb{R}^n$, input $\mathbf{u}(t) \in \mathbb{R}^m$, output $\mathbf{y}(t) \in \mathbb{R}^m$, the flow matrix $\mathbf{E}(t,\mathbf{x}) \in \mathbb{R}^{l\times n}$, time-flow function $\mathbf{r}(t,\mathbf{x}) \in \mathbb{R}^l$, effort function $\mathbf{z}(t,\mathbf{x}) \in \mathbb{R}^k$, structure-dissipation matrix $\mathbf{A} \in \mathbb{R}^{l\times k}$ with $\mathbf{VA} = \mathbf{J} - \mathbf{R}$, structure matrix $\mathbf{J} = -\mathbf{J}^{\mathrm{T}}$, dissipation matrix $\mathbf{R} = \mathbf{R}^{\mathrm{T}} \geq 0$, port matrix $\mathbf{B}(t,\mathbf{x}) \in \mathbb{R}^{l\times m}$, projection-type matrix $\mathbf{V}(t,\mathbf{x}) \in \mathbb{R}^{k\times l}$, and the gradient of the Hamiltonian $\mathcal{H}$ satisfies $\partial_{\mathbf{x}}\mathcal{H} = \mathbf{E}^{\mathrm{T}}\mathbf{V}^{\mathrm{T}}\mathbf{z}$, and $\partial_t\mathcal{H} = \mathbf{z}^{\mathrm{T}}\mathbf{V}\mathbf{r}$ pointwise.

Remark 2. If $\mathbf{V} = \mathbf{I}$ and $\mathbf{z}(t,\mathbf{x}) \in \mathbb{R}^l$, then Definition 1 reduces to the one in Mehrmann and Morandin (2019).

For simplicity, in the example that follows, we will neglect dissipative effects. To point out the issues with the state-of-the-art descriptor formalism, let us consider a special form of the two-phase flow model as in Bansal et al. (2021a):

$$\begin{aligned}
\partial_t m_g &= -\partial_\xi(m_g v),\\
\partial_t m_\ell &= -\partial_\xi(m_\ell v),\\
\partial_t v &= -\partial_\xi\Big(\frac{v^2}{2}\Big) - \frac{1}{m_g+m_\ell}\partial_\xi p,\\
0 &= \frac{m_g}{\rho_g} + \frac{m_\ell}{\rho_\ell} - 1, \ \text{(volume conservation)},\\
0 &= p - \rho_g^2 u_g'(\rho_g), \ \text{(E.O.S. for gas phase)},\\
0 &= p - \rho_\ell^2 u_\ell'(\rho_\ell), \ \text{(E.O.S. for liquid phase)},
\end{aligned} \tag{1}$$

where $m_g := \alpha_g\rho_g$, $m_\ell := \alpha_\ell\rho_\ell$, α_ℓ and α_g, resp., denote liquid and gas void fraction, ρ_ℓ and ρ_g refer to the density of the liquid and the gas phase, resp., v is the common fluid velocity, p is the common pressure, $\xi \in \Omega$ denotes spatial domain, u_g and u_ℓ, resp., represent the internal energy of the gaseous and liquid phase, and u_i' with $i = \{g,\ell\}$ denote the partial derivative of the internal energy associated to the i-th phase w.r.t. the fluid density of the i-th phase.

The Hamiltonian functional for the above conservative zero-slip DFM can be expressed as:

$$\mathcal{H} = \int_\Omega \Big(m_g u_g(\rho_g) + m_\ell u_\ell(\rho_\ell) + \frac{1}{2}m_g v_g^2 + \frac{1}{2}m_\ell v_\ell^2\Big)d\Omega. \tag{2}$$

Remark 3. Consider that algebraic constraints in (1) *are eliminated and that we have three PDEs and as many number of unknowns. The model in this form admits a pH realization; see Bansal et al. (2021a). Hence, this simplified set up is a good model problem to check the potential of existing pH descriptor realizations and the need for generalization, if any. The vectors/matrices/operators, in accordance with Definition 1, are as follows:*

$$\mathbf{z} = \begin{pmatrix}\delta_{m_g}\mathcal{H}\\ \delta_{m_\ell}\mathcal{H}\\ \delta_v\mathcal{H}\end{pmatrix}, \ \mathbf{x} = \begin{pmatrix}m_g\\ m_\ell\\ v\end{pmatrix}, \ \mathbf{E} = \begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix},$$

$$\mathbf{A} = \begin{pmatrix} 0 & 0 & -\partial_\xi(\frac{m_g}{m_g+m_\ell}\cdot)\\ 0 & 0 & -\partial_\xi(\frac{m_\ell}{m_g+m_\ell}\cdot)\\ -\frac{m_g}{m_g+m_\ell}\partial_\xi & -\frac{m_\ell}{m_g+m_\ell}\partial_\xi & 0\end{pmatrix}.$$

We consider the mapping $\mathbf{V} = \mathbf{E}$. We notice that $\mathbf{VA} =: \mathbf{J}$ is skew-adjoint under periodic boundary conditions. We also have $\mathbf{E}^T\mathbf{V}^T\mathbf{z} = [\delta_{m_g}\mathcal{H}, \delta_{m_\ell}\mathcal{H}, \delta_v\mathcal{H}]^T = \delta_{\mathbf{x}}\mathcal{H}$.

Now consider that, unlike Remark 3, we do not eliminate constraints and $\mathbf{x} = [m_g, m_\ell, v, \rho_g, \rho_\ell, p]^T$. The variational derivatives are:

$$\begin{cases}\delta_{m_g}\mathcal{H} = \dfrac{v^2}{2} + u_g(\rho_g), \quad \delta_{m_\ell}\mathcal{H} = \dfrac{v^2}{2} + u_\ell(\rho_\ell),\\ \delta_v\mathcal{H} = (m_g+m_\ell)v, \quad \delta_{\rho_g}\mathcal{H} = m_g\dfrac{\partial u_g}{\partial\rho_g} = m_g u_g',\\ \delta_{\rho_\ell}\mathcal{H} = m_\ell\dfrac{\partial u_\ell}{\partial\rho_\ell} = m_\ell u_\ell', \quad \delta_p\mathcal{H} = 0, \ \text{and}\end{cases} \tag{3}$$

$$\mathbf{z} = \begin{pmatrix}\delta_{m_g}\mathcal{H}\\ \delta_{m_\ell}\mathcal{H}\\ \delta_v\mathcal{H}\\ \delta_{\rho_g}\mathcal{H}\\ \delta_{\rho_\ell}\mathcal{H}\\ \frac{m_g}{\rho_g}+\frac{m_\ell}{\rho_\ell}-1\\ p-\rho_g^2u_g'(\rho_g)\\ p-\rho_\ell^2u_\ell'(\rho_\ell)\end{pmatrix}, \mathbf{x} = \begin{pmatrix}m_g\\ m_\ell\\ v\\ \rho_g\\ \rho_\ell\\ p\end{pmatrix}, \mathbf{E} = \begin{pmatrix}1&0&0&0&0&0\\0&1&0&0&0&0\\0&0&1&0&0&0\\0&0&0&0&0&0\\0&0&0&0&0&0\\0&0&0&0&0&0\end{pmatrix}.$$

As per Definition 1. we should have

$$\mathbf{E}^T\mathbf{V}^T\mathbf{z} = [\delta_{m_g}\mathcal{H}, \delta_{m_\ell}\mathcal{H}, \delta_v\mathcal{H}, \delta_{\rho_g}\mathcal{H}, \delta_{\rho_\ell}\mathcal{H}, 0]^T = \delta_{\mathbf{x}}\mathcal{H}.$$

However, any choice of $\mathbf{V} \in \mathbb{R}^{8\times6}$ along with other matrices will not be able to ensure $\mathbf{E}^T\mathbf{V}^T\mathbf{z} = \delta_{\mathbf{x}}\mathcal{H}$. We believe that a generalization to Definition 1 is hence possible. The aforementioned possibility of generalization holds irrespective of the structure of the operator A.

Remark 4. The aforementioned issue will exist even if we choose a different state vector, say $\mathbf{x} = [\alpha_g, \alpha_\ell, v, \rho_g, \rho_\ell, p]$.

Remark 5. We have observed that single-phase flow models can be cast in a pH descriptor form in line with Def. 1.

2.2 Another possible methodology

In order to explain more challenges, we next consider a simple setting in the scope of single-phase flow models. The model is governed by the following set of equations:

$$\begin{aligned}\partial_t\rho + \partial_\xi(\rho v) &= 0,\\ \partial_t(\rho v) + \partial_\xi(\rho v^2 + p) &= 0,\\ \rho = g(p) &= p/c^2,\end{aligned} \tag{4}$$

where ξ denotes the spatial domain, and c represents the speed of sound in the fluid medium. The Hamiltonian $\mathcal{H}$:

$$\mathcal{H}(\rho,v,p) = \int_\Omega \frac{1}{2}\rho v^2 + \rho\mathcal{U}(\rho)d\Omega, \ \text{where } d\mathcal{U} = \frac{p}{\rho^2}d\rho. \tag{5}$$

Two possible realizations (under the same choice of state coordinate vector $\mathbf{x} := [\rho, v, p]^T$) are as follows:

$$\underbrace{\begin{pmatrix}1&0&0\\0&1&0\\0&0&0\end{pmatrix}}_{\mathrm{E}}\begin{pmatrix}\partial_t\rho\\ \partial_t v\\ \partial_t p\end{pmatrix} = \underbrace{\begin{pmatrix}0&-1&0\\-1&0&0\\0&0&1\end{pmatrix}}_{\mathrm{J}}\partial_\xi\begin{pmatrix}\frac{\delta\mathcal{H}}{\delta\rho}\\ \frac{\delta\mathcal{H}}{\delta v}\\ \frac{\delta\mathcal{H}}{\delta p}\end{pmatrix} - \underbrace{\begin{pmatrix}0\\0\\ \frac{p}{\rho}g'(p)\end{pmatrix}}_{\mathrm{B}}.$$

$$\underbrace{\begin{pmatrix}1&0&0\\0&1&0\\1&0&-g'\end{pmatrix}}_{\mathrm{F}}\begin{pmatrix}\partial_t\rho\\ \partial_t v\\ \partial_t p\end{pmatrix} = \underbrace{\begin{pmatrix}0&-1&0\\-1&0&0\\0&0&0\end{pmatrix}}_{\tilde{J}}\partial_\xi\begin{pmatrix}\frac{\delta\mathcal{H}}{\delta\rho}\\ \frac{\delta\mathcal{H}}{\delta v}\\ \frac{\delta\mathcal{H}}{\delta p}\end{pmatrix}; \ g' = 1/c^2.$$

In view of above realizations, general representation reads:

$$\mathbf{E}\dot{\mathbf{x}} = \mathbf{J}\delta_{\mathbf{x}}\mathcal{H} - \mathbf{B}, \quad \text{where } \mathbf{E} \text{ is singular.} \tag{6}$$

or,

$$\mathbf{F}\dot{\mathbf{x}} = \tilde{\mathbf{J}}\delta_{\mathbf{x}}\mathcal{H}, \quad \text{where } \mathbf{F} \text{ is invertible.} \tag{7}$$

Building on (7), under choice of states: $\mathbf{x} := [\rho, v, p]^T$, we have: $\mathbf{F}\dot{\mathbf{x}} = \mathbf{J}\delta_{\mathbf{x}}\mathcal{H} = \mathbf{P_1}\partial_\xi\delta_{\mathbf{x}}\mathcal{H}$, which can be rewritten as:

$$\mathbf{F}\dot{\mathbf{x}} = \mathbf{P_1}\frac{\partial}{\partial\xi}(\frac{\delta\mathcal{H}}{\delta\mathbf{x}}). \tag{8}$$

The time-derivative of the Hamiltonian functional reads:

$$\frac{d}{dt}\mathcal{H} = \frac{\delta\mathcal{H}}{\delta\mathbf{x}}^T\dot{\mathbf{x}} = \frac{\delta\mathcal{H}}{\delta\mathbf{x}}^T\Big(\mathbf{F}^{-1}\mathbf{P_1}\frac{\partial}{\partial\xi}\Big)\frac{\delta\mathcal{H}}{\delta\mathbf{x}}. \tag{9}$$

The above equation can also be written as:

$$\frac{d}{dt}\mathcal{H} = \dot{\mathbf{x}}^T\frac{\delta\mathcal{H}}{\delta\mathbf{x}} = \frac{\delta\mathcal{H}}{\delta\mathbf{x}}^T\Big(\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi\Big)^T\frac{\delta\mathcal{H}}{\delta\mathbf{x}}.$$

Using the above two representations, the time derivative of the Hamiltonian functional can be written as:

$$\frac{d}{dt}\mathcal{H} = \frac{1}{2}\frac{\delta\mathcal{H}}{\delta\mathbf{x}}^T\underbrace{\Big(\mathbf{F}^{-1}\mathbf{P_1}\frac{\partial}{\partial\xi} + (\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi)^T\Big)}_{\mathbf{O}}\frac{\delta\mathcal{H}}{\delta\mathbf{x}}.$$

Analysis of the operator, $\mathbf{O}$, will dictate if we have the right properties of the matrices and the operators. $\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + (\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi)^T = 0$ will enforce skew-adjointness and ensure that $\frac{d\mathcal{H}}{dt} = 0$ for a conservative system. We can write:

$$\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + (\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi)^T = \mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + (\mathbf{P_1}\partial_\xi)^T\mathbf{F}^{-T}. \tag{10}$$

The transpose of $\mathbf{P_1}\partial_\xi$ is: $(\mathbf{P_1}\partial_\xi)^T = -\mathbf{P_1}^T\partial_\xi$. A partial derivative acting on $\mathbf{F}^{-T}$ is known to be evaluated as:

$$\partial_\xi o\mathbf{F}^{-T} = \partial_\xi\mathbf{F}^{-T} + \mathbf{F}^{-T}\partial_\xi. \tag{11}$$

Using (11), the right-hand-side of (10) simplifies to:

$$\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi - \mathbf{P_1}^T\Big(\partial_\xi\mathbf{F}^{-T} + \mathbf{F}^{-T}\partial_\xi\Big). \tag{12}$$

Since $\mathbf{F}$ does not vary spatially, using (10) and (12), we have:

$$\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + (\mathbf{P_1}\partial_\xi)^T\mathbf{F}^{-T} = \Big(\mathbf{F}^{-1}\mathbf{P_1} - \mathbf{P_1}^T\mathbf{F}^{-T}\Big)\partial_\xi. \tag{13}$$

For the representation given by (8) and $\rho = \frac{p}{c^2}$ (i.e., $g' = \frac{1}{c^2}$), the term $\Big(\mathbf{F}^{-1}\mathbf{P_1} - \mathbf{P_1}^T\mathbf{F}^{-T}\Big)$ turns out to be:

$$\Big(\mathbf{F}^{-1}\mathbf{P_1} - \mathbf{P_1}^T\mathbf{F}^{-T}\Big) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & c^2 \\ 0 & -c^2 & 0 \end{pmatrix}. \tag{14}$$

We would have wished to have the term at the right-hand-side of (14) to be zero. However, this is not the case. This hints that we need to introduce extra degrees of freedom, say through a weighting matrix, to ensure that we obtain a (pH) model formulation that has the right properties.

2.3 Proposed methodology

In Sections 2.1 and 2.2, we have seen that there exists a possibility to generalize existing pH model representations. We now propose a novel pH formalism; see Theorem 6.

Theorem 6. A mathematical model expressed in the form: $\mathbf{E}\dot{\mathbf{x}} = (\mathbf{J} - \mathbf{R})\mathbf{z}$*, where the inverse of the (known) matrix/operator* $\mathbf{E}$ *might not necessarily exist, possesses a pH structure if the gradient of the Hamiltonian satisfies* $\partial_{\mathbf{x}}\mathcal{H} = \mathbf{N}\mathbf{z}$*, the weighting matrix* $\mathbf{W}$ *is decomposed as* $\mathbf{W} = \mathbf{E}^\star\mathbf{M}\mathbf{E}$ *with* $\star$ *denoting the adjoint, the equation*

$$\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{J} + \mathbf{J}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big) = 0 \tag{15}$$

holds, and $\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{R} + \mathbf{R}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big)$ *is (formally) self-adjoint and positive semi-definite (PSD) for the matrix differential operator setting. Furthermore, if we ignore resistive effects, the operators* $\mathbf{E}, \mathbf{M}, \mathbf{J}, \mathbf{N}$ *should obey the relation:* $\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{J} + \mathbf{J}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big) = 0$*. If we define* $\tilde{\mathbf{N}} = \mathbf{E}\mathbf{N}$*, then* (15)*, which can be written as:*

$$\Big(\tilde{\mathbf{N}}^\star\mathbf{M}\mathbf{J} + \mathbf{J}^\star\mathbf{M}\tilde{\mathbf{N}}\Big) = 0, \tag{16}$$

should hold. Here, $\mathbf{E}$ *and* $\mathbf{J}$ *are known quantities, and* $\mathbf{N}$ *and* $\mathbf{M}$ *are unknowns or degrees of freedom. For the conservative case, we could, in principle, make any choice for* $\mathbf{N}$ *(or* $\mathbf{M}$*) and find the (other) unknown* $\mathbf{M}$ *(or* $\mathbf{N}$*) by solving* (16)*. Inherently, the choice for* $\mathbf{N}$ *(or* $\mathbf{M}$*) should be such that the solutions to* (16) *exist. We could also assume that* $\tilde{\mathbf{N}}^\star\mathbf{M} = \mathbf{M}\tilde{\mathbf{N}} = \hat{\mathbf{M}}$*. Under this assumption, the model admits a pH structure if the following two relations hold:*

$$\hat{\mathbf{M}}\mathbf{J} + \mathbf{J}^\star\hat{\mathbf{M}} = 0, \quad \tilde{\mathbf{N}}^\star\mathbf{M} - \mathbf{M}\tilde{\mathbf{N}} = 0. \tag{17}$$

Proof. For the proof, we verify the conditions under which the rate of change of Hamiltonian, i.e., $\frac{d\mathcal{H}}{dt}$, along the solutions of the mathematical model is less than or equal to zero. To this end, we compute

$$\begin{aligned}\frac{d\mathcal{H}}{dt} &= \Big(\frac{\partial\mathcal{H}}{\partial\mathbf{x}}\Big)^\star\mathbf{W}\dot{\mathbf{x}} = \dot{\mathbf{x}}^\star\mathbf{W}\Big(\frac{\partial\mathcal{H}}{\partial\mathbf{x}}\Big) \\ &= \frac{1}{2}\Big(\Big(\frac{\partial\mathcal{H}}{\partial\mathbf{x}}\Big)^\star\mathbf{W}\dot{\mathbf{x}} + \dot{\mathbf{x}}^\star\mathbf{W}\Big(\frac{\partial\mathcal{H}}{\partial\mathbf{x}}\Big)\Big) \\ &= \frac{1}{2}\Big(\mathbf{z}^T\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{J} + \mathbf{J}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big)\mathbf{z} - \\ &\qquad \mathbf{z}^T\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{R} + \mathbf{R}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big)\mathbf{z}\Big).\end{aligned}$$

The dissipation inequality is satisfied (only) if the first term in the last equality equals zero, i.e., (15) holds, and the second term in the last equality, i.e., $\Big(\mathbf{N}^\star\mathbf{E}^\star\mathbf{M}\mathbf{R} + \mathbf{R}^\star\mathbf{M}\mathbf{E}\mathbf{N}\Big)$ is (formally) self-adjoint and PSD.

Remark 7. It can be shown that if $\mathbf{W} = \mathbf{E}^\star\mathbf{M}\mathbf{E} = \mathbf{I}$ *(identity matrix),* $\mathbf{E}\mathbf{E}^\star\mathbf{M} = \mathbf{I}$*, and* $\mathbf{N} = \mathbf{E}^\star$*, where* $\mathbf{E}$*, in Theorem 6, under restrictions on the dimension of the variable* $\mathbf{z}$*, carries the same meaning as in Definition 1, then Theorem 6 reduces to the definition in Mehrmann and Morandin (2019). Furthermore, if* $\mathbf{N}$*,* $\mathbf{E}$*, and* $\mathbf{J}$ *in Theorem 6, are resp. equivalent to* $\mathbf{E}^\star\mathbf{V}^\star$*,* $\mathbf{E}$*, and* $\mathbf{A}$ *(in absence of resistive effects) in Definition 1,* $\mathbf{W} = \mathbf{E}^\star\mathbf{M}\mathbf{E} = \mathbf{I}$*,* $\mathbf{E}\mathbf{E}^\star\mathbf{M} = \mathbf{I}$*, then Theorem 6, with no restriction on* $\mathbf{z}$*, reduces to the definition in Mehrmann and Unger (2022).*

Remark 8. The boundary effects have been ignored in the new formulation, but can be easily taken into account.

The first equation in (17) is an operator (homogeneous) Lyapunov/Riccati equation for a known $\mathbf{J}$. The second equation in (17) represents a homogeneous operator Sylvester equation for an unknown $\mathbf{M}$, and is similar to an operator T-Riccati equation for an unknown $\tilde{\mathbf{N}}$. To the best of our knowledge, no work exists in the scope of obtaining numerical solutions to the operator T-Riccati equations. However, it is worth mentioning that only recently some works as in Benner et al. (2022); Benner and Palitta (2020) have started to address the question pertaining to numerical solutions of (a general class of) matrix T-Riccati equations. As far as research on numerical solutions, exis-

tence, etc., of operator Riccati/Lyapunov/Sylvester equations is concerned, quite some work has been done, for e.g., see Curtain and Pritchard (1976).

In the sequel, we only consider the setting where one is interested in (non-linear) descriptor realizations of conservative physical system discussed in Section 2.2. Using the principles discussed earlier in Section 2.2 and Section 2.3, the rate of change of Hamiltonian $\mathcal{H}$ along the solutions of the model should be zero. Mathematically, this means:

$$\Big(\frac{\partial \mathcal{H}}{\partial \mathbf{x}}\Big)^T \Big(\mathbf{W}\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + \Big(\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi\Big)^T \mathbf{W}\Big)\frac{\partial \mathcal{H}}{\partial \mathbf{x}} = 0, \quad (18)$$

where $\mathbf{F}$ and $\mathbf{P_1}$ carry the meaning as introduced in Section 2.2. For (18) to hold, we should have:

$$\mathbf{W}\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + \Big(\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi\Big)^T \mathbf{W} = 0. \quad (19)$$

The above equation can be rewritten as shown next:

$$\begin{aligned} &\mathbf{W}\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi + \Big(\mathbf{P_1}\partial_\xi\Big)^T \mathbf{F}^{-T}\mathbf{W} = 0, \\ &\mathbf{W}\mathbf{F}^{-1}\mathbf{P_1}\partial_\xi - \mathbf{P_1}^T\partial_\xi \circ (\mathbf{F}^{-T}\mathbf{W}) = 0, \end{aligned} \quad (20)$$

where $\hat{a} \circ \hat{b}$ denotes the action of $\hat{a}$ on $\hat{b}$. Assuming that $\mathbf{F}$ and $\mathbf{P_1}$ are not spatially varying, (20) reduces to

$$\mathbf{W}\mathbf{F}^{-1}\mathbf{P_1} - \mathbf{P_1}^T\mathbf{F}^{-T}\mathbf{W} = 0, \quad (21)$$

which, for an unknown $\mathbf{W}$, is a homogeneous Sylvester equation. It is not trivial to solve such an equation using MATLAB or other tools since they return $\mathbf{W} = \mathbf{0}$. In order to obtain a non-zero solution, although non-unique, we next briefly discuss the solution methodology.

Remark 9. If $\mathbf{E} = \mathbf{I}$ *(identity matrix),* $\mathbf{N} = \mathbf{I}$*, and* $\mathbf{J}$ *is a (formally) skew-adjoint matrix differential operator, then* (16) *or* (17) *reduce to* (21) *for the representation* (8)*.*

Homogeneous Sylvester Equation Consider a simplified form of the term appearing on the left-hand-side of (21):

$$G(\mathbf{W}) = \mathbf{W}\tilde{\mathbf{A}} - \tilde{\mathbf{A}}^T\mathbf{W}, \quad (22)$$

where $\tilde{\mathbf{A}}$, in the sequel, denotes $\tilde{\mathbf{A}} = \mathbf{F}^{-1}\mathbf{P_1}$. Next, we form the unknown $\mathbf{W}$ in the following way:

$$\mathbf{W}_{eigenfn} = ab^T; \;\; a, b \in \mathbb{R}^n, \quad (23)$$

where n stands for the dimension of the (square) matrix/operator (say $\mathbf{J}$), a and b are eigenvectors associated to the matrix $\tilde{\mathbf{A}}^T$; i.e., $\tilde{\mathbf{A}}^T a = \lambda a$; $\tilde{\mathbf{A}}^T b = \mu b$ or $b^T\tilde{\mathbf{A}} = \mu b^T$. Next, $\mathbf{W}_{eigenfn}$ applied to $\tilde{\mathbf{A}}$ yields:

$$\mathbf{W}_{eigenfn}\tilde{\mathbf{A}} = ab^T\tilde{\mathbf{A}} = a\mu b^T = \mu\mathbf{W}_{eigenfn}, \quad (24)$$

and $\tilde{\mathbf{A}}^T$ applied to $\mathbf{W}_{eigenfn}$ yields:

$$\tilde{\mathbf{A}}^T\mathbf{W}_{eigenfn} = \tilde{\mathbf{A}}^T ab^T = \lambda ab^T = \lambda\mathbf{W}_{eigenfn}. \quad (25)$$

As a consequence, (22) can be written as:

$$G(\mathbf{W}_{eigenfn}) = (\lambda + \mu)\mathbf{W}_{eigenfn}. \quad (26)$$

It can be said that if both $\mathbf{W}_{eigenfn}$ and $\mathbf{W}^T_{eigenfn}$ are solutions to the homogeneous Sylvester equation, then $\mathbf{W}_{eigenfn} + \mathbf{W}^T_{eigenfn}$ is also its solution.

Using the above methodology, the weighting matrix $\mathbf{W}$ can be obtained for the problem considered in Section 2.2. As an example, for $c = 316$, we can compute the eigenvectors associated to $\mathbf{P_1}^T\mathbf{F}^{-T}$ and, subsequently, compute several possible values of $\mathbf{W}$ using (23). One possible solution is:

$$\mathbf{W} = \begin{bmatrix} 0.5 & 0.5 & 0 \\ -0.5 & -0.5 & 0 \\ 0 & 0 & 0 \end{bmatrix}. \quad (27)$$

3. CONCLUSION AND FUTURE WORKS

This work attempted to develop a more general port-Hamiltonian (pH) descriptor framework for multi-phase fluid dynamical (and non-linear physical) systems. It is worth mentioning that although we have a methodology to obtain the weighting matrix $\mathbf{W}$, the matrix $\mathbf{W}$ is not invertible. The future work(s) will deal with computing an invertible $\mathbf{W}$, and with the identification of more conditions on different matrices/operators involved (e.g., $\mathbf{J}, \mathbf{R}$) such that numerical solutions to the resulting operator equations exist. We eventually aim to develop a (conditional) pH descriptor framework for the general case of the Drift Flux Model for which the state-of-the-art pH formalism (Definition 1) seems unsuitable.

ACKNOWLEDGEMENTS

We would like to acknowledge Hans Zwart and Philipp Schulze for insightful discussions.

Abstract: In this effort, a novel operator theoretic framework is developed for data-driven solution of optimal control problems. The developed methods focus on the use of trajectories (i.e., time-series) as the fundamental unit of data for the resolution of optimal control problems in dynamical systems. Trajectory information in the dynamical systems is embedded in a reproducing kernel Hilbert space (RKHS) through what are called occupation kernels. The occupation kernels are tied to the dynamics of the system through the densely defined Liouville operator. The pairing of Liouville operators and occupation kernels allows for lifting of nonlinear finite-dimensional optimal control problems into the space of infinite-dimensional linear programs over RKHSs.

Keywords: optimal control, operator theoretic methods in systems theory, nonlinear systems and control

1. INTRODUCTION

Numerical solutions of optimal control problems are obtained by using Pontryagin's maximum principle Pontryagin et al. (1962) to convert the optimal control problem into a two-point boundary value problem von Stryk and Bulirsch (1992); Betts (1998) or a nonlinear programming problem Hargraves and Paris (1987); Huntington (2007); Fahroo and Ross (2008); Rao et al. (2010); Darby et al. (2011); Garg et al. (2011). While there is a rich history of literature on the topic of numerical optimal control, the computational efficiency of numerical optimal control is limited by that of nonlinear programming, where solutions of large problems can be computationally prohibitive and the solutions, when available, are typically only locally optimal.

Based on the seminal work of Lasserre Lasserre (2010) on moments and positive polynomials, occupation measure approaches that convert a nonlinear optimal control problem into an infinite dimensional linear program that can be efficiently solved using sum of squares based convex programming methods were developed in results such as Lasserre et al. (2008); Majumdar et al. (2014); Claeys et al. (2016); Zhao et al. (2017).

Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the sponsoring agencies.

While computationally efficient, techniques that utilize occupation measures are typically only applicable to systems where the functions that describe the dynamics, the cost functions, and the constraint sets are polynomials. The techniques developed in this paper also convert finite dimensional nonlinear optimal control problems into infinite dimensional linear programs, but utilize a reproducing kernel Hilbert space framework. An advantage of framing the infinite dimensional linear program within the reproducing kernel Hilbert space framework is that the developed tools are applicable to optimal control problems with a broader range of cost functions and constraining sets. Principally, the advantage is realized by exchanging the moment problem for occupation measures with the more flexible approximation abilities of reproducing kernel Hilbert spaces.

2. REPRODUCING KERNEL HILBERT SPACES

Definition 1. A real-valued *reproducing kernel Hilbert space* (RKHS), H, over a set $X \subset \mathbb{R}^n$ is a Hilbert space of functions $f : X \mapsto \mathbb{R}$ such that for every $x \in X$, the evaluation functional $E_x f := f(x)$ is bounded.

By the Reisz representation theorem, for each $x \in X$ there is a corresponding function $k_x \in H$ such that $\langle f, k_x \rangle_H = f(x)$, where $\langle f, g \rangle_H$ denotes the inner product. For each RKHS, there is a uniquely identified *kernel function*, $K(x, y) := \langle k_y, k_x \rangle_H$, such that for any finite collection of points, $\{x_i\}_{i=1}^M$, the corresponding Gram matrix, $(K(x_i, x_j))_{i,j=1}^M$, is positive semi-definite.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

The importance of RKHSs lies in their ability to perform as function approximators. In particular, just as the collection of polynomials is dense inside of the space of continuous functions over compact subsets of $\mathbb{R}^n$, *universal* RKHSs are those spaces that are also dense in the space of continuous functions over compact subsets of $\mathbb{R}^n$. Moreover, the following lemma demonstrates that it is sufficient to consider linear combinations of the kernel functions themselves for function approximation when the kernel is in a universal RKHS (See (Steinwart and Christmann, 2008, Theorem 4.21)).

Lemma 1. Consider the subset $S := \{K(\cdot, y) : y \in X\}$ of a RKHS H over a set X with kernel K. Then span S is dense in H with respect to the Hilbert space norm. Moreover, if K is continuous, then span S is dense in H with respect to the uniform norm over restrictions to compact subsets of X.

3. PROBLEM FORMULATION

Let $H(Y)$ be a real-valued RKHS of continuous functions over the set Y. Let X and D be compact subsets of $\mathbb{R}^n$, U a compact subset of $\mathbb{R}^m$, $\Sigma := [0, T] \times X$, and $S = \Sigma \times U$. Throughout the rest of this manuscript the RKHSs $H(X)$, $H(D)$ and $H(\Sigma)$ denote the RKHSs obtained through the functions in $H(S)$ where the inputs have been projected to X, D, and Σ, respectively. Let $f : [0, T] \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ be a locally Lipschitz function and consider the dynamical system

$$\dot{x} = f(t, x, u), \qquad x(0) = x_0 \in \mathbb{R}^n. \tag{1}$$

A state of the dynamical system corresponding to the initial condition x_0 and controller $u : [0, T] \mapsto \mathbb{R}^m$ will be written as $\phi_f(t; x_0, u)$.

For a fixed T, the optimal control problem is formulated as the need to minimize the cost

$$J(x(\cdot), u(\cdot)) = \int_0^T h(t, x(t), u(t))\mathrm{d}t + F(x(T)), \tag{2}$$

for functions $h \in H(S)$ and $F \in H(D)$, over the set of differentiable functions $x : [0, T] \to \mathbb{R}^n$ and continuous functions $u[0, T] \to \mathbb{R}^m$ subject to the constraints (1). For ease of exposition, the formulation considered here is more restrictive than strictly necessary. The methods developed in the following can be extended to include measurable control signals and absolutely continuous state trajectories.

In the following, occupation kernels and Liouville operators, first introduced in Rosenfeld et al. (2020) are utilized to lift the nonlinear optimal control problem into the space of infinite-dimensional linear programs.

4. OCCUPATION KERNELS AND THE COST FUNCTIONAL

Whenever $(t, x(t), u(t)) \in S$ for all $t \in [0, T]$, the functional $g \mapsto \int_0^T g(t, x(t), u(t))\mathrm{d}t$, that maps from $H(S)$ to $\mathbb{R}$, is linear and bounded. Indeed, given the kernel function K_S corresponding to $H(S)$, it can be seen that

$$\left|\int_0^T g(t,x(t),u(t))\mathrm{d}t\right| \leq \left|\int_0^T \langle g, K_S(\cdot,(t,x(t),u(t)))\rangle_{H(S)}\mathrm{d}t\right|$$

$$\leq T\|g\|_{H(S)} \sup_{[0,T]} \sqrt{K_S((t,x(t),u(t)),(t,x(t),u(t)))}$$

$$\leq T\|g\|_{H(S)} \sup_{y\in S} \sqrt{K_S(y,y)}.$$

As such, by the Reisz representation theorem, there exists a function $\Gamma_{x(\cdot),u(\cdot)} \in H(S)$ such that $\int_0^T g(t, x(t), u(t))\mathrm{d}t = \langle g, \Gamma_{x(\cdot),u(\cdot)}\rangle_{H(S)}$. The function $\Gamma_{x(\cdot),u(\cdot)}$ is the *occupation kernel* corresponding to the signals $x(\cdot)$ and $u(\cdot)$. Note that at this juncture, the signals $x(\cdot)$ and $u(\cdot)$ are independent, i.e., $x(\cdot)$ is not necessarily a trajectory of the dynamical system (1) in response to $u(\cdot)$.

The occupation kernel itself may be expressed as

$$\Gamma_{x(\cdot),u(\cdot)}(y) = \int_0^T K_S(y, (t, x(t), u(t)))\mathrm{d}t.$$

Moreover,

$$\|\Gamma_{x(\cdot),u(\cdot)}\|^2_{H(S)} = \int_0^T \int_0^T K((\tau,x(\tau),u(\tau)),(t,x(t),u(t)))d\tau\mathrm{d}t, \tag{3}$$

and when $K(x, y) = \Phi(\|x-y\|_2)$ is a radial basis function, such as the Wendland RBF or the Gaussian RBF, (3) may be bounded as $\|\Gamma_{x(\cdot),u(\cdot)}\|^2_{H(S)} \leq T^2\Phi(0)$.

Using the occupation kernels and the reproducing property $\langle F, K_D(\cdot, y)\rangle H_D = F(y)$ of the kernel function $K_D \in H_D$ corresponding to the RKHS $H(D)$, the cost functional in (2) can be expressed as

$$J(x(\cdot), u(\cdot)) = \langle h, \Gamma_{x(\cdot),u(\cdot)}\rangle_{H(S)} + \langle F, K_D(\cdot, x(T))\rangle_{H(D)}. \tag{4}$$

Note that the cost functional is linear with respect to the kernels $\Gamma_{x(\cdot),u(\cdot)}$ and K_D. If the dynamical system that constrains $x(\cdot)$ to be a solution in response to $u(\cdot)$ can also be expressed as a linear constraint on the space of kernels, the optimal control problem can be posed as a linear program in the infinite dimensional kernel space.

5. SYSTEM DYNAMICS AND THE TOTAL DERIVATIVE OPERATOR

In the following, a formulation of the dynamics in terms of total derivative operators is developed to construct the aforementioned linear constraint.

Definition 2. Define the *total derivative operator with symbol* f denoted by $A_f : \mathcal{D}(A_f) \to H(S)$ as $[A_f g](t, x, u) := \frac{\partial}{\partial t}g(t, x) + f(t, x, u) \cdot \nabla_x g(t, x)$ where the domain $\mathcal{D}(A_f)$ is defined cannonically as

$$\mathcal{D}(A_f) = \{g \in H(\Sigma) : A_f g \in H(S)\}. \tag{5}$$

The total derivative operator is seldom a compact operator. As such, to analyze the relationship between the total derivative operator and the occupation kernels, the theory of densely defined operators is leveraged.

Definition 3. (Densely Defined Operator). Given a set $\mathcal{D}(A) \subset H$, a linear operator $A : \mathcal{D}(A) \to H$ is said to be densely defined when $\mathcal{D}(A)$ is dense in H.

Differentiation is a canonical example of a densely defined operator. The following example, while not posed over a

RKHS, demonstrates this property of differentiation over the Hilbert space $L^2[0,1]$.

Example 1. Let $A = \frac{d}{dt}$ and suppose that the Hilbert space in question is $L^2[0,1]$. Since the derivative of any polynomial is again a polynomial and polynomials are dense in $L^2[0,1]$, $\mathcal{D}(A) := \{p : p \text{ is a polynomial over } [0,1]\}$ is a dense domain for A. It is also clear that $\mathcal{D}(A)$ cannot be extended to all of $L^2[0,1]$ as $f(t) = \sqrt{t}$ is in $L^2[0,1]$ and $\frac{d}{dt}f(t) = \frac{1}{2\sqrt{t}}$ is not.

The relationship between the total derivative operator and the occupation kernels is expressed through the adjoint of the total derivative operator, and for the development to be cogent, the adjoint needs to be densely defined. Since adjoints of closed operators over a Hilbert space are densely defined (Pedersen, 2012, Chapter 5), closedness of the total derivative operator is analyzed in the following.

Definition 4. Let A be an operator over H. A is said to be closed, if whenever $\{g_m\}_{m=1}^{\infty} \subset A$, $g_n \to f$ and $Ag_n \to h$ according to the Hilbert space norm, then $f \in \mathcal{D}(A)$ and $Af = h$.

The following theorem establishes a connection between the total derivative operator and signals $x(\cdot)$ and $u(\cdot)$ whenever $x(\cdot)$ is a solution of (1) under $u(\cdot)$. For brevity of notation, let $\Gamma_{x_0,u,f}$ denote the occupation kernel $\Gamma_{\phi_f(\cdot,x_0,u(\cdot)),u(\cdot)}$.

Theorem 1. The operator A_f introduced in Definition 2 is closed. Moreover, for an admissible trajectory $t \mapsto (t, x(t), u(t))$, with initial condition x_0, and that resides within a compact set for all $t \in [0,T]$, the function $\Gamma_{x_0,u,f}$ is in the domain of the adjoint of A_f.

Proof. Suppose that $\{g_m\}_{m=0}^{\infty} \subset \mathcal{D}(A_f) \subset H(\Sigma)$ such that $g_m \to g \in H(\Sigma)$ and $A_f g_m \to q \in H(S)$. Since the differentiability of the functions in H is inherited from the kernel function (see (Steinwart and Christmann, 2008, Corollary 4.36)), the function $\frac{\partial}{\partial x_i}g$ is well defined for each $g \in H(\Sigma)$ (but $\frac{\partial}{\partial x_i}g$ is not necessarily a function in $H(\Sigma)$). However, for any fixed t and x the mapping $p \mapsto \frac{\partial}{\partial x_i}p(t,x)$ is a continuous linear functional over $H(\Sigma)$. By (Steinwart and Christmann, 2008, Corollary 4.36),

$$\left|\frac{\partial}{\partial x_i}g_m(t,x) - \frac{\partial}{\partial x_i}g(t,x)\right| = \left|\frac{\partial}{\partial x_i}\left(g_m(t,x) - g(t,x)\right)\right| \leq \|g_m - g\|_{H(\Sigma)}\sqrt{\partial_i\partial_{i+n}K_\Sigma(((t,x)),((t,x)))}.$$

Hence, $\frac{\partial}{\partial x_i}g_m(t,x) \to \frac{\partial}{\partial x_i}g(t,x)$ for each $x \in X$ and $i = 1,\ldots,n$. Hence, $\frac{\partial}{\partial t}g_m(t,x) + f(t,x,u)\cdot\nabla_x g_m(t,x) \to \frac{\partial}{\partial t}g(t,x) + f(t,x,u)\cdot\nabla_x g(t,x)$ as $f(t,x,u)$ is constant with respect to m. Thus, $h = Ag$ and $g \in \mathcal{D}(A_f)$, and A_f is closed with the domain given in Definition 2.

To demonstrate that $\Gamma_{x_0,u,f}$ is in the domain of A_f^*, note that

$$\begin{aligned}&\left|\int_0^T \frac{\partial}{\partial t}g(t,x(t)) + f(t,x(t),u(t))\nabla_x g(t,x(t))dt\right| \\ &= \left|\int_0^T \dot{g}(t,x(t))dt\right| = |g(T,x(T)) - g(0,x(0))| \\ &= \left|\langle g, K_\Sigma(\cdot,(T,x(T))) - K_\Sigma(\cdot,(0,x(0)))\rangle_{H(\Sigma)}\right| \\ &\leq \|g\|_{H(\Sigma)}\|K_\Sigma(\cdot,(T,x(T))) - K_\Sigma(\cdot,(0,x(0)))\|_{H(\Sigma)}.\end{aligned}$$

Finally, given bounds on T and $\|x(t)\|_2$, a bound on $\|K_\Sigma(\cdot,(T,x(T))) - K_\Sigma(\cdot,(0,x(0)))\|_{H(\Sigma)}$ may be established. Thus, the functional over $\mathcal{D}(A_f)$ given as $g \mapsto \langle A_f g, \Gamma_{x_0,u,f}\rangle$ is bounded when $t \mapsto (t,x(t),u(t))$ is a trajectory of the system. It follows that the function $\Gamma_{x_0,u,f}$ is in the domain of the adjoint of the operator A_f. That is,

$$\langle A_f g, \Gamma_{x_0,u,f}\rangle_{H(S)} = \langle g, A_f^*\Gamma_{x_0,u,f}\rangle_{H(\Sigma)} = g(T,x(T)) - g(0,x(0)) \quad (6)$$

for all $g \in \mathcal{D}(A_f)$. □

Through consideration of (6) for an admissible trajectory satisfying the hypothesis of Theorem 1, $g \in \mathcal{D}(A_f)$ and setting $g_T(x) \equiv g(T,x) \in H(D)$, it can be observed that

$$\begin{aligned}\langle g, K_\Sigma(\cdot,(0,x_0))\rangle_{H(\Sigma)} &= g(0,x(0)) \\ &= -\langle g, A_f^*\Gamma_{x_0,u,f}\rangle + g(T,x(T)) \\ &= \langle -A_f g, \Gamma_{x_0,u,f}\rangle_{H(S)} + \langle g_T, K_D(\cdot,x(T))\rangle_{H(D)} \\ &= \langle(-A_f g, g_T), (\Gamma_{x_0,u,f}, K_D(\cdot,x(T)))\rangle_{H(S)\times H(D)}.\end{aligned}$$

Letting $\mathcal{L}_f : \mathcal{D}(A_f) \to H(S) \times H(D)$ denote the linear mapping $\mathcal{L}_f g = (-A_f g, g_T)$, it follows that $\langle g, \mathcal{L}_f^*(\Gamma_{x_0,u,f}, K_D(\cdot,x(T)))\rangle_{H(\Sigma)} = \langle g, K_\Sigma(\cdot,(0,x_0))\rangle_{H(\Sigma)}$ for all $g \in H(\Sigma)$. Hence, the linear constraint

$$\mathcal{L}_f^*(\Gamma_{x(\cdot),u(\cdot)}, K_D(\cdot,x(T))) = K_\Sigma(\cdot,(0,x_0)) \quad (7)$$

serves as a necessary condition for $x(\cdot)$ to be a trajectory of (1) in response to the control signal $u(\cdot)$.

6. A REFORMULATION OF THE OPTIMAL CONTROL PROBLEM

Using (4) and (7), the optimal control problem is expressed as an infinite dimensional linear program P given by

$$\min_{\Gamma_{x(\cdot),u(\cdot)},K_D(\cdot,x(T))} \langle(\Gamma_{x(\cdot),u(\cdot)},K_D(\cdot,x(T))),(h,F)\rangle_{H(S)\times H(D)}$$
$$\text{subject to: } \mathcal{L}_f^*(\Gamma_{x(\cdot),u(\cdot)},K_D(\cdot,x(T))) = K_\Sigma(\cdot,(0,x_0)).$$

To solve P, finite-dimensional representation of the decision variables $\Gamma_{x(\cdot),u(\cdot)}$ and $K_D(\cdot,x(T))$ is required. The representation is cogent under the following assumptions.

Assumption 1. A_f is densely defined on $H(\Sigma)$ together with a countable basis for $\mathcal{D}(A_f)$, given as $\{\sigma_m\}_{m=1}^{\infty} \subset \mathcal{D}(A_f)$. Furthermore, for all $s \in S$, the kernel functions satisfy $K_S(\cdot,s) \in \mathcal{D}(A_f)$.

Under Assumption 1, the optimal control problem can be expressed as the need to find the optimal real valued weights $\{w_i\}_{i=1}^{M_S}$ and $\{v_i\}_{i=1}^{M_D}$ that provide approximations for $\Gamma_{x(\cdot),u(\cdot)}$ and $K_D(\cdot,x(T))$ as

$$\Gamma_{x(\cdot),u(\cdot)}(\cdot) \approx \sum_{i=1}^{M_S} w_i K_S(\cdot,s_i) \quad (8)$$

$$K_D(\cdot,x(T)) \approx \sum_{i=1}^{M_D} v_i K_D(\cdot,d_i), \quad (9)$$

where $\{s_i\}_{i=1}^{M_S} \subset S$ is a collection of center in S, and $\{d_i\}_{i=1}^{M_D} \subset D$ is a collection of centers in D. The objective function of P can then be evaluated as

$$\langle(\Gamma_{x(\cdot),u(\cdot)}, K_D(\cdot, x(T))), (h, F)\rangle_{H(S)\times H(D)} \approx$$
$$\left\langle \left(\sum_{i=1}^{M_S} w_i K_S(\cdot, s_i), \sum_{i=1}^{M_D} v_i K_D(\cdot, d_i)\right), (h, F)\right\rangle_{H(S)\times H(D)}$$
$$= \sum_{i=1}^{M_S} w_i \langle K_S(\cdot, s_i), h\rangle_{H(s)} + \sum_{i=1}^{M_D} v_i \langle K_D(\cdot, d_i), F\rangle_{H(D)}$$
$$= \sum_{i=1}^{M_S} w_i h(s_i) + \sum_{i=1}^{M_D} v_i F(d_i). \quad (10)$$

Similarly, the constraint in P is satisfied provided $\langle \mathcal{L}_f g, (\Gamma_{x(\cdot),u(\cdot)}, K_D(\cdot, x(T)))\rangle_{H(S)\times H(D)} = g(0, x_0)$ for all $g \in \mathcal{D}(A_f)$, which in turn, is satisfied provided $\langle \mathcal{L}_f \sigma_m, (\Gamma_{x(\cdot),u(\cdot)}, K_D(\cdot, x(T)))\rangle_{H(S)\times H(D)} = \sigma_m(0, x_0)$ for all $m = 1, \cdots, \infty$. Selecting a finite set of basis functions $\{\sigma_1, \ldots, \sigma_{M_b}\}$, the constraint of P can thus be approximated using M_b linear constraints of the form

$$\sum_{i=1}^{M_D} v_i \sigma_m(T, d_i) - \sum_{i=1}^{M_S} w_i A_f \sigma_m(s_i) = \sigma_m(0, x_0), \quad (11)$$

for $m = 1, \cdots, M_b$. The optimal control problem thus admits the finite-rank representation

$$P_f : \min_{\{w_i\}_{i=1}^{M_S}, \{v_i\}_{i=1}^{M_D}} \sum_{i=1}^{M_S} w_i h(s_i) + \sum_{i=1}^{M_D} v_i F(d_i)$$
$$\text{subject to: } \sum_{i=1}^{M_D} v_i \sigma_m(T, d_i) - \sum_{i=1}^{M_S} w_i A_f \sigma_m(s_i) = \sigma_m(0, x_0),$$

for $m = 1, \cdots, M_b$. To ensure that the optimization problem is bounded, (3) may be employed as $\|\Gamma_{x_0,u,f}\|^2 \leq T^2\Phi(0)$, when K_S is the Gaussian or Wendland RBF, and $\|K(\cdot, x(T))\|^2 \leq \sup_{y\in D} K(y, y)$. Alternatively, $\Phi(0)$ may be replaced by an appropriate supremum bound. Depending on the selection of the kernel, a theoretically achievable approximation of $\Gamma_{x_0,u,f}$ and $K_D(\cdot, x(T))$ can be justified based on the density (or *fill distance*) of the centers within their respective parent sets.

7. CONCLUSION

In this abstract, the concepts of occupation kernels and total derivative operators are utilized to lift a nonlinear optimal control problem into a linear infinite-dimensional optimal control problem over functions in a RKHS. A finite-rank representation of the infinite-dimensional problem is obtained using kernel functions of the RKHSs and a countable basis for the domain of the total derivative operator. The authors plan to include an expanded introduction that places this work in the context of other lifting techniques such as occupation measures, provide a procedure to extract the optimal value function from a solution of P_f, and add a few example problems that demonstrate the utility of the developed methods.

Dirac structure for spatial multidimensional port-Hamiltonian Systems

Nathanael Skrepek *

* *Department of Mathematics and Science, University of Wuppertal, Germany, (e-mail: skrepek@uni-wuppertal.de)*

Abstract: We regard port-Hamiltonian systems on multidimensional spatial domains. We show that there are multiple (slightly different) Dirac structures assigned to such systems. Moreover, we point out that not every Dirac structure admits well-posedness of the corresponding system.

Keywords: Dirac structures, Port-Hamiltonian Systems, Infinite Dimensional Systems Theory.

1. INTRODUCTION

We regard the spatial multidimensional port-Hamiltonian systems and associate Dirac structures with theses systems. The Dirac structures that we investigate differ mainly in the boundary spaces. We will mainly focus on the linear port-Hamiltonian systems that were introduced in Skrepek (2021). However, we can also cover systems with a non quadratic Hamiltonians. In particular we associate a Dirac structure to systems of the form

$$\begin{aligned}\frac{\partial}{\partial t}x(t,\zeta) &= \sum_{i=1}^{n}\frac{\partial}{\partial \zeta_i}\begin{bmatrix}0 & L_i\\ L_i^{\mathsf{H}} & 0\end{bmatrix}\frac{\delta H(x(t,\zeta))}{\delta x} + P_0\frac{\delta H(x(t,\zeta))}{\delta x}\\ x(0,\zeta) &= x_0(\zeta),\end{aligned}$$

where L_i are matrices, P_0 is a skew-adjoint matrix, L_i^{H} denotes the Hermitian transposed (complex conjugated transposed) matrix of L_i, H is the Hamiltonian, $t \geq 0$ and $\zeta \in \Omega \subseteq \mathbb{R}^n$. Additionally, we will consider boundary ports later.

Dirac structures are one of the key elements in port-Hamiltonian modeling. They unify the description of complex interactions in physical systems. For further background see e.g. van der Schaft and Maschke (2002); Le Gorrec et al. (2005).

In Macchelli et al. (2004) they already introduced Dirac (Stokes-Dirac) structures for such systems, but they assume all functions to be smooth. Nevertheless they use the L^2 inner product as a dual pairing for the effort and flow space, which leads to an incomplete pairing. However, if you work with a complete L^2 space, the difficulty arises when you have to deal with trace operators. Also in Brugnoli et al. (2019) they regarded the Mindlin plate and showed that there is a Dirac structure associated to this system, but they refer to Macchelli et al. (2004) for the justification, which as already pointed out only deals with smooth function spaces.

The codomain of the trace operators will be *called boundary* space. One choice is $\mathsf{L}^2(\partial\Omega)$ as boundary space, which seems very natural but has disadvantages when it comes to solution theory. On the other hand we can consider the boundary spaces that were introduced in Skrepek (2021), which establish a *quasi Gelfand triple* with $\mathsf{L}^2(\partial\Omega)$ as pivot space. A quasi Gelfand triple is also a concept that was introduced in Skrepek (2021), which generalizes Gelfand triples (rigged Hilbert spaces). We will show for both choices of boundary spaces that there is Dirac structure associated to the system.

2. PRELIMINARY

Our general assumption is that $\Omega \subseteq \mathbb{R}^n$ is open and has a bounded Lipschitz boundary (Ω itself can be unbounded). Moreover, $\mathbb{K}$ denotes the scalar field, which can be either $\mathbb{R}$ or $\mathbb{C}$. We want to point out that the following is also possible with boundary operators that act only on a part of $\partial\Omega$. However, for simplicity we reduce ourselves to boundary operators that act on the entire boundary. For an extensive treatment of this section see Skrepek (2021).

Definition 2.1. Let $L = (L_i)_{i=1}^n$, where $L_i \in \mathbb{K}^{m_1\times m_2}$. Then we define

$$L_\partial \coloneqq \sum_{i=1}^{n}\partial_i L_i \quad \text{and} \quad L_\partial^{\mathsf{H}} \coloneqq (L^{\mathsf{H}})_\partial = \sum_{i=1}^{n}\partial_i L_i^{\mathsf{H}}$$

as operators from $\mathcal{D}'(\Omega)^{m_2}$ to $\mathcal{D}'(\Omega)^{m_1}$ and from $\mathcal{D}'(\Omega)^{m_1}$ to $\mathcal{D}'(\Omega)^{m_2}$, respectively (differential operators on the space of distributions). Furthermore, we define the space

$$\mathsf{H}(L_\partial,\Omega) \coloneqq \left\{f \in \mathsf{L}^2(\Omega,\mathbb{K}^{m_2}) \,\middle|\, L_\partial f \in \mathsf{L}^2(\Omega,\mathbb{K}^{m_1})\right\}.$$

This space is endowed with the inner product

$$\langle f,g\rangle_{\mathsf{H}(L_\partial,\Omega)} \coloneqq \langle f,g\rangle_{\mathsf{L}^2(\Omega,\mathbb{K}^{m_2})} + \langle L_\partial f, L_\partial g\rangle_{\mathsf{L}^2(\Omega,\mathbb{K}^{m_1})}.$$

We denote the outward pointing normed normal vector on $\partial\Omega$ by ν and its i-th component by ν_i. Moreover, we define

$$L_\nu \coloneqq \sum_{i=1}^{n}\nu_i L_i \colon \begin{cases}\mathsf{L}^2(\partial\Omega,\mathbb{K}^{m_2}) \to \mathsf{L}^2(\partial\Omega,\mathbb{K}^{m_1}),\\ f \mapsto \sum_{i=1}^{n}\nu_i L_i f,\end{cases}$$

and $L_\nu^{\mathsf{H}} \coloneqq (L^{\mathsf{H}})_\nu$.

We can and will regard L_∂ as an unbounded operator on $\mathsf{L}^2(\Omega)$ with domain $\mathsf{H}(L_\partial,\Omega)$.

For these differential operators exists an integration by parts formula, which is essentially a consequence of the generalized Stokes theorem. Since this integration by parts formula plays an important role for the Dirac structures we will introduce, these Dirac structure are also called

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Stokes-Dirac structures. We will first formulate the result for smooth functions. For a proof see (Skrepek, 2021, Lemma 3.8)

Lemma 2.2. For $f \in \mathsf{C}^\infty(\mathbb{R}^n)$ and $g \in \mathsf{C}^\infty(\mathbb{R}^n)$ we have

$$\langle L_\partial f, g\rangle_{\mathsf{L}^2(\Omega)} + \langle f, L_\partial^{\mathsf{H}} g\rangle_{\mathsf{L}^2(\Omega)} = \langle L_\nu f, g\rangle_{\mathsf{L}^2(\partial\Omega)}.$$

Clearly, we can easily extend this result by continuity to $f \in \mathsf{H}^1(\Omega)$ and $g \in \mathsf{H}^1(\Omega)$. However, we can even extend this result to $f \in \mathsf{H}(L_\partial, \Omega)$ and $g \in \mathsf{H}(L_\partial^{\mathsf{H}}, \Omega)$.

In order to do this we have to introduce new boundary spaces. First of all, since the inner product $\langle L_\nu f, g\rangle_{\mathsf{L}^2(\partial\Omega)}$ does only depend on the part of g which is in $\mathsf{L}^2_\pi(\partial\Omega) \coloneqq \overline{\operatorname{ran} L_\nu}$ we can add the orthogonal projection P_L from $\mathsf{L}^2(\partial\Omega)$ onto $\mathsf{L}^2_\pi(\partial\Omega)$ to g. Hence, we have

$$\langle L_\partial f, g\rangle_{\mathsf{L}^2(\Omega)} + \langle f, L_\partial^{\mathsf{H}} g\rangle_{\mathsf{L}^2(\Omega)} = \langle L_\nu f, P_L g\rangle_{\mathsf{L}^2(\partial\Omega)}.$$

To be more precise there is actually a trace operator involved in the $\mathsf{L}^2(\partial\Omega)$-inner product. We will denote the composition of this trace operator with P_L by π_L. We will endow $\operatorname{ran}\pi_L$ with the range norm

$$\|\phi\|_{\mathrm{ran}} \coloneqq \inf\left\{ \|g\|_{\mathsf{H}(L_\partial^{\mathsf{H}},\Omega)} \,\middle|\, \pi_L g = \phi, g \in \mathsf{C}(\mathbb{R}^n)\right\}$$

and denote the completion of this space (w.r.t. $\|\cdot\|_{\mathrm{ran}}$) by $\mathcal{V}_L$. There exists a continuous extension of π_L to $\mathsf{H}(L_\partial^{\mathsf{H}}, \Omega)$ denoted by $\bar\pi_L$. This extension is surjective. Moreover, we can also continuously extend L_ν to a surjective mapping from $\mathsf{H}(L_\partial, \Omega)$ to $\mathcal{V}_L'$ denoted by $\bar L_\nu$. Hence, we obtain

Corollary 2.3. For $f \in \mathsf{H}(L_\partial, \Omega)$ and $g \in \mathsf{H}(L_\partial^{\mathsf{H}}, \Omega)$ we have

$$\langle L_\partial f, g\rangle_{\mathsf{L}^2(\Omega)} + \langle f, L_\partial^{\mathsf{H}} g\rangle_{\mathsf{L}^2(\Omega)} = \langle \bar L_\nu f, \bar\pi_L g\rangle_{\mathcal{V}_L', \mathcal{V}_L}.$$

We say that $\bar L_\nu f$ is an element of $\mathsf{L}^2(\partial\Omega)$, if there is an $h_f \in \mathsf{L}^2(\partial\Omega)$ such that

$$\langle h_f, \pi_L g\rangle_{\mathsf{L}^2(\partial\Omega)} = \langle \bar L_\nu f, \pi_L g\rangle_{\mathcal{V}_L', \mathcal{V}_L} \quad \forall\, g \in \mathsf{C}^\infty(\mathbb{R}^n).$$

Accordingly, we say $\bar\pi_L g$ is in $\mathsf{L}^2(\partial\Omega)$, if there is an $h_g \in \mathsf{L}^2(\partial\Omega)$ such that

$$\langle L_\nu f, h_g\rangle_{\mathsf{L}^2(\partial\Omega)} = \langle L_\nu f, \bar\pi_L g\rangle_{\mathcal{V}_L', \mathcal{V}_L} \quad \forall\, f \in \mathsf{C}^\infty(\mathbb{R}^n).$$

3. PORT-HAMILTONIAN SYSTEMS

We regard port-Hamiltonian systems of the form

$$\begin{aligned}
\frac{\partial}{\partial t}x(t,\zeta) &= \sum_{i=1}^{n} \frac{\partial}{\partial \zeta_i}\begin{bmatrix} 0 & L_i \\ L_i^{\mathsf{H}} & 0\end{bmatrix}\frac{\delta H(x(t,\zeta))}{\delta x} \\
&\qquad + P_0 \frac{\delta H(x(t,\zeta))}{\delta x} \\
u(t,\xi) &= [0\ L_\nu]\,\frac{\delta H(x(t,\xi))}{\delta x} \\
y(t,\xi) &= [\pi_L\ 0]\,\frac{\delta H(x(t,\xi))}{\delta x} \\
x(0,\zeta) &= x_0(\zeta),
\end{aligned} \tag{1}$$

where $t \in \mathbb{R}_+$, $\zeta \in \Omega$, $\xi \in \partial\Omega$ and $\frac{\delta H(x)}{\delta x}$ denotes the variational derivative of the Hamiltonian H. The functions u and y are the boundary ports. We will regarding the state function $x\colon \mathbb{R}_+ \times \Omega \to \mathbb{K}^m$ as $x\colon \mathbb{R}_+ \to \mathsf{L}^2(\Omega;\mathbb{K}^m)$ by setting $x(t) = x(t,\cdot)$. This convention allows us to rewrite (1) as

$$\begin{aligned}
\dot x &= \left(\begin{bmatrix} 0 & L_\partial \\ L_\partial^{\mathsf{H}} & 0\end{bmatrix} + P_0\right)\frac{\delta H(x)}{\delta x}, \\
u &= \begin{bmatrix} 0 & \bar L_\nu\end{bmatrix}\frac{\delta H(x)}{\delta x}, \\
y &= [\bar\pi_L\ 0]\,\frac{\delta H(x)}{\delta x}, \\
x(0) &= x_0.
\end{aligned} \tag{2}$$

We regard this system in $\mathsf{L}^2(\Omega)$. In particular we say $-\dot x$ is the inner flow variable, $\frac{\delta H(x)}{\delta x}$ is the inner effort, u is the boundary flow and y is the boundary effort.

The following example will show that Maxwell's equations fit the previous system.

Example 3.1. Let us regard the matrices

$$L_1 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0\end{bmatrix},\ L_2 = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0\end{bmatrix},\ \text{and } L_3 = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0\end{bmatrix}.$$

We can easily see that $L_i^{\mathsf{H}} = -L_i$. Furthermore, the corresponding differential operator is

$$L_\partial = \begin{bmatrix} 0 & -\partial_3 & \partial_2 \\ \partial_3 & 0 & -\partial_1 \\ -\partial_2 & \partial_1 & 0\end{bmatrix} = \operatorname{rot} = -L_\partial^{\mathsf{H}}.$$

The corresponding operator L_ν that acts on $\mathsf{L}^2(\partial\Omega)$ can be written as a vector cross product

$$L_\nu f = \begin{bmatrix} 0 & -\nu_3 & \nu_2 \\ \nu_3 & 0 & -\nu_1 \\ -\nu_2 & \nu_1 & 0\end{bmatrix}\begin{bmatrix} f_1 \\ f_2 \\ f_3\end{bmatrix} = \nu \times f.$$

It can be calculated that the projection P_L on $\overline{\operatorname{ran} L_\nu}$ is given by

$$P_L g = (\nu \times g) \times \nu.$$

Hence, $\pi_L g = (\nu \times g\big|_{\partial\Omega}) \times \nu$.

Inserting the identities of the previous example into (2) gives a version of Maxwell's equations.

4. DIRAC STRUCTURES

We will regard the inner flow space $\mathcal{F}_{\mathrm{in}} \coloneqq \mathsf{L}^2(\Omega)$, the inner effort space $\mathcal{E}_{\mathrm{in}} \coloneqq \mathsf{L}^2(\Omega)$. For the boundary flow space $\mathcal{F}_\partial$ we will either use $\mathsf{L}^2_\pi(\partial\Omega)$, $\mathcal{V}_L'$, or $\{0\}$. Accordingly we will use for the boundary effort space $\mathcal{E}_\partial$ either $\mathsf{L}^2_\pi(\partial\Omega)$, $\mathcal{V}_L'$, or $\{0\}$. Clearly, we choose $\mathcal{F}_\partial$ and $\mathcal{E}_\partial$ always such that $\mathcal{F}_\partial' = \mathcal{E}_\partial$. We set flow space $\mathcal{F} \coloneqq \mathcal{F}_{\mathrm{in}} \times \mathcal{F}_\partial$ and effort space $\mathcal{E} \coloneqq \mathcal{E}_{\mathrm{in}} \times \mathcal{E}_\partial$.

Note that $\mathcal{F}$, $\mathcal{E}$ is a dual pair, its dual pairing is given, depending on the spaces $\mathcal{F}_\partial$ and $\mathcal{E}_\partial$, by

$$\begin{gathered}
\langle\cdot,\cdot\rangle_{\mathsf{L}^2(\Omega)} + \langle\cdot,\cdot\rangle_{\mathsf{L}^2(\partial\Omega)}, \\
\langle\cdot,\cdot\rangle_{\mathsf{L}^2(\Omega)} + \langle\cdot,\cdot\rangle_{\mathcal{V}_L',\mathcal{V}_L}, \\
\text{or } \langle\cdot,\cdot\rangle_{\mathsf{L}^2(\Omega)}.
\end{gathered}$$

Definition 4.1. Let $\mathcal{F}$, $\mathcal{E}$ be Banach spaces and $\langle\cdot,\cdot\rangle_{\mathcal{F},\mathcal{E}}$ a dual pairing for these spaces. Then we define the *canonical symmetric pairing*

$$\left\langle\!\!\left\langle \begin{bmatrix} f \\ e\end{bmatrix}, \begin{bmatrix} \hat f \\ \hat e\end{bmatrix}\right\rangle\!\!\right\rangle \coloneqq \langle f, \hat e\rangle_{\mathcal{F},\mathcal{E}} + \langle e, \hat f\rangle_{\mathcal{E},\mathcal{F}},$$

where $\langle e, \hat f\rangle_{\mathcal{E},\mathcal{F}} \coloneqq \overline{\langle \hat f, e\rangle_{\mathcal{F},\mathcal{E}}}$. We will denote orthogonality with respect to $\langle\!\langle\cdot,\cdot\rangle\!\rangle$ by $\perp_{\langle\!\langle,\rangle\!\rangle}$.

If $\mathcal{F} = \mathcal{E}$ is a Hilbert space, then the dual pairing $\langle \cdot, \cdot \rangle_{\mathcal{F},\mathcal{E}}$ is given by the inner product $\langle \cdot, \cdot \rangle_{\mathcal{F}}$.

Definition 4.2. Let $\mathcal{F}$, $\mathcal{E}$ be a dual pair. Then $\mathcal{D} \subseteq \mathcal{F} \times \mathcal{E}$ is a *Dirac structure*, if $\mathcal{D}^{\perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle}} = \mathcal{D}$.

The space $\mathcal{F} \times \mathcal{E}$ is called the *bond space*.

Theorem 4.3. Let $\mathcal{F}_\partial = \mathcal{E}_\partial = \{0\}$. We will ignore the second component of $\mathcal{F}$ and $\mathcal{E}$ as $\mathcal{F} \cong \mathcal{F}_{\text{in}}$ and $\mathcal{E} \cong \mathcal{E}_{\text{in}}$. Then

$$\mathcal{D} \coloneqq \left\{ \begin{bmatrix} f \\ e \end{bmatrix} \in \mathcal{F} \times \mathcal{E} \;\middle|\; f = -\begin{bmatrix} 0 & L_\partial \\ L_\partial^{\mathsf{H}} & 0 \end{bmatrix} e,\ \begin{bmatrix} \bar{\pi}_L & 0 \end{bmatrix} e = 0 \right\}$$

is a Dirac structure.

We can also replace the condition $\begin{bmatrix} \bar{\pi}_L & 0 \end{bmatrix} e = 0$ in the previous theorem by $\begin{bmatrix} 0 & \bar{L}_\nu \end{bmatrix} e = 0$.

Proof. By Corollary 2.3, it is not hard to see that $J \coloneqq \left[\begin{smallmatrix} 0 & L_\partial \\ L_\partial^{\mathsf{H}} & 0 \end{smallmatrix}\right]$ with the boundary condition $\begin{bmatrix} \bar{\pi}_L & 0 \end{bmatrix} e = 0$ is skew-adjoint. Hence, for $\left[\begin{smallmatrix} \hat{f} \\ \hat{e} \end{smallmatrix}\right] \in \mathcal{D}^{\perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle}}$ the equation

$$\left\langle\!\!\left\langle \left[\begin{smallmatrix} -Je \\ e \end{smallmatrix}\right], \left[\begin{smallmatrix} \hat{f} \\ \hat{e} \end{smallmatrix}\right] \right\rangle\!\!\right\rangle = \langle -Je, \hat{e} \rangle_{\mathsf{L}^2(\Omega)} + \langle e, \hat{f} \rangle_{\mathsf{L}^2(\Omega)} = 0$$

implies $\hat{f} = -J\hat{e}$.

On the other by the skew-adjointness of J it follows immediately that $\left[\begin{smallmatrix} -Je \\ e \end{smallmatrix}\right] \perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle} \left[\begin{smallmatrix} -J\hat{e} \\ \hat{e} \end{smallmatrix}\right]$. □

Theorem 4.4. Let $\mathcal{F}_\partial = \mathcal{E}_\partial = \mathsf{L}^2_\pi(\partial\Omega)$. Then

$$\mathcal{D}_1 \coloneqq \left\{ \begin{bmatrix} f \\ f_\partial \\ e \\ e_\partial \end{bmatrix} \in \mathcal{F} \times \mathcal{E} \;\middle|\; f = -\underbrace{\begin{bmatrix} 0 & L_\partial \\ L_\partial^{\mathsf{H}} & 0 \end{bmatrix}}_{=:J} e, \begin{bmatrix} f_\partial \\ e_\partial \end{bmatrix} = \begin{bmatrix} 0 & \bar{L}_\nu \\ \bar{\pi}_L & 0 \end{bmatrix} e \right\}$$

is a Dirac structure.

Recall the canonical symmetric pairing is given by

$$\left\langle\!\!\left\langle \begin{bmatrix} f \\ f_\partial \\ e \\ e_\partial \end{bmatrix}, \begin{bmatrix} \hat{f} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \right\rangle\!\!\right\rangle \coloneqq \langle f, \hat{e} \rangle_{\mathsf{L}^2(\Omega)} + \langle e, \hat{f} \rangle_{\mathsf{L}^2(\Omega)} + \langle f_\partial, \hat{e}_\partial \rangle_{\mathsf{L}^2(\partial\Omega)} + \langle e_\partial, \hat{f}_\partial \rangle_{\mathsf{L}^2(\partial\Omega)}.$$

Proof. It can be easily shown by Corollary 2.3 that $\mathcal{D}_1 \subseteq \mathcal{D}_1^{\perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle}}$.

Let $\begin{bmatrix} \hat{f} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \in \mathcal{D}_1^{\perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle}}$. Then we have for any $\begin{bmatrix} f \\ f_\partial \\ e \\ e_\partial \end{bmatrix} \in \mathcal{D}_1$:

$$0 = \left\langle\!\!\left\langle \begin{bmatrix} f \\ f_\partial \\ e \\ e_\partial \end{bmatrix}, \begin{bmatrix} \hat{f} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \right\rangle\!\!\right\rangle.$$

We choose $e \in \mathsf{C}_{\mathrm{c}}^\infty(\Omega)$, which implies that $\begin{bmatrix} -Je \\ 0 \\ e \\ 0 \end{bmatrix} \in \mathcal{D}_1$ and

$$0 = \left\langle\!\!\left\langle \begin{bmatrix} -Je \\ 0 \\ e \\ 0 \end{bmatrix}, \begin{bmatrix} \hat{f} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \right\rangle\!\!\right\rangle = \langle -Je, \hat{e} \rangle + \langle e, \hat{f} \rangle.$$

This gives

$$\langle Je, \hat{e} \rangle = \langle e, \hat{f} \rangle \quad \text{for all} \quad e \in \mathsf{C}_{\mathrm{c}}^\infty(\Omega),$$

and by distributional definition of J we conclude $\hat{f} = -J\hat{e}$. Note that according to the dimensions of the L_i we can split e into $\begin{bmatrix} e_1 \\ e_2 \end{bmatrix}$ and accordingly we can split $\hat{e}$. This gives

$$\begin{aligned} &\langle -Je, \hat{e} \rangle_{\mathsf{L}^2(\Omega)} + \langle e, -J\hat{e} \rangle_{\mathsf{L}^2(\Omega)} \\ &\quad = -\langle L_\partial e_2, \hat{e}_1 \rangle_{\mathsf{L}^2(\Omega)} - \langle L_\partial^{\mathsf{H}} e_1, \hat{e}_2 \rangle_{\mathsf{L}^2(\Omega)} \\ &\qquad - \langle e_1, L_\partial \hat{e}_2 \rangle_{\mathsf{L}^2(\Omega)} - \langle e_2, L_\partial^{\mathsf{H}} \hat{e}_1 \rangle_{\mathsf{L}^2(\Omega)} \\ &\quad = -\langle \bar{L}_\nu e_2, \bar{\pi}_L \hat{e}_1 \rangle_{\mathcal{V}_L', \mathcal{V}_L} - \langle \bar{\pi}_L e_1, \bar{L}_\nu \hat{e}_2 \rangle_{\mathcal{V}_L, \mathcal{V}_L'}. \end{aligned}$$

Hence, for $e \in \operatorname{dom} J \cap \{ g \mid \bar{\pi}_L g_1, \bar{L}_\nu g_2 \in \mathsf{L}^2_\pi(\partial\Omega) \}$ arbitrary we have

$$\begin{aligned} 0 &= \left\langle\!\!\left\langle \begin{bmatrix} -Je \\ \bar{L}_\nu e_2 \\ e \\ \bar{\pi}_L e_1 \end{bmatrix}, \begin{bmatrix} -J\hat{e} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \right\rangle\!\!\right\rangle \\ &= -\langle \bar{L}_\nu e_2, \bar{\pi}_L \hat{e}_1 \rangle_{\mathcal{V}_L', \mathcal{V}_L} - \langle \bar{\pi}_L e_1, \bar{L}_\nu \hat{e}_2 \rangle_{\mathcal{V}_L, \mathcal{V}_L'} \\ &\qquad + \langle \bar{L}_\nu e_2, \hat{e}_\partial \rangle_{\mathsf{L}^2(\partial\Omega)} + \langle \bar{\pi}_L e_1, \hat{f}_\partial \rangle_{\mathsf{L}^2(\partial\Omega)}. \end{aligned}$$

Choose $e_1 \in \ker \bar{\pi}_L$ and $e_2 \in \mathsf{C}^\infty(\mathbb{R}^n)$ arbitrary, then

$$0 = \langle \bar{L}_\nu e_2, \hat{e}_\partial \rangle_{\mathsf{L}^2(\partial\Omega)} - \langle \bar{L}_\nu e_2, \bar{\pi}_L \hat{e}_1 \rangle_{\mathcal{V}_L', \mathcal{V}_L},$$

which implies $\hat{e}_\partial = \bar{\pi}_L \hat{e}_1$. Analogously, we can show that $\hat{f}_\partial = \bar{L}_\nu \hat{e}_2$, which implies $\begin{bmatrix} \hat{f} \\ \hat{f}_\partial \\ \hat{e} \\ \hat{e}_\partial \end{bmatrix} \in \mathcal{D}_1$ and therefore $\mathcal{D}_1^{\perp_{\langle\!\langle\cdot,\cdot\rangle\!\rangle}} \subseteq \mathcal{D}_1$. □

Theorem 4.5. Let $\mathcal{F}_\partial = \mathcal{V}_L'$ and $\mathcal{E}_\partial = \mathcal{V}_L$. Then

$$\mathcal{D}_2 \coloneqq \left\{ \begin{bmatrix} f \\ f_\partial \\ e \\ e_\partial \end{bmatrix} \in \mathcal{F} \times \mathcal{E} \;\middle|\; f = -\underbrace{\begin{bmatrix} 0 & L_\partial \\ L_\partial^{\mathsf{H}} & 0 \end{bmatrix}}_{=:J} e, \begin{bmatrix} f_\partial \\ e_\partial \end{bmatrix} = \begin{bmatrix} 0 & \bar{L}_\nu \\ \bar{\pi}_L & 0 \end{bmatrix} e \right\}$$

is a Dirac structure.

The proof is a copy of the proof of Theorem 4.4. Only in the last step (for $\hat{e}_\partial = \bar{\pi}_L \hat{e}_1$) we have to use the surjectivity of $\bar{L}_\nu$.

Note that the Dirac structures $\mathcal{D}_1$ from Theorem 4.4 and $\mathcal{D}_2$ from Theorem 4.5 are almost the same. In particular, we even have $\mathcal{D}_1 \subsetneq \mathcal{D}_2$ $(n > 1)$ and $\mathcal{D}_1$ is dense in $\mathcal{D}_2$. The reason why it is possible that nevertheless both are Dirac structures is because they are in different bond spaces.

For the initial boundary control systems the bond space of $\mathcal{D}_1$ is in some sense not suitable as the boundary operators do not map surjectively into $\mathsf{L}^2_\pi(\partial\Omega)$ (only densely). This is problematic for solution theory. On the other hand the bond space of $\mathcal{D}_2$ does not have this problem. And indeed it is possible to develop solution theory for this bond space, see Skrepek (2021).

5. CONCLUSION

One crucial tool to show that the defined sets are indeed Dirac structures were the boundary spaces $\mathcal{V}_L$ and $\mathcal{V}_L'$. These spaces helped us to make sure that all calculations are meaningful, even if we did not know whether the traces are $\mathsf{L}^2(\partial\Omega)$.

Moreover, with this general approach we have shown that there are Dirac structures for the wave equation, Maxwell's equations, and the Mindlin plate.

Abstract: We propose a distributed nonparametric algorithm for solving measure-valued optimization problems with additive objectives. Such problems arise in several contexts in stochastic learning and control including Langevin sampling from an unnormalized prior, mean field neural network learning and Wasserstein gradient flows. The proposed algorithm comprises a two-layer alternating direction method of multipliers (ADMM). The outer-layer ADMM generalizes the Euclidean consensus ADMM to the Wasserstein consensus ADMM, and to its entropy-regularized version Sinkhorn consensus ADMM. The inner-layer ADMM turns out to be a specific instance of the standard Euclidean ADMM. The overall algorithm realizes operator splitting for gradient flows in the manifold of probability measures.

Keywords: Distributed algorithm, Wasserstein gradient flow, optimal transport.

1. INTRODUCTION

We consider measure-valued optimization problems of the form

$$\arg\inf_{\mu\in\mathcal{P}_2(\mathbb{R}^d)} F_1(\mu) + F_2(\mu) + \ldots + F_n(\mu) \tag{1}$$

for some finite integer $n > 1$, where $\mathcal{P}_2(\mathbb{R}^d)$ denotes the space of Borel probability measures over $\mathbb{R}^d$ with finite second moments. We suppose that the functionals $F_i : \mathcal{P}_2(\mathbb{R}^d) \mapsto \mathbb{R}$ are convex for all $i \in [n]$. If the optimization in (1) is instead over $\mathcal{P}_{2,\text{ac}}(\mathbb{R}^d)$, defined as the subset of $\mathcal{P}_2(\mathbb{R}^d)$ such that its elements are absolutely continuous w.r.t. the Lebesgue measure, then we can rewrite [1] (1) as

$$\arg\inf_{\rho} F_1(\rho) + F_2(\rho) + \ldots + F_n(\rho) \tag{2}$$

where the decision variable ρ is a joint PDF over $\mathbb{R}^d$ with finite second moment.

Problems of the form (1) and (2) arise in several contexts in statistics, machine learning, and control theory. This includes sampling from an unnormalized prior via Langevin Monte Carlo (see e.g., Stramer and Tweedie (1999a,b); Jarner and Hansen (2000); Roberts and Stramer (2002); Vempala and Wibisono (2019)), policy optimization in reinforcement learning (see e.g., Zhang et al. (2018); Chu et al. (2019); Zhang et al. (2020)), stochastic prediction (see e.g., Jordan et al. (1998); Ambrosio et al. (2005); Caluya and Halder (2019b,a)) and estimation (see e.g., Halder and Georgiou (2017, 2018, 2019)), density control (see e.g., Caluya and Halder (2021a,b)), mean field analysis of neural supervised (see e.g., Chizat and Bach (2018); Mei et al. (2018); Rotskoff and Vanden-Eijnden (2018); Sirignano and Spiliopoulos (2020)) and unsupervised learning (see e.g., Domingo-Enrich et al. (2020)).

Let $F := F_1 + \ldots + F_n$. There is a natural connection between problems of the form (1) and that of the Wasserstein gradient flow

$$\frac{\partial\mu}{\partial t} = -\nabla^{W_2} F(\mu) := \nabla\cdot\left(\mu\frac{\delta F}{\delta\mu}\right), \tag{3}$$

where ∇ denotes the d dimensional Euclidean gradient, and $\frac{\delta}{\delta\mu}$ denotes the functional derivative w.r.t. μ. The operator ∇^{W_2} in (3) denotes the gradient w.r.t. the 2-Wasserstein metric W_2 between a pair of probability measures $\mu_x, \mu_y \in \mathcal{P}_2\left(\mathbb{R}^d\right)$, defined as

$$W_2\left(\mu_x,\mu_y\right) := \left(\inf_{\pi\in\Pi\left(\mu_x,\mu_y\right)}\int_{\mathbb{R}^{2d}} c\left(\boldsymbol{x},\boldsymbol{y}\right)\,\mathrm{d}\pi(\boldsymbol{x},\boldsymbol{y})\right)^{\frac{1}{2}}, \tag{4}$$

where $\Pi\left(\mu_x,\mu_y\right)$ is the set of joint probability measures or couplings over the product space $\mathbb{R}^{2d}$, having $\boldsymbol{x}$ marginal μ_x, and $\boldsymbol{y}$ marginal μ_y. We use the ground cost $c\left(\boldsymbol{x},\boldsymbol{y}\right) := \|\boldsymbol{x}-\boldsymbol{y}\|_2^2$, the squared Euclidean distance in $\mathbb{R}^d$. It is well-known (Villani, 2003, Ch. 7) that W_2 defines a metric on $\mathcal{P}_2\left(\mathbb{R}^d\right)$. For notational ease, we henceforth drop the subscript from W_2, and simply use W. The minimizer π^{opt} in (4) is referred to as the *optimal transportation plan*, and if $\mu \in \mathcal{P}_{2,\text{ac}}(\mathbb{R}^d)$, then π^{opt} is supported on the graph of the *optimal transport map* T^{opt} pushing μ_x to μ_y.

The connection between (1) and (3) is that the minimizer of (1) may be realized as the stationary solution of (3). Conversely, if one is interested in the (possibly transient) solution of a PDE of the form (3), then it might be possible to compute the same by performing discrete time-stepping realizing gradient descent for (1).

⋆ This work is partially supported by NSF grants 1923278, 2112755.

[1] with slight abuse of notation in the sense (2) uses the same symbols F_i as in (1) for the additive functionals.

In recent years, several algorithms have been proposed for solving measure-valued optimization problems, see e.g., Benamou et al. (2016); Peyré (2015); Carlier et al. (2017); Carrillo et al. (2021); Mokrov et al. (2021); Alvarez-Melis et al. (2021). In this work, we explore the possibility of leveraging the additive structure of the objective in (1) for distributed nonparametric computation.

2. MAIN IDEA

We relabel the argument of the functional F_i in (1) as μ_i for all $i \in [n]$, and then impose the consensus constraint $\mu_1 = \mu_2 = \ldots = \mu_n$. Denoting

$$\mathcal{P}_2^{n+1}(\mathbb{R}^d) := \underbrace{\mathcal{P}_2(\mathbb{R}^d) \times \ldots \times \mathcal{P}_2(\mathbb{R}^d)}_{n+1 \text{ times}},$$

we then rewrite (1) as

$$\underset{(\mu_1,\ldots,\mu_n,\zeta)\in\mathcal{P}_2^{n+1}(\mathbb{R}^d)}{\arg\inf} \quad F_1(\mu_1) + F_2(\mu_2) + \ldots + F_n(\mu_n) \tag{5a}$$

$$\text{subject to} \quad \mu_i = \zeta \quad \text{for all } i \in [n]. \tag{5b}$$

Akin to the standard (Euclidean) augmented Lagrangian, we define the *Wasserstein augmented Lagrangian*

$$L_\alpha(\mu_1, \ldots, \mu_n, \zeta, \nu_1, \ldots, \nu_n) := \sum_{i=1}^{n} \left\{ F_i(\mu_i) + \frac{\alpha}{2} W^2(\mu_i, \zeta) + \int_{\mathbb{R}^d} \nu_i(\boldsymbol{\theta}) \left(\mathrm{d}\mu_i - \mathrm{d}\zeta\right) \right\} \tag{6}$$

where $\nu_i(\boldsymbol{\theta})$, $i \in [n]$, are the Lagrange multipliers for the constraints in (5b), and $\alpha > 0$ is a regularization constant.

Motivated by the Euclidean alternating direction method of multipliers (ADMM), we set up the recursions

$$\mu_i^{k+1} = \underset{\mu_i\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; L_\alpha\left(\mu_1, \ldots, \mu_n, \zeta^k, \nu_1^k, \ldots, \nu_n^k\right) \tag{7a}$$

$$\zeta^{k+1} = \underset{\zeta\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; L_\alpha\left(\mu_1^{k+1}, \ldots, \mu_n^{k+1}, \zeta, \nu_1^k, \ldots, \nu_n^k\right) \tag{7b}$$

$$\nu_i^{k+1} = \nu_i^k + \alpha\left(\mu_i^{k+1} - \zeta^{k+1}\right) \tag{7c}$$

where $i \in [n]$, and the recursion index $k \in \mathbb{N}_0$ (the set of whole numbers $\{0, 1, 2, \ldots\}$). We view (7a)-(7b) as primal updates, and (7c) as dual ascent.

Let $\nu_{\text{sum}}^k(\boldsymbol{\theta}) := \sum_{i=1}^{n} \nu_i^k(\boldsymbol{\theta})$, $k \in \mathbb{N}_0$. Substituting (6) in (7), dropping the terms independent of the decision variable in the respective arg inf, and re-scaling, the recursions (7) simplify to

$$\begin{aligned}\mu_i^{k+1} &= \underset{\mu_i\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; \frac{1}{2} W^2\left(\mu_i, \zeta^k\right) + \frac{1}{\alpha}\left\{ F_i(\mu_i) + \int_{\mathbb{R}^d} \nu_i^k(\boldsymbol{\theta}) \mathrm{d}\mu_i \right\} \\ &= \mathrm{prox}^W_{\frac{1}{\alpha}\left(F_i(\cdot) + \int \nu_i^k \mathrm{d}(\cdot)\right)}\left(\zeta^k\right), \end{aligned} \tag{8a}$$

$$\begin{aligned}\zeta^{k+1} &= \underset{\zeta\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; \sum_{i=1}^{n} \left\{ \frac{1}{2} W^2\left(\mu_i^{k+1}, \zeta\right) - \frac{1}{\alpha} \int_{\mathbb{R}^d} \nu_i^k(\boldsymbol{\theta}) \mathrm{d}\zeta \right\} \\ &= \underset{\zeta\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; \left\{ \left(\sum_{i=1}^{n} W^2\left(\mu_i^{k+1}, \zeta\right) \right) - \frac{2}{\alpha} \int_{\mathbb{R}^d} \nu_{\text{sum}}^k(\boldsymbol{\theta}) \mathrm{d}\zeta \right\}, \end{aligned} \tag{8b}$$

$$\nu_i^{k+1} = \nu_i^k + \alpha\left(\mu_i^{k+1} - \zeta^{k+1}\right), \tag{8c}$$

wherein we use the notation $\mathrm{prox}^W_{G(\cdot)}(\zeta)$ to denote the *Wasserstein proximal operator* of the functional $G(\cdot)$, acting on $\zeta \in \mathcal{P}_2\left(\mathbb{R}^d\right)$, given by

$$\mathrm{prox}^W_{G(\cdot)}(\zeta) := \underset{\mu\in\mathcal{P}_2(\mathbb{R}^d)}{\arg\inf} \; \frac{1}{2} W^2(\mu, \zeta) + G(\mu). \tag{9}$$

We can view (9) as a generalization of the finite dimensional Euclidean proximal operator

$$\mathrm{prox}^{\|\cdot\|_2}_g(\boldsymbol{z}) := \underset{\boldsymbol{x}\in\mathbb{R}^d}{\arg\inf} \; \frac{1}{2}\|\boldsymbol{x} - \boldsymbol{z}\|_2^2 + g(\boldsymbol{x}). \tag{10}$$

We refer to (8) as the *Wasserstein consensus ADMM* – the notion generalizes its finite dimensional Euclidean counterpart in the sense (8a)-(8b) are analogues of the so-called x and z updates, respectively; see e.g., (Parikh and Boyd, 2014, Ch. 5.2.1). However, important difference arises in (8b) compared to its Euclidean counterpart due to the sum of squares of Wasserstein distances. In the Euclidean case, the corresponding z update can be analytically performed in terms of the arithmetic mean of the x updates. While (8b) does involve a *generalized mean* of the updates from (8a), we now have *Wasserstein barycentric proximal* of a linear functional. In other words, (8b) amounts to computing the Wasserstein barycenter of n measures $\{\mu_1^{k+1}, \ldots, \mu_n^{k+1}\}$ with a linear regularization involving ν_{sum}^k.

The proximal updates (8a) are closely related to the Wasserstein gradient flows generated by the respective (scaled) free energy functionals

$$\Phi_i(\mu_i) := F_i(\mu_i) + \int_{\mathbb{R}^d} \nu_i^k \mathrm{d}\mu_i, \quad \mu_i \in \mathcal{P}_2(\mathbb{R}^d), \quad i \in [n].$$

Under mild assumptions on Φ_i, as $1/\alpha \downarrow 0$, the sequence $\{\mu_i^k(\alpha)\}_{k\in\mathbb{N}_0}$ generated by the proximal updates (8a) converge to the measure-valued solution trajectory $\widetilde{\mu}_i(t, \cdot)$, $t \in [0, \infty)$, generated by the initial value problems (IVPs)

$$\frac{\partial \widetilde{\mu}_i}{\partial t} = -\nabla^W \Phi_i\left(\widetilde{\mu}_i\right), \; \widetilde{\mu}_i(t = 0, \cdot) = \widetilde{\mu}_i^0(\cdot), \; i \in [n]. \tag{11}$$

Thus, in a rather generic setting, performing the proximal updates (8a) in parallel across the index $i \in [n]$, amounts to performing distributed time updates for the approximate transient solutions of the IVPs (11).

Important examples of F_i include $\int V(\boldsymbol{\theta})\mathrm{d}\mu_i(\boldsymbol{\theta})$ (potential energy for some suitable advection potential V), $\beta^{-1}\int \log \mu_i(\boldsymbol{\theta})\mathrm{d}\mu_i(\boldsymbol{\theta})$ (internal energy with the "inverse temperature" parameter $\beta > 0$), $\int_{\mathbb{R}^{2d}} U(\boldsymbol{\theta}, \boldsymbol{\sigma})\mathrm{d}\mu_i(\boldsymbol{\theta})\mathrm{d}\mu_i(\boldsymbol{\sigma})$ (interaction energy for some symmetric positive definite interaction potential U).

To numerically realize the recursions (8), we consider a sequence of discrete probability distributions $\{\boldsymbol{\mu}_1^k, \ldots, \boldsymbol{\mu}_n^k, \boldsymbol{\zeta}^k\}$ indexed by $k \in \mathbb{N}_0$ where each distribution is a probability vector of length $N \times 1$, representative of the respective probability values at N samples. Thus, for each fixed $k \in \mathbb{N}_0$, the tuple

$$\left(\boldsymbol{\mu}_1^k, \ldots, \boldsymbol{\mu}_n^k, \boldsymbol{\zeta}^k\right) \in \underbrace{\Delta^{N-1} \times \ldots \times \Delta^{N-1}}_{n+1 \text{ times}} =: \left(\Delta^{N-1}\right)^{n+1}.$$

Likewise, for each fixed $k \in \mathbb{N}_0$, the Lagrange multipliers $\left(\boldsymbol{\nu}_1^k, \ldots, \boldsymbol{\nu}_n^k\right) \in \mathbb{R}^{nN}$, and $\boldsymbol{\nu}_{\text{sum}}^k = \sum_{i=1}^{n} \boldsymbol{\nu}_i^k \in \mathbb{R}^N$.

Given probability vectors $\boldsymbol{\xi}, \boldsymbol{\eta} \in \Delta^{N-1}$, let $\Pi_N\left(\boldsymbol{\xi}, \boldsymbol{\eta}\right) := \{\boldsymbol{M} \in \mathbb{R}^{N\times N} \mid \boldsymbol{M} \geq \boldsymbol{0} \text{ (elementwise)}, \boldsymbol{M}\boldsymbol{1} = \boldsymbol{\xi}, \boldsymbol{M}^\top\boldsymbol{1} = \boldsymbol{\eta}\}$. Also, let $\boldsymbol{C} \in \mathbb{R}^{N\times N}$ denote the squared Euclidean distance matrix for the sampled data $\{\boldsymbol{\theta}_r\}_{r\in[N]}$ in $\mathbb{R}^d$, i.e.,

the entries of the matrix $\boldsymbol{C}$ are $\boldsymbol{C}(i,j) := \|\boldsymbol{\theta}_i - \boldsymbol{\theta}_j\|_2^2$ for all $i,j \in [N]$.

For each $i \in [n]$ and $k \in \mathbb{N}_0$, we write the discrete version of (8) as

$$\begin{aligned}\boldsymbol{\mu}_i^{k+1} &= \operatorname{prox}^{W}_{\frac{1}{\alpha}\left(F_i(\boldsymbol{\mu}_i)+\langle \boldsymbol{\nu}_i^k, \boldsymbol{\mu}_i\rangle\right)}\left(\boldsymbol{\zeta}^k\right)\\ &= \operatorname*{arg\,inf}_{\boldsymbol{\mu}_i \in \Delta^{N-1}} \left\{ \min_{\boldsymbol{M}\in\Pi_N(\boldsymbol{\mu}_i,\boldsymbol{\zeta}^k)} \frac{1}{2}\langle \boldsymbol{C}, \boldsymbol{M}\rangle + \frac{1}{\alpha}\left(F_i(\boldsymbol{\mu}_i) + \langle \boldsymbol{\nu}_i^k, \boldsymbol{\mu}_i\rangle\right)\right\},\end{aligned} \tag{12a}$$

$$\boldsymbol{\zeta}^{k+1} = \operatorname*{arg\,inf}_{\boldsymbol{\zeta}\in\Delta^{N-1}} \left\{ \left(\sum_{i=1}^{n} \min_{\boldsymbol{M}_i \in \Pi_N\left(\boldsymbol{\mu}_i^{k+1}, \boldsymbol{\zeta}\right)} \frac{1}{2}\langle \boldsymbol{C}, \boldsymbol{M}_i\rangle \right) - \frac{2}{\alpha}\langle \boldsymbol{\nu}_{\text{sum}}^k, \boldsymbol{\zeta}\rangle \right\}, \tag{12b}$$

$$\boldsymbol{\nu}_i^{k+1} = \boldsymbol{\nu}_i^k + \alpha\left(\boldsymbol{\mu}_i^{k+1} - \boldsymbol{\zeta}^{k+1}\right), \tag{12c}$$

wherein (12a)-(12b) used the discrete version of the squared Wasserstein distance.

Replacing the squared Wasserstein distance in (8) by the entropy a.k.a. Sinkhorn regularized squared Wasserstein distance, modify the recursions (12) as

$$\begin{aligned}\boldsymbol{\mu}_i^{k+1} &= \operatorname{prox}^{W_\varepsilon}_{\frac{1}{\alpha}\left(F_i(\boldsymbol{\mu}_i)+\langle \boldsymbol{\nu}_i^k, \boldsymbol{\mu}_i\rangle\right)}\left(\boldsymbol{\zeta}^k\right)\\ &= \operatorname*{arg\,inf}_{\boldsymbol{\mu}_i \in \Delta^{N-1}} \left\{ \min_{\boldsymbol{M}\in\Pi_N(\boldsymbol{\mu}_i,\boldsymbol{\zeta}^k)} \left\langle \frac{1}{2}\boldsymbol{C} + \varepsilon \log \boldsymbol{M}, \boldsymbol{M}\right\rangle \right.\\ &\qquad \left. + \frac{1}{\alpha}\left(F_i(\boldsymbol{\mu}_i) + \langle \boldsymbol{\nu}_i^k, \boldsymbol{\mu}_i\rangle\right)\right\},\end{aligned} \tag{13a}$$

$$\begin{aligned}\boldsymbol{\zeta}^{k+1} = \operatorname*{arg\,inf}_{\boldsymbol{\zeta}\in\Delta^{N-1}} \left\{ \left(\sum_{i=1}^{n} \min_{\boldsymbol{M}_i \in \Pi_N\left(\boldsymbol{\mu}_i^{k+1}, \boldsymbol{\zeta}\right)} \left\langle \frac{1}{2}\boldsymbol{C} + \varepsilon \log \boldsymbol{M}_i, \boldsymbol{M}_i\right\rangle \right) \right.\\ \left. - \frac{2}{\alpha}\langle \boldsymbol{\nu}_{\text{sum}}^k, \boldsymbol{\zeta}\rangle \right\},\end{aligned} \tag{13b}$$

$$\boldsymbol{\nu}_i^{k+1} = \boldsymbol{\nu}_i^k + \alpha\left(\boldsymbol{\mu}_i^{k+1} - \boldsymbol{\zeta}^{k+1}\right), \tag{13c}$$

where $\varepsilon > 0$ is a regularization parameter. In the remaining, we summarize novel results that enable us to numerically perform the recursions (13).

3. RESULTS

3.1 The $\boldsymbol{\mu}$ Update

The Sinkhorn regularized recursion (13a) allows us to get semi-analytical handle on the nested minimization via strong duality. Specifically, consider the convex functions $F_i, G_i : \Delta^{N-1} \mapsto \mathbb{R}$ for all $i \in [n]$ where $G_i(\boldsymbol{\mu_i}) := F_i(\boldsymbol{\mu}_i) + \langle \boldsymbol{\nu}_i^k, \boldsymbol{\mu}_i\rangle$, and denote the Legendre-Fenchel conjugate of G_i as G_i^*. Following (Karlsson and Ringh, 2017, Lemma 3.5), (Caluya and Halder, 2019a, Sec. III), the Lagrange dual problem associated with (13a) is

$$\begin{aligned}\left(\boldsymbol{\lambda}_{0i}^{\text{opt}}, \boldsymbol{\lambda}_{1i}^{\text{opt}}\right) = \operatorname*{arg\,max}_{\boldsymbol{\lambda}_{0i}, \boldsymbol{\lambda}_{1i} \in \mathbb{R}^N} \left\{ \langle \boldsymbol{\lambda}_{0i}, \boldsymbol{\zeta}_k\rangle - G_i^*\left(-\boldsymbol{\lambda}_{1i}\right) \right.\\ \left. - \alpha\varepsilon\left(\exp\left(\frac{\boldsymbol{\lambda}_{0i}^\top}{\alpha\varepsilon}\right)\exp\left(-\frac{\boldsymbol{C}}{2\varepsilon}\right)\exp\left(\frac{\boldsymbol{\lambda}_{1i}}{\alpha\varepsilon}\right)\right)\right\},\ i \in [n].\end{aligned} \tag{14}$$

Using (14), the proximal updates in (13a) can then be recovered from the following proposition.

Proposition 1. ((Karlsson and Ringh, 2017, Lemma 3.5), (Caluya and Halder, 2019a, Theorem 1)) Given $\alpha, \varepsilon > 0$, the squared Euclidean distance matrix $\boldsymbol{C} \in \mathbb{R}^{N\times N}$, and the probability vector $\boldsymbol{\zeta}^k \in \Delta^{N-1}$, $k \in \mathbb{N}_0$. Let $\mathbf{0}$ denote the $N \times 1$ vector of zeros. For $i \in [n]$, the vectors $\boldsymbol{\lambda}_{0i}^{\text{opt}}, \boldsymbol{\lambda}_{1i}^{\text{opt}} \in \mathbb{R}^N$ in (14) solve the system

$$\exp\left(\frac{\boldsymbol{\lambda}_{0i}^{\text{opt}}}{\alpha\varepsilon}\right) \odot \left(\exp\left(-\frac{\boldsymbol{C}}{2\varepsilon}\right)\exp\left(\frac{\boldsymbol{\lambda}_{1i}^{\text{opt}}}{\alpha\varepsilon}\right)\right) = \boldsymbol{\zeta}_k, \tag{15a}$$

$$\mathbf{0} \in \partial_{\boldsymbol{\lambda}_{1i}^{\text{opt}}} G_i^*\left(-\boldsymbol{\lambda}_{1i}^{\text{opt}}\right) - \exp\left(\frac{\boldsymbol{\lambda}_{1i}^{\text{opt}}}{\alpha\varepsilon}\right) \odot \left(\exp\left(-\frac{\boldsymbol{C}^\top}{2\varepsilon}\right)\exp\left(\frac{\boldsymbol{\lambda}_{0i}^{\text{opt}}}{\alpha\varepsilon}\right)\right). \tag{15b}$$

The proximal update $\boldsymbol{\mu}_i^{k+1}$ in (13a) is given by

$$\boldsymbol{\mu}_i^{k+1} = \exp\left(\frac{\boldsymbol{\lambda}_{1i}^{\text{opt}}}{\alpha\varepsilon}\right) \odot \left(\exp\left(-\frac{\boldsymbol{C}^\top}{2\varepsilon}\right)\exp\left(\frac{\boldsymbol{\lambda}_{0i}^{\text{opt}}}{\alpha\varepsilon}\right)\right). \tag{16}$$

We point out an important special case: if $F_i(\boldsymbol{\mu}_i) = \beta^{-1}\langle \log \boldsymbol{\mu}_i, \boldsymbol{\mu}_i\rangle$ where $\beta > 0$, then Proposition 1 reduces exactly to (Caluya and Halder, 2019a, Theorem 1) allowing further simplification of (15b). Then, (15) can be solved via certain cone-preserving block coordinate iteration proposed in (Caluya and Halder, 2019a, Sec. III.B,C) that is provably contractive. This makes the proximal update (16) semi-analytical in the sense the pair $\left(\boldsymbol{\lambda}_{0i}^{\text{opt}}, \boldsymbol{\lambda}_{1i}^{\text{opt}}\right)$ needs to be numerically computed by performing the block coordinate iteration while "freezing" the index $k \in \mathbb{N}_0$. With the converged pair $\left(\boldsymbol{\lambda}_{0i}^{\text{opt}}, \boldsymbol{\lambda}_{1i}^{\text{opt}}\right)$, the evaluation (16) is analytical for each $k \in \mathbb{N}_0$.

In our context, another case of interest is when F_i and hence G_i, is linear in $\boldsymbol{\mu}_i$. The following result shows that the proximal update $\boldsymbol{\mu}_i^{k+1}$ in this case can be computed analytically, obviating the zero order hold sub-iterations mentioned above.

Theorem 1. Given $\boldsymbol{a} \in \mathbb{R}^N \setminus \{\mathbf{0}\}$, let $\boldsymbol{\Phi}(\boldsymbol{\mu}) := \langle \boldsymbol{a}, \boldsymbol{\mu}\rangle$ for $\boldsymbol{\mu} \in \Delta^{N-1}$. Let $\boldsymbol{C} \in \mathbb{R}^{N\times N}$ be the squared Euclidean distance matrix, and for $\varepsilon > 0$, let $\boldsymbol{\Gamma} := \exp\left(-\boldsymbol{C}/2\varepsilon\right)$. For any $\boldsymbol{\zeta} \in \Delta^{N-1}$, $\alpha > 0$, we have

$$\operatorname{prox}^{W_\varepsilon}_{\frac{1}{\alpha}\boldsymbol{\Phi}}(\boldsymbol{\zeta}) = \exp\left(-\frac{1}{\alpha\varepsilon}\boldsymbol{a}\right) \odot \left(\boldsymbol{\Gamma}^\top\left(\boldsymbol{\zeta} \oslash \left(\boldsymbol{\Gamma}\exp\left(-\frac{1}{\alpha\varepsilon}\boldsymbol{a}\right)\right)\right)\right). \tag{17}$$

3.2 The $\boldsymbol{\zeta}$ Update

The update (13b) can be seen as a problem of computing the Sinkhorn regularized Wasserstein barycenter with an extra linear regularization. Let $W^2_{\varepsilon,\boldsymbol{\mu}_i}(\boldsymbol{\zeta}) := \min_{\boldsymbol{M}_i \in \Pi_N(\boldsymbol{\mu}_i, \boldsymbol{\zeta})} \left\langle \frac{1}{2}\boldsymbol{C} + \varepsilon \log \boldsymbol{M}_i, \boldsymbol{M}_i\right\rangle$, $\varepsilon > 0$, for given $\boldsymbol{\mu}_i \in \Delta^{N-1}$ for all $i \in [n]$, and for a given squared Euclidean distance matrix $\boldsymbol{C} \in \mathbb{R}^{N\times N}$. Let the superscript * denote the Legendre-Fenchel conjugate. Following (Cuturi and Peyré, 2016, Sec. 4.1), some calculations show that the dual problem corresponding to (13b) becomes

$$\begin{aligned}\left(\boldsymbol{u}_1^{\text{opt}}, \ldots, \boldsymbol{u}_n^{\text{opt}}\right) = \operatorname*{arg\,min}_{(\boldsymbol{u}_1,\ldots,\boldsymbol{u}_n)\in\mathbb{R}^{nN}} \sum_{i=1}^{n} \left(W^2_{\varepsilon,\boldsymbol{\mu}_i^{k+1}}\right)^*(\boldsymbol{u}_i)\\ \text{subject to} \quad \sum_{i=1}^{n} \boldsymbol{u}_i = \frac{2}{\alpha}\boldsymbol{\nu}_{\text{sum}}^k.\end{aligned} \tag{18}$$

Consequently, the update (13b) can be performed by first solving the problem (18), and then invoking the primal-dual relation $\boldsymbol{\zeta}^{\text{opt}} = \nabla_{\boldsymbol{u}_i}\left(W^2_{\varepsilon,\boldsymbol{\mu}_i}\right)^*\left(\boldsymbol{u}_i^{\text{opt}}\right) \in \Delta^{N-1}\, \forall i \in [n]$, at the minimizer of (18). It turns out that (18) leads to an inner layer Euclidean ADMM whose structure allows efficient distributed computation.

The results summarized above lead to an overall algorithm realizing operator splitting for gradient flows in the manifold of probability measures, which solve (1) via distributed computation. Numerical experiments (not reported herein due to page constraints) on several test problems of the form (1) reveal that the proposed framework has good computational performance.

On Scale Fragilities in Localized Consensus

Emma Tegling *

* *Department of Automatic Control, Lund University, P.O. Box 118, SE-221 00 Lund, Sweden*(emma.tegling@control.lth.se).

Abstract: We consider the prototypical networked control problem of distributed consensus in networks of agents with integrator dynamics of order two or higher ($n \geq 2$). We assume all feedback to be localized in the sense that each agent has a bounded number of neighbors and consider a scaling of the network through the addition of agents. We show that standard consensus algorithms that rely on relative state feedback and fixed gains can be subject to scale fragilities, meaning that stability is lost as the network grows. For high-order agents ($n \geq 3$), we prove that no consensus algorithm is what we term *scalably stable*. That is, while a given algorithm may allow a small network to converge, it causes instability if the network grows beyond a certain finite size. This holds in families of network graphs whose algebraic connectivity, that is, the smallest non-zero Laplacian eigenvalue, is decreasing towards zero in network size (equivalently, non-expanding graphs). For second-order consensus ($n = 2$), we prove that the same scale fragility applies to classes of directed graphs that have a complex Laplacian eigenvalue approaching the origin (e.g. directed ring graphs). We derive algebraic conditions for the affected graphs, and discuss how the consensus algorithm can be modified to retrieve scalable stability.

Keywords: Distributed control, large-scale systems, robustness, algebraic graph theory. AMS Subject classification: 93A14, 93A15.

1. INTRODUCTION

Characterizing the dynamic behaviors of networked or multi-agent systems has been an active research area for many years. In particular, since the works by Fax and Murray (2004), Olfati-Saber and Murray (2004), and Jadbabaie et al. (2003), the prototypical sub-problem of distributed consensus has been the subject of significant research efforts. While the particular modeling aspects vary, the consensus objective is to coordinate agents in a network to a common state of agreement. Engineering applications range from distributed computing and sensing to power grid synchronization and coordination of vehicles.

In this work, we consider a consensus algorithm of order n, where each agent $i \in \{1, 2, \dots, N\}$ in a network is modeled as an n^{th} order integrator, and the control input is a weighted sum of relative feedback terms with respect to the agent's neighbors. That is,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} x_i^{(0)}(t) &= x_i^{(1)}(t) \\ &\vdots \\ \frac{\mathrm{d}}{\mathrm{d}t} x_i^{(n-2)}(t) &= x_i^{(n-1)}(t) \\ \frac{\mathrm{d}}{\mathrm{d}t} x_i^{(n-1)}(t) &= u_i(t), \end{aligned} \tag{1}$$

with the state $x_i^{(0)}(t) = x_i(t) \in \mathbb{R}$, and

$$u_i = -\sum_{k=0}^{n-1} a_k \sum_{j \in \mathcal{N}_i} w_{ij}(x_i^{(k)} - x_j^{(k)}), \tag{2}$$

where the $a_k > 0$ are fixed gains and w_{ij} are edge weights in the network graph. For $n = 1$ this reduces to the familiar first-order, or information, consensus algorithm. For $n = 2$, we obtain second-order consensus, which is often used to model formation control in multi-vehicle networks. The problem for $n \geq 3$, to which several results in this work pertain, has also received significant attention, see e.g. Ren et al. (2007); Rezaee and Abdollahi (2015); Zuo et al. (2018). This can be viewed as an important theoretical generalization of the first- and second-order algorithms, but also has practical relevance. For example, position, velocity, as well as acceleration feedback play a role in flocking behaviors, resulting in a model where $n = 3$ Ren et al. (2007).

Existing literature has typically focused on deriving conditions for convergence of a given set of agents to consensus, and how such conditions depend on various properties of the network. We take a different perspective and focus on the *scalability* of given consensus algorithm (2) to ever larger networks. In other words, we assume that interactions between agents are *fixed* (i.e., pre-designed) and *localized*, and grow the network through the addition of more and more agents. Formally, we model the consensus algorithm over a *family* of network graphs $\{\mathcal{G}_N\}_{N\to\infty}$ with a common upper bound on nodal degrees.

We show that consensus of order $n \geq 2$ is subject to a *scale fragility* in certain graph families. This implies that stability (and thereby convergence to consensus) is lost if

⋆ This work was partially supported by the Wallenberg AI, Autonomous Systems and Software Program (WASP) funded by the Knut and Alice Wallenberg Foundation and the Swedish Research Council through grant 2019-00691.

the network grows beyond some *finite* size. For $n \geq 3$, our result is particularly clear-cut: the consensus algorithm (2) lacks what we term *scalable stability* in any family of graphs whose algebraic connectivity decreases towards zero in network size N. This is true in any *non-expanding* graph family, meaning all bounded-degree graphs where connections are, in a sense, localized.

For second-order consensus ($n = 2$), the scale fragility applies to particular classes of directed graphs with a complex Laplacian eigenvalue that approaches the origin as N increases. This includes, for example, directed ring graphs. The particular result for ring graphs has previously been reported in Cantos et al. (2016); Herman (2016), but our work provides a generalization. The result implies that ring-shaped vehicular formations that, e.g, use adaptive cruise control modeled as in Gunter et al. (2021), are at risk of becoming unstable.

The key results summarized in this extended abstract are presented in detail in Tegling et al. (2022) with preliminary versions appearing in Tegling et al. (2019a,b) .

2. NOTATION AND PROBLEM SETUP

Consider a network modeled by the graph $\mathcal{G}_N = \{\mathcal{V}_N, \mathcal{E}_N\}$ with $N = |\mathcal{V}_N|$ nodes. The set $\mathcal{E}_N \subset \mathcal{V}_N \times \mathcal{V}_N$ contains the edges, each of which has an associated nonnegative weight w_{ij}. The graph $\mathcal{G}_N$, which in general will be a directed graph, is a member of a sequence, or family, of graphs $\{\mathcal{G}_N\}_{N\to\infty}$. We remark that $\mathcal{G}_N$ need not be a subgraph of $\mathcal{G}_{N+1}$. The graph Laplacian L of $\mathcal{G}_N$ is defined as follows:

$$[L]_{ij} = \begin{cases} -w_{ij} & \text{if } j \neq i \text{ and } j \in \mathcal{N}_i \\ \sum_{k\in\mathcal{N}_i} w_{ik} & \text{if } j = i \\ 0 & \text{otherwise,} \end{cases} \tag{3}$$

where $\mathcal{N}_i$ defines the neighborhood of node $i \in \mathcal{V}_N$, that is, the set of nodes j such that $(i, j) \in \mathcal{E}_N$. Denote by λ_l (or $\lambda_l(\mathcal{G}_N)$ where explicitness is needed) with $l = 1, \ldots, N$ the eigenvalues of L. Zero is a simple eigenvalue of L if and only if the graph has a connected spanning tree, which we assume henceforth. Remaining eigenvalues are in the complex right half plane (RHP), and numbered so that $0 = \lambda_1 < \mathrm{Re}\{\lambda_2\} \leq \ldots \leq \mathrm{Re}\{\lambda_N\}$.

Defining the system state $\xi = [x^{(0)}, x^{(1)}, \ldots, x^{(n-1)}]^T \in \mathbb{R}^{Nn}$ and making use of L, we can write the system's closed-loop dynamics (1)–(2) as

$$\frac{\mathrm{d}}{\mathrm{d}t}\xi = \underbrace{\begin{bmatrix} 0 & I_N & 0 & \cdots & 0 \\ 0 & 0 & I_N & \cdots & \vdots \\ 0 & 0 & 0 & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & I_N \\ -a_0 L & -a_1 L & -a_2 L & \cdots & -a_{\mathrm{n}-1} L \end{bmatrix}}_{\mathcal{A}} \xi. \tag{4}$$

3. RESULTS

We first state a number of important assumptions that underlie our analysis:

Assumption 1. (Finite gains). The controller gains are finite, that is, $a_k \leq a_{\max} < \infty$ for all $k = 0, 1, \ldots, n$.

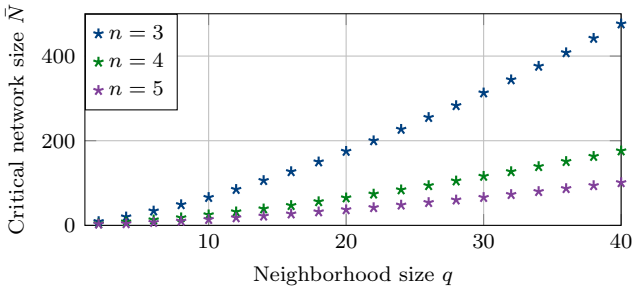

Fig. 1. Critical network size $\bar{N}$ for an n^{th} order consensus algorithm. The graph is an undirected path graph where each node is connected to its q nearest neighbors. Increasing the neighborhood size q here increases $\bar{N}$ faster than linearly (we also derive the exact scaling).

Assumption 2. (Fixed gains). The gains a_k for all $k = 0, 1, \ldots, n$ do not change if the underlying graph changes. That is, the gains are fixed with respect to the graph family $\{\mathcal{G}_N\}_{N\to\infty}$. In particular, they are independent of N.

We will impose the following assumptions on the network graph:

Assumption 3. (Bounded neighborhoods). All nodes in the graph family $\{\mathcal{G}_N\}_{N\to\infty}$ have a neighborhood of size at most q, where q is fixed and independent of N. That is,

$$|\mathcal{N}_i| \leq q \quad \forall i \in \mathcal{V}_N. \tag{5}$$

Assumption 4. (Finite weights). The edge weights in each $\mathcal{G}_N$ are finite, that is, $w_{ij} \leq w_{\max} < \infty$ for all $(i, j) \in \mathcal{E}_N$, where $w_{\max}$ is fixed and independent of N.

Assumptions 3–4 imply that we consider networks with bounded nodal degrees.

3.1 Scalable stability in high-order consensus

The network of agents is said to be achieving consensus if $x_i^{(k)} \to x_j^{(k)}$ for all $i, j \in \mathcal{V}_N$, all $k = 0, 1, \ldots, n-1$, and for any initial state. It is known that the algorithm (2) achieves consensus if the eigenvalues of the system matrix $\mathcal{A}$ defined in (4) are in the left half plane, apart from exactly n zero eigenvalues that are associated with the drift of the network average Ren et al. (2007). We focus on a scenario where these conditions may hold for small network sizes N, but where one or more eigenvalues leaves the left half plane and causes instability as the network grows beyond some network size $\bar{N}$. In these cases, we say the control algorithm lacks *scalable stability*.

Definition 1. (Scalable stability). A consensus control design is *scalably stable* if the resulting closed-loop system achieves consensus over *any* graph in the family $\{\mathcal{G}_N\}_{N\to\infty}$ of finite size N.

We are now ready to summarize our main results. First, we prove that high order ($n \geq 3$) consensus is subject to a scale fragility.

Theorem 3.1. If $n \geq 3$, no control on the form (2) subject to Assumptions 1–2, is scalably stable in graph families where the sequence $\mathrm{Re}\{\lambda_2(\mathcal{G}_N)\} \to 0$ as $N \to \infty$.

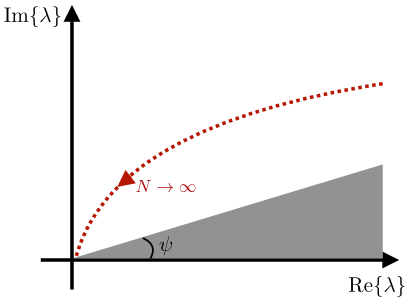

Fig. 2. Illustration of the condition in Theorem 3.2. The example trajectory shows λ_2 of a directed ring graph.

The proof relies on the Routh-Hurwitz criteria for polynomials with complex-valued coefficients. It is found in Tegling et al. (2022).

Theorem 3.1 implies that high-order consensus does not scale in graph families where the algebraic connectivity is decreasing in network size. This applies to all bounded-degree graph families except expander graphs (see Section 3.2). Instability will occur at the smallest size N for which the Routh-Hurwitz criteria are violated, and at least one eigenvalue crosses to the RHP. We will denote this critical network size $\bar{N}$. In Figure 1 we display $\bar{N}$ for $n = 3, 4, 5$ in an unweighted path graph.

Remark 1. In high-order leader-follower consensus, scalable stability is never attained in undirected bounded-degree graph families. This is because the smallest eigenvalue of the *grounded* graph Laplacian $\bar{\lambda}_1(\mathcal{G}_N) \leq \frac{q}{N-1} w_{\max} \to 0$. This also implies that consensus over any expander graph family (where λ_2 remains large, despite bounded nodal degrees) is *fragile* towards grounding, i.e., towards one agent becoming a leader, since $\bar{\lambda}_1(\mathcal{G}_N) \ll \lambda_2(\mathcal{G}_N)$.

Second-order consensus lacks scalable stability in certain families of *directed* graphs with complex eigenvalues:

Theorem 3.2. If $n \geq 2$, no control on the form (2), subject to Assumptions 1–2, is scalably stable in graph families where, for a fixed index $\bar{l} < N$,

(1) $\mathrm{Re}\{\lambda_{\bar{l}}(\mathcal{G}_N)\} \to 0$ as $N \to \infty$, *and*
(2) for each N and at least one $l \in \{2, 3, ..., \bar{l}\}$ it holds $\arg\{\lambda_l(\mathcal{G}_N)\} > \psi$, where $\psi \in (0, \pi/2)$ is a constant angle independent of N.

A particular graph family where Theorem 3.2 applies is directed ring graphs (a ring graph that is not undirected) with uniform edge weights. This was already observed in Cantos et al. (2016); Herman (2016). We show that it extends to toric lattices and their fuzzes. More generally, however, it is an open graph-theoretical challenge [1] to characterize graph families that have complex-valued eigenvalues and can be affected by the scale fragility we describe.

3.2 An algebraic condition for non-expanding graphs

In Theorem 3.1, we showed that high-order consensus lacks stable scalability in any graph family that has an algebraic connectivity that decreases towards zero as the network grows. This is true in any undirected graph family that is not an expander family. Expander families are defined by an isoperimetric constant that is lower bounded. We do not include the formal definition, which is combinatoric, here, but refer the reader to, e.g., Chung (1997). Intuitively, a large isoperimetric constant implies that every part of the graph is well interconnected with every other – the graph has no "bottleneck". Instead, we propose a novel algebraic condition for undirected graphs that have a bottleneck and are therefore not expander graphs.

For this purpose, partition a graph's vertex set into three disjoint sets X_0, X_1, X_2 so that $X_0 \cup X_1 \cup X_2 = \mathcal{V}$ and $|X_0| = N_0$,$|X_1| = N_1$, $|X_2| = N_2$. Each node in X_0 is connected to at least one node in both X_1 and X_2, but no edges connect X_1 and X_2 directly. See also Fig. 3. In other words, X_0 is the boundary set of both X_1 and X_2. This partitioning is always possible, unless the graph is complete (note that X_0, X_1, X_2 need not be connected subgraphs).

By re-numbering the nodes, the graph Laplacian becomes

$$L = \begin{bmatrix} L_1 & L_{10} & 0_{N_1 \times N_2} \\ L_{10}^T & L_0 & L_{03}^T \\ 0_{N_2 \times N_1} & L_{30} & L_2 \end{bmatrix}. \tag{6}$$

If N_0 can be made small in relation to both N_1 and N_2, we say that the graph has a bottleneck. The following lemma shows that if the bottleneck remains as the network grows, then $\{\lambda_2(\mathcal{G}_N)\} \to 0$.

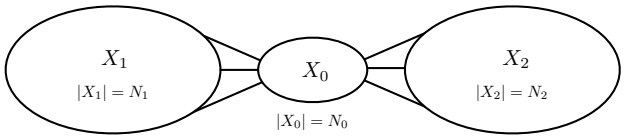

Fig. 3. Illustration for Lemma 3.3.

Lemma 3.3. Let $\{\mathcal{G}_N\}_{N\to\infty}$ be an undirected graph family subject to Assumptions 3–4. If every graph $\mathcal{G}_N$ in the family can be partitioned as outlined above in such a way that $N_0/N_1 \to 0$ and $N_0/N_2 \to 0$ as $N \to \infty$, then $\{\lambda_2(\mathcal{G}_N)\} \to 0$ as $N \to \infty$.

The proof relies on the Rayleigh-Ritz theorem and the assumption on bounded nodal degrees.

Remark 2. The specific scaling of $\lambda_2(\mathcal{G}_N)$ in N is known for several classes of graphs. For example, for planar graphs, $\lambda_2(\mathcal{G}_N) \leq \frac{8qw_{\max}}{N}$.

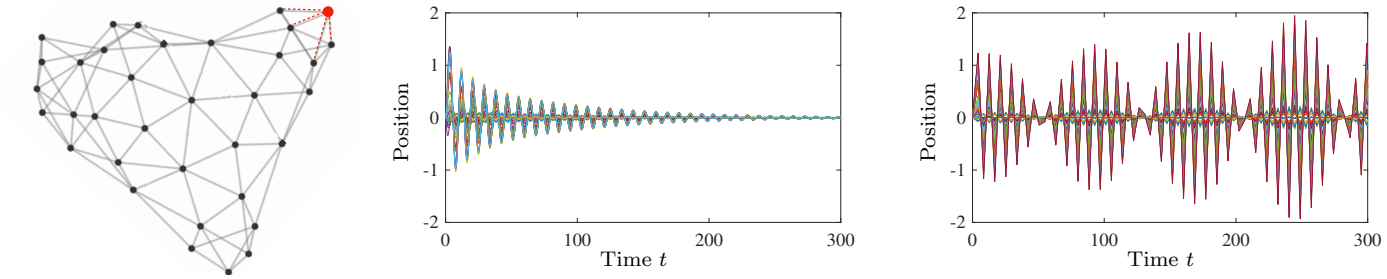
Example 1. To illustrate Theorem 3.1, we consider a third-order consensus algorithm:

$$x_i^{(3)} = -\sum_{j\in\mathcal{N}_i} \left[0.5(x_i - x_j) + (\dot{x}_i - \dot{x}_j) + (\ddot{x}_i - \ddot{x}_j)\right],$$

over the 34-node graph depicted in Figure 4a with unit edge weights. Here, $\lambda_2(\mathcal{G}_{34}) = 0.536$ and the system achieves consensus. Adding a 35^{th} node along with 4 connecting edges gives $\lambda_2(\mathcal{G}_{35}) = 0.493$ and the system becomes unstable, see Fig. 4c. [2]

[1] One we hope to discuss with experts at MTNS 2022!

[2] This particular value for $\lambda_2(\mathcal{G}_{35})$ depends on the placement of the 35^{th} node. Other placements can allow the critial $\bar{N} > 35$, but instability occurs eventually.



(a) Network graph (b) $N = 34$ (c) $N = 35$

Fig. 4. Simulation of 3rd order consensus over graph depicted in (a) subject to random initial accelerations. In (b) the network's 34 agents converge to an equilibrium. In (c) a 35th node has been added, indicated by red color in the graph. This addition leads to instability. The plots (b) and (c) show position trajectories relative to Agent no. 1.

4. DISCUSSION

The scale fragilities we describe here can in principle be attributed to two model features. First, the relative state feedback upon which the consensus algorithm is based. It is known that a restriction to relative feedback imposes performance and design limitations; an issue that was recently analyzed formally in Jensen and Bamieh (2022). In our work, we discuss how scalability can be retrieved if the controller has access to absolute feedback.

Second, the locality property, that is, bounded nodal neighborhoods, is key for our results. A natural question is therefore how nodal neighborhoods would need to scale to alleviate the scale fragility. Interestingly, we can prove that it can suffice to grow neighborhoods as $q \sim N^{2/3}$. We note that this only holds for leaderless consensus; leader-follower consensus still requires neighborhoods proportional to N.

We remark that, in order to be able to discuss a given controller's scalability in a network of increasing size, the assumption that it be fixed is necessary. That is, the controller cannot be re-tuned as the network grows. By re-tuning the consensus algorithm (2), either by changing the gains a_k, weights w_{ij}, or by relaxing the locality assumption, scalable stability can be retrieved. Such a re-tuning requires knowledge of *global* properties of the system. Still, the design of controller re-tuning protocols is an interesting direction for future research.

Abstract: Recent theoretical and numerical results on a constrained optimal control problem of Bolza type for a class of parabolic equations obtained by the authors are presented. We study the case when the cost functional is quadratic and comprises the norm of a control and the distance of the system trajectory from the desired evolution profile, the constraint is imposed on the final state that should be steered within a prescribed distance to a given target and the control enters the system through the initial condition.The theoretical results provide a formula for the optimal control and the numerical algorithm is based on efficient rational Krylov approximation techniques.

Keywords: optimal control; parabolic equations; homogenization; rational Krylov spaces; spectral calculus

1. INTRODUCTION

We consider a sequence of optimal control problems associated to the heat equation with rapidly oscillating coefficients. The cost functional to be minimised is quadratic and comprises the norm of a control and the distance of the system trajectory from the desired evolution profile. The constraint is imposed on the final state at time $T > 0$ that should be steered within a prescribed distance to a given target.

The control enters the system through the initial condition, and we deal with an inverse problem (of initial source identification) from the optimal control viewpoint. Initial control problems for parabolic equations are less investigated than distributed or boundary ones. A reason for that is due to the strong dissipativity of parabolic equations, which make the inverse problem numerically very challenging. The problem has been tackled by different approaches Fabre et al. (1995); Meidner and Vexler (2007); Li et al. (2014); Casas et al. (2015). In order to successfully address these difficulties we apply a recently developed approach, based on the spectral calculus for self-adjoint operators and a geometrical representation of the problem (Grubišić et al. (2021)). In the paper the authors first obtained a closed-form expression for the control solution as a function of the self-adjoint operator governing the dynamics of the system. The numerical computations were achieved by exploring efficient rational Krylov approximation techniques for resolvents from Berljafa and Güttel (2017), by which one constructs a rational approximant of the aforementioned function of the operator.

⋆ The research was done while the first author was visiting Chair of Dynamics, Control and Numerics (Alexander von Humboldt Professorship) at Friedrich-Alexander-Universität Erlangen-Nürnberg, with the support of the DAAD (Research Stays for University Academics and Scientists, 2021 programme) and Alexander von Humboldt-Professorship.

2. PROBLEM FORMULATION AND THE SOLUTION FORMULA

Let A be a self–adjoint operator bounded below on an infinite dimensional Hilbert space $\mathcal{H}$. For $u \in \mathcal{H}$ we consider the Cauchy problem

$$y'(t) + Ay(t) = 0, \quad t > 0,$$
$$y(0) = u.$$

By $(S_t)_{t\geq 0}$ we denote the semigroup generated by $-A$.

The optimal control problem Given $\epsilon, T > 0$ and $y^* \in \mathcal{H}$ we introduce the constrained minimisation problem

$$\min_{u\in\mathcal{H}} \left\{ J(u) \colon \left\| S_T u - y^* \right\| \leq \epsilon \right\} \tag{1}$$

where

$$J(u) = \frac{\alpha}{2}\|u\|^2 + \frac{1}{2}\int_0^T \beta(t) \left\| S_t u - w(t) \right\|^2 \mathrm{d}t, \tag{2}$$

$\alpha > 0$ and $\beta \in L^\infty((0,T);[0,\infty))$ are weights of the cost, and $w \in L^2((0,T);\mathcal{H})$ is the target trajectory. □

By using classical convex optimization techniques (e.g. (Peypouquet, 2015, Section 3.6)) one can show that the problem is well posed and admits the unique solution that we denote by $\hat{u}$.

If the solution of the unconstrained problem

$$\tilde{u} = \min_{u\in\mathcal{H}} \{J(u)\}$$

drives the system to the ε ball around the target, then the solutions of the two problems coincide and the original

problem can be relaxed by considering the unconstrained one, which is easier to handle. This case we exclude from further analysis.

If the problem can not be relaxed to the corresponding unconstrained one, then the optimal final state lies on the boundary of the target ball (Lazar et al., 2017, Proposition 2.1). In such a way one can associate a Lagrange functional to the problem and obtain the formula for the solution. The formula was first obtained in Lazar et al. (2017) and subsequently further developed and elaborated in details in Grubišić et al. (2021).

Theorem 1. The optimal initial state is given by

$$\hat{u} = (\mu^\epsilon S_{2T} + \Psi)^{-1}(\mu^\epsilon S_T y^* + \psi), \tag{3}$$

where

$$\Psi = \alpha\,\mathrm{Id} + \int_0^T \beta(t) S_{2t} dt, \quad \psi = \int_0^T \beta(t) S_t w(t) dt,$$

and $\mu^\epsilon \geq 0$ is the unique solution of

$$\Phi(\mu) = \epsilon \tag{4}$$

if $\epsilon < \|\tilde{y} - y^*\| = \|\Psi^{-1} S_T \psi - y^*\|$, and zero otherwise. Here $\Phi\colon [0,\infty) \to [0,\infty)$ is the function defined by

$$\Phi(\mu) = \|y^* - (\mu S_{2T} + \Psi)^{-1}(\mu S_{2T} y^* + S_T \psi)\|. \tag{5}$$

□

Formula (3) is almost explicit, up to the scalar μ^ϵ which corresponds to the optimal Lagrange multiplier.

3. NUMERICAL IMPLEMENTATION OF THE SOLUTION OF THE OPTIMAL CONTROL PROBLEM

In the numerical implementation we first devise a method for solving the equation (4). Hereby we explore efficient Krylov subspace techniques that allow us to approximate a (generalised) exponential functions of an operator appearing in the equation (5) by a series of linear problems.

The approximation is obtained by using the award winning `rkfit` algorithm from Berljafa and Güttel (2017). This is a rational Krylov function fitting algorithm which has also been implemented in Matlab within the Rational Krylov Toolbox.

The algorithm approximates a function of an operator by a rational function r, hereby using the equality

$$(v, S_t v) - (v, r(A)v) = \int_{-\infty}^{\kappa} \left(\mathrm{e}^{t\lambda} - r(\lambda)\right) \mathrm{d}(E(\lambda)v, v), \tag{6}$$

where $E(\cdot)$ denotes the spectral measure of the self-adjoint operator A (Kato (1995)).

In the next step the rational function r is rewritten in a partial fractions form

$$r(z) = r_0 + \frac{r_1}{z - \zeta_1} + \cdots \frac{r_d}{z - \zeta_d}.$$

This provides application of a function of the operator A of the form

$$S_t \approx r_0 I + \sum_{i=1}^{d} r_i (A - \zeta_i)^{-1},$$

where $\zeta_i,\ i = 1, \ldots, d$, belong to the resolvent set of A.

Once the above approximations are provided, one can use any root finding algorithm based only on function evaluation to robustly approximate the root of (4).

The optimal control is then obtained by solving the linear equation (3). Note that the expressions entering it are of the same form as those appearing in the equation for the optimal Lagrange multiplier (4).

The efficiency of the procedure was confirmed by numerical examples, including several constrained optimization problems in 1D and 2D, with variable and non-smooth coefficients and acting on irregular domains. ALso the sensitivity analysis of the solution was provided.

Port-Hamiltonian modeling of power networks with distributed transmission lines

Hannes Gernandt * **Dorothea Hinsen** *

* *Technische Universität Berlin, Straße des 17. Juni 136, 10623 Berlin (e-mail: {gernandt, hinsen}@math.tu-berlin.de).*

Abstract: In this talk we consider power networks consisting of loads and generators which are interconnected via transmission lines. Here we use a distributed model for the transmission lines and provide a port-Hamiltonian formulation as a boundary control system and show the exponential stability and a power-balance equation for classical solutions.

Keywords: Distributed port-Hamiltonian systems, Infinite Dimensional Systems Theory, Systems on Graphs, Descriptor Systems, Power Grids

1. OUTLINE

We consider power grid models consisting of loads and generators which are interconnected by transmission lines. Here we follow the port-Hamiltonian (pH) modeling approach to power grids which was developed in Fiaz et al. (2012); Fiaz et al. (2013); van der Schaft and Stegink (2016).

As a new aspect we consider distributed models for the transmission lines based on the telegrapher's equations. Although this model has been studied in Jacob and Zwart (2012a), to the best of our knowledge no interconnection of several transmission lines has been studied yet. Hence as a first contribution, we formulate the interconnected system of transmission lines and loads as a boundary control system and study the exponential stability of the semigroups. Second, we study the corresponding finite-dimensional port-Hamiltonian systems which are obtained after a spatial discretization of the transmission lines and add further port-Hamiltonian power generator models

2. PORT-HAMILTONIAN OPERATOR CLASS

The distributed transmission line on the spatial interval $[0,\ell]$ can be modeled by the telegraphers equations

$$\begin{aligned} C(\xi)\tfrac{\partial}{\partial t}V(t,\xi) &= -\tfrac{\partial}{\partial \xi}I(t,\xi) - G(\xi)V(t,\xi),\\ L(\xi)\tfrac{\partial}{\partial t}I(t,\xi) &= -\tfrac{\partial}{\partial \xi}V(t,\xi) - R(\xi)I(t,\xi), \qquad (1)\\ V(0,\xi) &= V^0(\xi), \quad I(0,\xi) = I^0(\xi) \end{aligned}$$

where $I : [0,\ell] \to \mathbb{R}^d$ is the current and $V : [0,\ell] \to \mathbb{R}^d$ is the voltage across the transmission line. We allow values in $\mathbb{R}^d$ for some $d \geq 1$ to include three phase models of transmission lines as well. Furthermore, $C(\xi) \geq c_0$ and $L(\xi) \geq l_0$ for all $\xi \in [0,\ell]$ and some $c_0, l_0 > 0$, $R(\xi) \geq 0$ and $G(\xi) \geq 0$.

This motivates the following modifications and generalizations of the pH model:

(M1) We consider an arbitrary Hilbert space X with scalar product $\langle \cdot, \cdot \rangle$ and define on $X \times X$ the block operator

$$A = \begin{bmatrix} -G & D \\ D & -R \end{bmatrix}$$

where $D : X \supset \operatorname{dom} D \to X$ is closed, densely defined and skew-symmetric, i.e. $D \subseteq -D^*$. Furthermore, we assume that G, R are bounded and fulfill $\langle Rx, x\rangle \geq 0$ and $\langle Gx, x\rangle \geq 0$ for all $x \in X$;

(M2) $\mathcal{H} : X \times X \to X \times X$ is bounded and fulfills $\langle \mathcal{H}x, x\rangle \geq m\|x\|^2$;

(M3) Instead of specifying the domain of A in terms of the boundary flow and boundary effort f_∂ and e_∂, we assume that the symmetric operator $\mathrm{i}D$ has a so called *boundary triplet* $\{\mathcal{X}, \Gamma_0, \Gamma_1\}$, see e.g. Behrndt et al. (2020).

Assuming (M1)-(M3), we consider the following boundary control system

$$\dot{x}(t) = \begin{bmatrix} -G & D^* \\ D^* & -R \end{bmatrix} \mathcal{H}x, \quad \Gamma_0\mathcal{H}x(t) = u(t), \quad \Gamma_1\mathcal{H}x(t) = y(t) \qquad (2)$$

where the mappings $\Gamma_0, \Gamma_1 : \operatorname{dom}(A^*\mathcal{H}) \to \mathcal{X}$ are given by a boundary triplet. Such systems were studied in a more general context in Malinen and Staffans (2006, 2007) and we demonstrate how their results can be applied to derive a power-balance equation for classical solutions x of (2)

$$\begin{aligned} &\langle \mathcal{H}x(t), x(t)\rangle - \langle \mathcal{H}x(0), x(0)\rangle \\ &\leq 2\int_0^t \operatorname{Re}\langle u(\tau), y(\tau)\rangle d\tau - \left\langle \begin{bmatrix} R & 0 \\ 0 & G \end{bmatrix} \mathcal{H}x(t), \mathcal{H}x(t) \right\rangle. \qquad (3) \end{aligned}$$

The power balance equation (3) implies that the considered boundary control systems are *impedance passive system* in the sense of Staffans (2002). For general systems which can be decomposed into a skew-adjoint and a dissipating part, and with bounded control operators a power balance equation for mild solutions was given in Philipp et al. (2021), see also Egger et al. (2018) for power balance equations for weak solutions.

Furthermore, we show that the operator

$$A := \begin{bmatrix} -G & D^* \\ D^* & -R \end{bmatrix}|_{\ker(\Gamma_0\mathcal{H})} = \begin{bmatrix} -G & -D^* \\ D & -R \end{bmatrix}$$

generates an exponentially stable semigroup if R is *uniformly positive*, i.e. there exists $r_0 > 0$ such that

$$\langle Rx, x\rangle \geq r_0\|x\|^2, \quad \text{for all } x \in X$$

together with either the surjectivity of D^*, or compact resolvent assumptions which are typically fulfilled in many transport network examples or beam networks. Note that if G is uniformly positive as well, then the exponential stability trivially follows from the well-known Lyapunov inequality.

The exponential stability and stabilizability for pH systems is well studied, see e.g. Villegas (2007); Villegas et al. (2009); Augner and Jacob (2014); Ramirez et al. (2014); Augner (2020); Trostorff and Waurick (2022) and in particular (Jacob and Zwart, 2012b, Chapter 9). But in these works the characterizations are mostly in terms of conditions on the boundary values of the Hamiltonian. Furthermore, there are some recent results Skrepek (2021) on stability of multi-dimensional pH systems. In particular, there are results on the strong and semi-uniform stability, see also Kurula and Zwart (2015) for a treatment of multi-dimensional pH systems.

3. NETWORK OF TRANSMISSION LINES

We consider a network of transmission lines described by a graph $\mathcal{G} = (V, E)$. Then for each line $e \in E$ with spatial domain $[0, \ell_e]$ for some $\ell_e > 0$, we consider in $X_e \times X_e = L^2([0,\ell_e],\mathbb{R}^d) \times L^2([0,\ell_e],\mathbb{R}^d)$ the following system

$$\mathfrak{A}_e = \begin{bmatrix} -G_e & -D_e^* \\ -D_e^* & -R_e \end{bmatrix}, \quad \mathcal{H}_e(\xi) = \begin{bmatrix} C_e(\xi)^{-1} & 0 \\ 0 & L_e(\xi)^{-1} \end{bmatrix},$$
$$\mathcal{H}_e(\xi)x_e(t,\xi) = \begin{pmatrix} V_e(t,\xi) \\ I_e(t,\xi) \end{pmatrix}$$

and show that a boundary triplet is given

$$\Gamma_0^e(x_e) := \begin{bmatrix} V_e(0) \\ V_e(\ell_e) \end{bmatrix}, \Gamma_1^e(x) := \begin{bmatrix} \mathrm{i}I_e(0) \\ -\mathrm{i}I_e(\ell_e) \end{bmatrix}.$$

If we consider now the operators based on establishing continuity of Γ_0^e at every vertex $v \in V$, then this leads to the node-type boundary triplet

$$\Gamma_0^V((x_e)_{e\in E}) = (V(v))_{v\in V},$$
$$\Gamma_1^V((x_e)_{e\in E}) = \big\{\mathrm{i}\sum_{e\sim v,(e,k)\sim v} \operatorname{sgn}(e,v) I_e(k\ell_e)\big\}_{v\in V},$$

where the sum is taken over all edges e which are adjacent to v and $k = 0, 1$. Hence the voltage controlled boundary control system is given by

$$\dot{x} = \mathfrak{A}\mathcal{H}, \quad u(t) = \Gamma_0^V x, \quad y(t) = \Gamma_1^V x$$

where

$$x = (x_e)_{e\in E}, \quad \mathfrak{A} := \oplus_{e\in E}\mathfrak{A}_e,$$
$$\mathcal{H} := \oplus_{e\in E} \begin{bmatrix} C_e(\xi)^{-1} & 0 \\ 0 & L_e(\xi)^{-1} \end{bmatrix}$$

this can be viewed as having a voltage input at every node.

Our results will then be applied to show stability and the power balance equation for this interconnected system.

Abstract: We study the dynamical behaviour of the SIR network model at individual nodes. In two particular cases of a network consisting of only two nodes, we show how this behaviour differs from the epidemic outbreak and monotonic decreasing trend that occur in the scalar case. The first case deals with a network in which contact is only direct from one node to another, while the second treats a network with all contacts equal to one. The result shown for this scenario remains true by continuity for all those networks sufficiently close in parameter space.

Keywords: Nonlinear Systems and Control

1. INTRODUCTION

In recent years, there has been an increased focus on mathematical models that can be used to simulate, analyse and prevent the evolution of epidemic infections and identify parameters that can define patterns of behaviour. The classical deterministic SIR epidemic model, as first presented in the pioneering work Kermack and McKendrick (1927), is a compartmental model consisting of a nonlinear system of three coupled differential equations describing the evolution of the fractions of susceptible, infected, and recovered individuals in a fully mixed closed population. The main feature of this model is the existence of a phase transition described in terms of a scalar parameter, known as the reproduction number, whose value can determine two fundamentally different behaviours of the epidemics. Specifically, if the reproduction number does not exceed 1, then the fraction of the infected individuals remains monotonically decreasing in time, and thus preventing an epidemic outbreak. In contrast, if the reproduction number exceeds the unitary threshold, then the fraction of infected individuals is initially increasing until reaching a peak, after which it starts to decrease monotonically and vanishes asymptotically in the large time limit. Most compartmental models of disease propagation, such as in Hethcote (2000), assume that populations are fully mixed, meaning that an infected individual is equally likely to spread the infection to any other member of the population. However, this assumption is unrealistic, as one infected individual is not equally likely to infect all others because in the real world each individual has contact with only a small fraction of the total population. In order to better describe a disease spread, several studies have considered topological properties of various networks and studied their effects on the epidemic processes taking place on these Newman (2002). Through the study of network SIR models, the topology of the graph has proved to be a determinant feature for the dynamics of the system, as in Mei et al. (2017) where a new threshold condition for epidemic behaviour is proposed in terms of network characteristics, initial conditions and infection parameters. It has been shown how a weighted average of the population of infected people is able to capture all the information on epidemic evolution, where the weights depend on network properties.

However, in individual nodes the dynamics may present different phenomena and our contribution concerns precisely the investigation of such scenarios. We will focus on two specific networks, in the first case there is a direct contact only from one node to another, while in the second case we will consider a particular network where the contact matrix has all entries equal to one.

2. NETWORK SIR MODEL

In this section, we introduce the network SIR model. Let us consider a weighted graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, A)$ with finite set of nodes $\mathcal{V} = \{1, 2, \dots, n\}$, set of directed links $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$, and a matrix A in $\mathbb{R}_+^{n\times n}$, whose entries embody the strength of both the infection and the contact frequency of members of subpopulation i with members of subpopulation j. For given recovery rate $\gamma > 0$, the network SIR epidemic model on a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, A)$ is the dynamical system

$$\begin{cases} \dot{x}_i = -x_i \sum_{j=1}^{n} a_{ij} y_j \\ \dot{y}_i = x_i \sum_{j=1}^{n} a_{ij} y_j - \gamma y_i \\ \dot{z}_i = \gamma y_i \end{cases} \tag{1}$$

for $i = 1, \dots, n$, where x_i, y_i, and z_i represent respectively the fractions of susceptible, infected, and recovered individuals in population i. Notice that (1) can be more compactly rewritten in its vectorial form

$$\begin{cases} \dot{x} = -diag(x)Ay \\ \dot{y} = diag(x)Ay - \gamma y \end{cases} \tag{2}$$

This model has been studied in Mei et al. (2017) and Nowzari et al. (2016). In particular, they show that if $y(0) > \mathbf{0}_n$, and $x(0) \geq \mathbf{0}_n$, then $t \mapsto x(t)$ and $t \mapsto y(t)$ are strictly positive for all $t \geq 0$. The strictly positivity of the solutions will be useful in the following theorem. It has also been proven that all solutions converge to an equilibrium point of the form $(x^*, 0, z^*) \in \mathbb{R}^{3n}_+$ such that $x^* + z^* = \mathbf{1}$ and that the locally asymptotically stable equilibrium points are those such that

$$\lambda_{\max}(\mathrm{diag}\,(x^*)A) < \gamma$$

where $\lambda_{\max}$ is the dominant eigenvalue of the nonnegative matrix $\mathrm{diag}\,(x^*)A$, which coincides with its spectral radius thanks to the Perron-Frobenius Theorem. Under the assumption of strong connectivity of the graph $\mathcal{G}$, (Mei et al., 2017, Theorem 7) shows that the quantity

$$R(t) = \lambda_{\max}(\mathrm{diag}\,(x(t))A)/\gamma$$

is decreasing along solutions and it plays a role similar to the one played by the reproduction number in the scalar SIR model. Specifically, if $R(0) \leq 1$ then the weighted average of the infected $v(0)'y(t)$ will be monotonically decreasing to 0 as t grows large, where $v(t)$ stands for the corresponding left-eigenvector of λ_{max} of the matrix $\mathrm{diag}\,(x(t))A$. On the other hand, if $R(0) > 1$, then the weighted average $v(0)'y(t)$ will be initially increasing (epidemic outbreak) and there exists some $\tau > 0$ such that $R(\tau) \leq 1$ and the weighted average $v(\tau)'y(t)$ will be decreasing to 0 for t in the interval $[\tau, +\infty)$. It is therefore possible to find a parallelism with the scalar case.

However, several simulations show how the dynamical behaviour at individual nodes can exhibit atypical phenomena compared to the unimodal or monotonically decreasing behaviour of the scalar case. We will investigate these phenomena, trying to determine which conditions are sufficient for them to occur and which are necessary to have a behaviour similar to the classical SIR case at each node. For this analysis from now on, we will focus on the case of a network consisting of two nodes.

3. TWO-NODES NETWORK

In this section, we will deal with the case of a network composed of two nodes in two different scenarios: in the first case, the contact only occurs directly from the second node to the other and not vice versa, while in the second one, we will consider an homogeneous network in which the contact matrix has all entries equal to 1.

3.1 One node cannot be infected by the other one

Consider the SIR model (1) in the case of a network composed of only two nodes, with the following infection/weight matrix

$$A = \begin{bmatrix} a_{11} & a_{12} \\ 0 & a_{22} \end{bmatrix} \tag{3}$$

In this scenario, the second node is isolated from the first in the sense that the individuals of the second node cannot be infected due to contacts with individuals of the first node. On the other hand, in the first node, the infection process occurs both due to infection within the node, and to infection received through contact with the second node. As the second node is unaffected by contact with the first, its dynamics is equivalent to scalar SIR dynamics. Therefore, if $a_{22}x_2(0) > \gamma$, then $t \mapsto y_2(t)$ is initially monotonically increasing, it shows an epidemic outbreak and then it becomes exponentially decreasing to 0. We assume for simplicity of notation $z(0) = \mathbf{0}$, but the results can be extended to the general case without loss of generality.

Let t_2 denote the time at which the peak of the second node occurs. We can derive t_2 from Harko et al. (2014), by using the fact that $z_2(0) = \mathbf{0}$ and $x_2(t_2) = \gamma/a_{22}$. Specifically,

$$t_2 = \int_1^{\frac{\gamma}{a_{22}x_2(0)}} \frac{ds}{s(-a_{22} - \gamma log(s) + a_{22}x_2(0)s)} \tag{4}$$

while the infected at the second node peak will be

$$y_2(t_2) = \frac{\gamma}{a_{22}} \ln\left(\frac{\gamma}{a_{22}x_2(0)}\right) - \frac{\gamma}{a_{22}x_2(0)} + 1. \tag{5}$$

Let us analyse the dynamics of the first node in this scenario.

Theorem 1. Consider the SIR model (1) in the case of a network composed of only two nodes with matrix (3). Suppose $(x_i(0), y_i(0), z_i(0))$ for $i = 1, 2$ as initial condition such that the following relations hold:

$$a_{11}x_1(0)y_1(0) + a_{12}x_1(0)y_2(0) - \gamma y_1(0) < 0 \tag{6}$$

$$(a_{22}x_2(0) - \gamma)y_2(0) > 0 \tag{7}$$

$$(x_1(0) - \gamma y_1(0)t_2)a_{12}y_2(t_2) > \gamma y_1(0) \tag{8}$$

where t_2 is the time instant at which the infected curve of the second node has the infection peak. Then,

a) $\dot{y}_1(0) < 0$ and $\dot{y}_2(0) > 0$

b) $\exists t^* \leq t_2$ such that $\dot{y}_1(t^*) > 0$.

Proof. The first statement is obvious from the relations in (6)-(7). Let us now assume by contradiction that the statement *b*) is false. This would mean that for $t \in [0, t_2]$,

$$\dot{y}_1(t) \leq 0 \quad \Rightarrow \quad y_1(t) \leq y_1(0) \tag{9}$$

From fundamental theorem of integral calculus, we can observe that

$$x_1(t_2) = x_1(0) + \int_0^{t_2} \dot{x}_1(s)ds \tag{10}$$

Since for all $t \in [0, t_2]$,

$$\dot{y}_1(t) = x_1(t)(a_{11}y_1(t) + a_{12}y_2(t)) - \gamma y_1(t) \tag{11}$$

$$= -\dot{x}_1(t) - \gamma y_1(t) \leq 0, \tag{12}$$

then $\dot{x}_1(t) \geq -\gamma y_1(t) \geq -\gamma y_1(0)$. Therefore

$$x_1(t_2) \geq x_1(0) - \int_0^{t_2} \gamma y_1(s)ds \geq x_1(0) - \gamma y_1(0)t_2. \tag{13}$$

We can state that

$$\dot{y}_1(t_2) = x_1(t_2)(a_{11}y_1(t_2) + a_{12}y_2(t_2)) - \gamma y_1(t_2) \tag{14}$$

$$> x_1(t_2)a_{12}y_2(t_2)) - \gamma y_1(t_2) \tag{15}$$

$$\geq (x_1(0) - \gamma y_1(0)t_2)a_{12}y_2(t_2) - \gamma y_1(t_2) \tag{16}$$

$$\geq \gamma y_1(0) - \gamma y_1(t_2) \geq 0 \tag{17}$$

where the first inequality follows from the strict positivity of $y(t)$, while the last one is true for (9). This is an absurd and therefore there must be a time instant $t^* \leq t_2$ such that the first derivative of y_1 becomes positive.

□

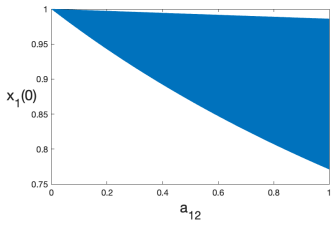

Fig. 1. Values of initial condition of the first node $x_1(0)$ as a_{12} varies, with the other parameters fixed.

Remark 1. Note that the theorem hypothesis of initial decreasing trend of y_1 and the validity of the relation (8) are not incompatible. In fact, if we decide to set the parameters $\gamma = 0.9$, $a_{22} = 1$, $a_{11} = 0.1$ and the initial condition of the second node $x_2(0) = 0.99$, we find that when a_{12} varies, the values of $x_1(0)$ that are admissible by the theorem are those shown in the Figure (1).

Remark 2. The theorem shows how an atypical behaviour can occur in this particular scenario. The curve of infected in the first node, instead of decreasing as it would if it were isolated, causes an outbreak of the epidemic with a second peak of infection (the first one is in initial condition) and then returns to decrease.

Let us now study a sufficient condition for this phenomenon not to occur.

Theorem 2. Consider the SIR model (1) in the case of a network composed of only two nodes with matrix (3). Suppose $(x_i(0), y_i(0), z_i(0))$ for $i = 1, 2$ as initial condition such that $x_2(0) < (a_{12}+\gamma)/(a_{12}+a_{22})$. Then, the following statements hold:

a) Define the set
$$\Omega = \{(x_1, y_1, x_2, y_2) \in [0,1]^4 : \dot{y}_1 < 0\} \tag{18}$$
then Ω is an invariant set for the dynamics,

b) For any initial condition such that $(x_1(0), y_1(0), y_2(0)) \notin \Omega$, there exists an instant $t^* > 0$:
$$(x_1(t), y_1(t), x_2(t), y_2(t)) \notin \Omega \quad \forall t < t^* \tag{19}$$
$$(x_1(t), y_1(t), x_2(t), y_2(t)) \in \Omega \quad \forall t > t^* \tag{20}$$

Proof. Regarding statement 3), consider initial conditions such that $(x_1(0), y_1(0), x_2(0), y_2(0)) \in \Omega$ and let $(x_i(t), y_i(t))$ be the corresponding solutions in node i.
We want to prove that $(x_1(t), y_1(t), x_2(t), y_2(t)) \in \Omega \quad \forall t$, i.e. if the first node has initial condition that make its curve of infected decreasing, then this curve will remain decreasing $\forall t \geq 0$. Suppose that exist an instant $t^* > 0$ such that
$$(x_1(t^*), y_1(t^*), x_2(t^*), y_2(t^*)) \in \delta\Omega, \tag{21}$$
where $\delta\Omega = \{(x_1, y_1, x_2, y_2) \in [0,1]^4 : \dot{y}_1 = 0\}$ and $(x_1(t), y_1(t), x_2(t), y_2(t)) \in \Omega \quad \forall t < t^*$.
Let us consider the first derivative of $\dot{y}_1$ with respect to time t.
$$\ddot{y}_1 = \dot{x}_1(a_{11}y_1 + a_{12}y_2) + x_1(a_{11}\dot{y}_1 + a_{12}\dot{y}_2) - \gamma\dot{y}_1 \tag{22}$$
Notice that, necessarily, $y_1(t^*) > 0$ and $\dot{y}_1(t^*) = 0$. We can observe that at t^*
$$\ddot{y}_1(t^*) = \dot{x}_1(a_{11}y_1 + a_{12}y_2) + a_{12}x_1\dot{y}_2 \tag{23}$$
$$= -x_1(a_{11}y_1 + a_{12}y_2)^2 + a_{12}x_1(a_{22}x_2 - \gamma)y_2 \tag{24}$$
If $a_{22}x_2(t^*) < \gamma$, then this quantity is negative.

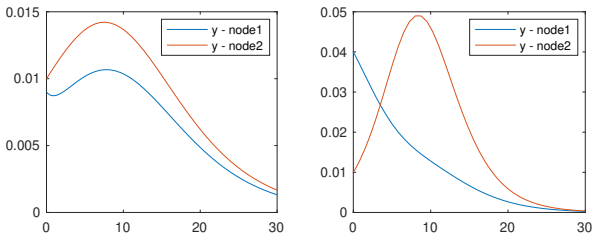

Fig. 2. Simulations of the network SIR model. The scenario on the left is under the assumptions of Theorem 1 and y_1 has a second peak of infection, while the one on the right meets the Theorem 2' assumptions and no multimodal behaviour occurs.

Otherwise, y_2 is still increasing and we have
$$\begin{aligned}\ddot{y}_1(t^*) &= -x_1(a_{11}y_1 + a_{12}y_2)^2 + a_{12}x_1(a_{22}x_2 - \gamma)y_2 \\ &< x_1y_2(-a_{12}^2y_2 + a_{12}a_{22}x_2 - a_{12}\gamma) \\ &< a_{12}x_1y_2(-a_{12}y_2(0) + a_{22}x_2(0) - \gamma) < 0\end{aligned}$$
where the first inequality holds because $a_{12}y_2(t) \leq a_{11}y_1(t) + a_{12}y_2(t)$ for all t, while the second one follows from the monotonically decreasing trend of x_2 and the still increasing behaviour of y_2. The final inequality is a direct consequence of the relation on the initial condition.
Hence, $\ddot{y}_1(t^*) < 0$ and, by continuity, we can state that $\ddot{y}_1 < 0$ in a neighborhood $(t^* - \epsilon, t^*]$. Since $\dot{y}_1$ is decreasing and, by construction, $\dot{y}_1 < 0$ for $t < t^*$, it is not possible that $\dot{y}_1(t^*) = 0$ and this proves the statement *a*).

For statement *b*), having shown the previous point, we only have to prove that exists an instant t^* such that $(x_1(t^*), y_1(t^*), x_2(t^*), y_2(t^*)) \in \Omega$. If this was not the case, then it would be $\dot{y}_1(t) > 0 \, \forall t$ and $y_1(t)$ would not tend to 0. Therefore $z_1(t)$ would blow up which is impossible for the first statement. □

In Figure 2, we compare the different behaviours of the infected curves in the two cases considered in the previous theorems.

3.2 Homogeneous network with $A = \beta\mathbf{1}\mathbf{1}'$

Let us now analyse a network in which the contact-infection matrix $A = \beta\mathbf{1}\mathbf{1}'$, where β is the explicit infection rate and with no distinction between individuals belonging to the same or different populations. We will focus on a particular scenario in which one node has an initial small fraction of infected, while the other one is initially totally susceptible. Also in this case, we find some initial conditions that ensure the occurrence of an atypical behaviour. The result shown is valid by continuity for all those sufficiently close in parameter space.

Theorem 3. Consider the network SIR model (1), complete contact graph with $A = \mathbf{1}\mathbf{1}'$, and unitary infection and recovery rates $\beta = \gamma = 1$. Let the initial condition
$$x_1(0) = 1 - \varepsilon\,, \quad y_1(0) = \varepsilon\,, \quad x_2(0) = 1\,, \quad y_2(0) = 0\,,$$
for some $0 < \varepsilon < \bar{\varepsilon}$, where
$$\bar{\varepsilon} = \min\{\varepsilon \in [0,1] : \varepsilon = \frac{1-\varepsilon}{2-\varepsilon}\Big(1 - \ln(2-\varepsilon)\Big)\}\,.$$
Then, the fraction of infected in the first population y_1 changes monotonicity exactly twice along the solution.

Proof. The dynamics is given by

$$\dot{x}_i = -2x_i\overline{y}\,, \qquad \dot{y}_i = 2x_i\overline{y} - y_i\,, \qquad i = 1, 2\,,$$

where

$$\overline{x} = (x_1 + x_2)/2\,, \qquad \overline{y} = (y_1 + y_2)/2\,,$$

are the mean aggregate variables. Notice that

$$\dot{\overline{x}} = -2\overline{x}\,\overline{y}\,, \qquad \dot{\overline{y}} = (2\overline{x} - 1)\overline{y}\,,$$

so that by scalar theory the quantity $\overline{x}+\overline{y}-\frac{1}{2}\ln\overline{x}$ remains constant along solutions, i.e. $\forall t \geq 0$,

$$\overline{x}(t) + \overline{y}(t) - \frac{1}{2}\ln\overline{x}(t) = \overline{x}(0) + \overline{y}(0) - \frac{1}{2}\ln\overline{x}(0)\,. \quad (25)$$

On the other hand, whenever $x_2 > 0$, we have

$$\left(\frac{\dot{x}_1}{x_2}\right) = \frac{\dot{x}_1 x_2 - x_1\dot{x}_2}{x_2^2} = 0$$

so the ratio x_1/x_2 remains constant along solutions, i.e.,

$$x_i(t)\overline{x}(0) = x_i(0)\overline{x}(t)\,, \qquad \forall t \geq 0\,,\ i = 1, 2\,. \quad (26)$$

Observe that

$$\dot{y}_1(0) = 2x_1(0)\overline{y}(0) - y_1(0) = -\varepsilon^2 < 0\,,$$

whereas

$$\dot{\overline{y}}(0) = (2\overline{x}(0) - 1)\overline{y}(0) = (1 - \varepsilon)\varepsilon/2 > 0\,.$$

Let $t^* > 0$ be the aggregate peak time, i.e., the time such that

$$\overline{x}(t^*) = 1/2, \qquad \dot{\overline{y}}(t^*) = 0\,.$$

It follows from (25) that

$$\overline{y}(t^*) = \overline{x}(0) + \overline{y}(0) - \frac{1}{2}\ln\overline{x}(0) - \overline{x}(t^*) + \frac{1}{2}\ln\overline{x}(t^*) \quad (27)$$

$$= \frac{1}{2}\Big(1 - \ln(2 - \varepsilon)\Big)\,, \quad (28)$$

while (26) implies that

$$x_1(t^*) = \frac{x_1(0)\overline{x}(t^*)}{\overline{x}(0)} = \frac{1 - \varepsilon}{2 - \varepsilon}\,. \quad (29)$$

Now, assume by contradiction that

$$\dot{y}_1(t) \leq 0\,, \qquad \forall t \geq 0\,. \quad (30)$$

In particular, this would in particular imply that

$$\begin{aligned} 0 \geq \dot{y}_1(t^*) &= 2x_1(t^*)\overline{y}(t^*) - y_1(t^*) \\ &= \frac{1 - \varepsilon}{2 - \varepsilon}\Big(1 - \ln(2 - \varepsilon)\Big) - y_1(t^*) \\ &\geq \frac{1 - \varepsilon}{2 - \varepsilon}\Big(1 - \ln(2 - \varepsilon)\Big) - y_1(0) \end{aligned}$$

So we would obtain that

$$y_1(0) = \varepsilon \geq \frac{1 - \varepsilon}{2 - \varepsilon}\Big(1 - \ln(2 - \varepsilon)\Big)$$

Therefore necessarily $\varepsilon \geq \bar{\varepsilon}$, thus violating the assumption. It then follows that there exists at least a time $\bar{t}$ such that $\dot{y}_1(\bar{t}) > 0$. The claim then follows, since $\dot{y}_1(0) < 0$ and $\lim_{t\to+\infty} y_1(t) = 0$. We have shown that the infected curve in the first node y_1 changes monotonicity at least twice along the solution. □

Based on the previous theorem and standard continuity arguments we can prove the following result.

Proposition 1. There exist values $\bar{\varepsilon} > 0$, $\underline{\beta} < 1 < \overline{\beta}$, and $\underline{\gamma} < 1 < \overline{\gamma}$, and an open subset of nonnegative matrices $\mathcal{M} \subseteq \mathbb{R}^{2\times 2}$ containing $\mathbf{1}\mathbf{1}'$ such that the network SIR model with $n = 2$ subpopulations, contact graph with weight matrix $A \in \mathcal{M}$, infection rate $\beta \in (\underline{\beta}, \overline{\beta})$, recovery rate $\gamma \in (\underline{\gamma}, \overline{\gamma})$ with any initial condition such that

$$0 < y_i(0) = 1 - x_i(0) < \bar{\varepsilon}\,, \qquad i = 1, 2\,,$$

has solution such that the faction of infected in the first population $y_1(t)$ is a multi-modal function of t.

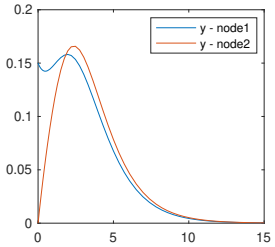

Fig. 3. Simulation of the SIR model on an homogeneous network where the second node is initially totally susceptible.

In Figure 3, we can observe the occurrence of this atypical behaviour also in this scenario: the curve of the infected in the first node is initially decreasing, then it becomes increasing to a peak of infection, and then decreasing to 0. We have considered a population characterized by a small initial fraction of infected people, such as to cause an exponential decrease to 0, using the scalar SIR model theory. However, if this first population meets a totally healthy one, it begins to infect it and then suffers a return wave of infection with a second peak (the first one was in its initial condition).

4. CONCLUSION

In this work, we analyse the behaviour of the network SIR model at each node in some particular cases and define sufficient conditions for the occurrence of an atypical phenomenon, compared to the classical SIR theory results. This phenomenon consists of the appearance of multi-modal dynamical behaviours at a single node and it has been shown in different scenarios of a two-nodes network.

Towards Funnel MPC for nonlinear systems with relative degree two ⋆

Dario Dennstädt *

* *Technische Universität Ilmenau, Weimarer Str. 25, 98693 Ilmenau, Germany (dario.dennstaedt@tu-ilmenau.de).*

Abstract: Funnel MPC, a novel Model Predictive Control (MPC) scheme, allows guaranteed output tracking of smooth reference signals with prescribed error bounds for nonlinear multi-input multi-output systems. To this end, the stage cost resembles the high-gain idea of funnel control. Without imposing additional output constraints or terminal conditions, the Funnel MPC scheme is initially and recursively feasible for systems with relative degree one and stable internal dynamics. Using an additional funnel for the derivative as a penalty term in the stage cost, these results can be also extended to single-input single-output systems with relative degree two.

Keywords: model predictive control, funnel control, output tracking, nonlinear systems

1. INTRODUCTION

Model Predictive Control (MPC) is a widely-used control technique for linear and nonlinear systems and has seen various applications, see e.g. Qin and Badgwell (2003). Key reasons for its success are its applicability to multi-input multi-output nonlinear systems and its ability to directly take control and state constraints into account. To this end, a finite-horizon Optimal Control Problem (OCP) is solved before the prediction horizon is shifted forward in time and the procedure is repeated ad infinitum, see e.g. Grüne and Pannek (2017) and Coron et al. (2020).

Recursive feasibility is essential for successfully applying MPC. This means, solvability of the OCP at a particular time instant has to automatically imply solvability of the OCP at the successor time instant. In order to achieve this, often, suitably designed terminal conditions (cost and constraints) are incorporated in the OCP to be solved at each time instant, see Rawlings et al. (2017). However, such (artificially introduced) terminal conditions increase the computational burden of solving the OCP and complicate the task of finding an initially-feasible solution. As a consequence, the domain of the MPC feedback controller might become significantly smaller, see e.g. Chen et al. (2003); González and Odloak (2009). This technique becomes considerably more involved in the presence of time-varying state constraints, see e.g. Manrique et al. (2014).

To overcome these restrictions, Funnel MPC (FMPC) was proposed in Berger et al. (2020). This allows output tracking such that the tracking error evolves in a pre-specified, potentially time-varying performance funnel. A "funnel-like" stage cost, which penalizes the tracking error and becomes infinite when approaching the funnel boundary, is used. By incorporating output constraints in the OCP and using properties of the system class in consideration, initial and recursive feasibility are shown – without imposing additional terminal conditions and independent of the length of the prediction horizon. The novel stage cost used in FMPC is inspired by funnel control, a model-free output-error feedback controller first proposed in Ilchmann et al. (2002). The funnel controller is an adaptive controller which allows output tracking within a prescribed performance funnel for a fairly large class of systems solely invoking structural assumptions, i.e. stable internal dynamics, known relative degree, and a sign-definite high-frequency gain matrix.

It is shown in Berger et al. (2021) that such funnel-inspired stage cost automatically ensure initial and recursive feasibility for a class of nonlinear systems with relative degree one and, in a certain sense, input-to-state stable internal dynamics. Since the requirement of a sign-definite gain matrix is omitted, the system class is larger than the one the original funnel controller is applicable to. Moreover, adding (artificial) output constraints to the OCP, as used in Berger et al. (2020), is superfluous. In numerical simulations, FMPC shows superior performance compared to both MPC with quadratic stage cost and funnel control.

Utilizing so-called feasibility constraints in the OCP and restricting the class of admissible funnel functions, the findings in Berger et al. (2021) are generalized to systems with arbitrary relative degree in Berger and Dennstädt (2022). We show that for single-input single-output systems with relative degree two the addition of such constraints to the Optimal Control Problem is not necessary. However, while previous results allow for an arbitrary short prediction horizon, a sufficiently long horizon – depending on the funnel – is necessary.

2. SYSTEM CLASS AND CONTROL OBJECTIVE

We consider control affine single-input single-output systems

$$\begin{aligned} \dot{x}(t) &= f(x(t)) + g(x(t))u(t), \quad x(t^0) = x^0, \\ y(t) &= h(x(t)), \end{aligned} \tag{1}$$

with $t^0 \in \mathbb{R}_{\geq 0}$, $x^0 \in \mathbb{R}^n$, functions $f \in \mathcal{C}^2(\mathbb{R}^n, \mathbb{R}^n)$, $g \in \mathcal{C}^2(\mathbb{R}^n, \mathbb{R}^{n})$, $h \in \mathcal{C}^3(\mathbb{R}^n, \mathbb{R})$ and a control function $u \in L^\infty_{\mathrm{loc}}(\mathbb{R}_{\geq 0}, \mathbb{R})$. The system (1) has a *solution* in the sense of *Carathéodory*, that is an absolutely continuous function $x : [t^0, \omega) \to \mathbb{R}^n$, $\omega > t^0$, with $x(t^0) = x^0$ which satisfies the ODE in (1) for almost all $t \in [t^0, \omega)$.

We recall the notion of relative degree for system (1). Assuming that f, g, h are sufficiently smooth, the Lie derivative of h along f is defined by $(L_f h)(x) := h'(x) f(x)$. Lie derivatives of higher order are recursively defined by $L_f^k h := L_f(L_f^{k-1} h)$, for $k \in \mathbb{N}$, with $L_f^0 h = h$. Then system (1) is said to have *(global and strict) relative degree* $r \in \mathbb{N}$, if $\forall\, k \in \{1, \dots, r-1\}\ \forall\, x \in \mathbb{R}^n$:

$$(L_g L_f^{k-1} h)(x) = 0 \quad \text{and} \quad (L_g L_f^{r-1} h)(x) \neq 0.$$

If (1) has relative degree r, then, under the additional assumptions provided in (Byrnes and Isidori, 1991, Cor. 5.6), there exists a diffeomorphic coordinate transformation

$$\Phi : \mathbb{R}^n \to \mathbb{R}^n, \Phi(x(t)) = (y(t), \dot{y}(t), \dots, y^{(r-1)}(t), \eta(t)) \tag{2}$$

which puts the system into Byrnes-Isidori form

$$\begin{aligned} y^{(r-1)}(t) &= p\big(y(t), \dot{y}(t), \dots, y^{(r-1)}(t), \eta(t)\big) \\ &\quad + \gamma\big(y(t), \dot{y}(t), \dots, y^{(r-1)}(t), \eta(t)\big)\, u(t), \quad \text{(3a)} \\ \dot{\eta}(t) &= q\big(y(t), \dot{y}(t), \dots, y^{(r-1)}(t), \eta(t)\big), \quad \text{(3b)} \end{aligned}$$

where $p \in \mathcal{C}^0(\mathbb{R}^n, \mathbb{R})$, $q \in \mathcal{C}^0(\mathbb{R}^n, \mathbb{R}^{n-r})$, $\gamma \in \mathcal{C}^0(\mathbb{R}^n, \mathbb{R})$ and $(y(t^0), \dot{y}(t^0), \dots, y^{(r-1)}(t^0), \eta(t^0)) = \Phi(x^0)$. Furthermore, we require the following *bounded-input, bounded-state* (BIBS) condition on the internal dynamics (3b):

$$\begin{aligned} &\forall\, c_0 > 0\ \exists\, c_1 > 0\ \forall\, t^0 \geq 0\ \forall\, \eta^0 \in \mathbb{R}^{n-r} \\ &\quad \forall\, \zeta \in L^\infty_{\mathrm{loc}}([t^0, \infty), \mathbb{R}^{rm}) : \ \big\|\eta^0\big\| + \|\zeta\|_\infty \leq c_0 \\ &\qquad \Longrightarrow \ \big\|\eta(\cdot; t^0, \eta^0, \zeta)\big\|_\infty \leq c_1, \end{aligned} \tag{4}$$

where $\eta(\cdot; t^0, \eta^0, \zeta) : [t^0, \infty) \to \mathbb{R}^{n-r}$ denotes the unique global solution of (3b) when $(y, \dots, y^{(r-1)})$ is substituted by ζ. The maximal solution $\eta(\cdot; t^0, \eta^0, \zeta)$ can indeed be extended to a global solution due to the BIBS condition (4).

Throughout this note we will assume that the system (1) has relative degree $r = 2$ and that there exists a diffeomorphism Φ as in (2) which puts the system into the Byrnes-Isidori form (3).

The objective is to design a control strategy which allows the output tracking of given reference trajectories $y_{\mathrm{ref}} \in W^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$ within pre-specified error bounds. To be precise, the tracking error $t \mapsto e(t) := y(t) - y_{\mathrm{ref}}(t)$ and its derivative $\dot{e}(t)$ shall evolve within the prescribed performance funnels

$$\mathcal{F}_{\psi_i} := \{\, (t, e) \in \mathbb{R}_{\geq 0} \times \mathbb{R} \mid \|e\| < \psi_i(t) \,\}, \quad i = 0, 1,$$

see also Figure 1. These funnels are determined by the choice of the functions ψ_0, ψ_1 belonging to

$$\mathcal{G}^0 := \left\{ \psi \in W^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R}) \;\middle|\; \inf_{t \geq 0} \psi(t) > 0 \right\}.$$

Note that the funnel ψ_i is uniformly bounded away from zero; i.e. there exists a boundary $\lambda > 0$ with $\psi_i(t) > \lambda$ for all $t \geq 0$. Thus, perfect or asymptotic tracking is not our control objective. However, λ can be chosen arbitrarily small.

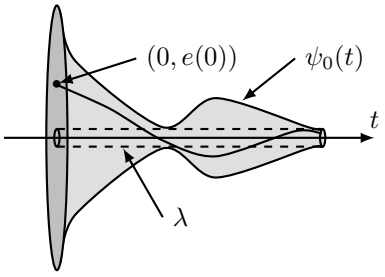

Fig. 1. Error evolution in a funnel $\mathcal{F}_{\psi_0}$ with boundary ψ_0.

If the error e evolves within the funnel $\mathcal{F}_{\psi_0}$ for some $\psi_0 \in \mathcal{G}^0$, then the derivative $\dot{e}$ has to satisfy at some point $t \geq 0$

$$\dot{e}(t) \leq \dot{\psi}_0(t) \text{ or } \dot{e}(t) \geq -\dot{\psi}_0(t).$$

Thus, the derivative funnel must be large enough for the error e to follow the funnel boundary ψ_0 and we therefore assume that $\psi = (\psi_0, \psi_1)$ is an element of

$$\mathcal{G}^1 := \left\{ (\psi_0, \psi_1) \in \mathcal{G}^0 \times \mathcal{G}^0 \;\middle|\; \exists\, \varepsilon > 0\, \forall\, t \geq 0 : \psi_1(t) \geq \varepsilon - \dot{\psi}_0(t) \right\}.$$

Typically, the specific application dictates constraints on the tracking error and thus indicates suitable choices for ψ.

3. FUNNEL MPC

In order to extend the results from Berger et al. (2021) to systems of the form (1) with relative degree two, we define, for $y_{\mathrm{ref}} \in W^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$, $t \geq 0$, and $\zeta = (\zeta^0, \zeta^1) \in \mathbb{R}^2$,

$$e_i(t, \zeta) := \zeta^i - y_{\mathrm{ref}}^{(i)}(t) \quad \text{for } i = 0, 1.$$

We propose, for $\psi = (\psi_0, \psi_1) \in \mathcal{G}^1$ and the design parameter $\lambda_u \geq 0$, the new *stage cost function*

$\ell : \mathbb{R}_{\geq 0} \times \mathbb{R}^2 \times \mathbb{R} \to \mathbb{R} \cup \{\infty\}$,

$$(t, \zeta, u) \mapsto \begin{cases} \sum_{i=0}^{1} \frac{1}{1 - \|e_i(t,\zeta)\|^2 / \psi_i(t)^2} + \lambda_u \|u\|^2, & \|e_i(t,\zeta)\| \neq \psi_i(t) \\ & \text{for } i = 0, 1 \\ \infty, & \text{else.} \end{cases} \tag{5}$$

By setting $\zeta = (y(t), \dot{y}(t))$, the terms $\frac{1}{1 - \|e_i(t,\zeta)\|^2 / \psi_i(t)^2}$ penalize the distance of the tracking error $e(t) = y(t) - y_{\mathrm{ref}}(t)$ and its derivative $\dot{e}(t)$ to their respective funnel boundaries $\psi_i(t)$. The parameter λ_u allows to adjust a suitable trade off between tracking performance and required control effort. The stage cost ℓ is motivated by the design of the funnel controller in Hackl et al. (2013) which also introduces an additional funnel for the derivative in order to generalize the results from Ilchmann et al. (2002) to systems with relative degree two.

Based on the stage cost (5), we define the Funnel MPC (FMPC) algorithm as follows.

Algorithm 1. (FMPC).
Given: System (1), reference signal $y_{\mathrm{ref}} \in W^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$, funnel function $\psi = (\psi_0, \psi_1) \in \mathcal{G}^1$, stage cost function ℓ as in (5), $M > 0$, $t^0 \in \mathbb{R}_{\geq 0}$, and $x^0 \in \mathbb{R}^n$ with

$$\Phi(x^0) \in \mathcal{D}_{t^0} := \left\{ (\zeta, \eta) \in \mathbb{R}^2 \times \mathbb{R}^{n-2} \;\middle|\; \begin{matrix} \|e_i(t_0, \zeta)\| < \psi_i(t_0) \\ \text{for } i = 0, 1 \end{matrix} \right\},$$

where Φ is the diffeomorphism from (2).
Set the time shift $\delta > 0$, the prediction horizon $T > \delta$ and initialize the current time $\hat{t} := t^0$.
Steps:

(a) Obtain a measurement of the state $x = \Phi^{-1}(y, \dot{y}, \eta)$ at time $\hat{t}$ and set $\hat{x} := x(\hat{t})$.

(b) Compute a solution $u^\star \in L^\infty([\hat{t}, \hat{t}+T], \mathbb{R})$ of the Optimal Control Problem (OCP)

$$\begin{aligned} \underset{u \in L^\infty([\hat{t},\hat{t}+T],\mathbb{R})}{\text{minimize}} \quad & \int_{\hat{t}}^{\hat{t}+T} \ell\big(t, (y(t), \dot{y}(t)), u(t)\big) \mathrm{d}t \\ \text{subject to} \quad & (1),\ x(\hat{t}) = \hat{x}, \\ & \|u(t)\| \leq M \quad \text{for } t \in [\hat{t}, \hat{t}+T] \end{aligned} \tag{6}$$

(c) Apply the feedback law

$$\mu : [\hat{t}, \hat{t}+\delta) \times \mathbb{R}^n \to \mathbb{R}, \quad \mu(t, \hat{x}) = u^\star(t) \tag{7}$$

to system (1). Increase $\hat{t}$ by δ and go to Step (a).

In practical application there usually is a limitation $M > 0$ on the maximal control that can be applied to the system 1. The constraint $\|u(t)\| \leq M$ in the OCP (6) ensures that the control signal meets this bound.

The following theorem shows that for systems with relative degree two the Funnel MPC Algorithm 1 is, given a sufficiently long prediction horizon $T > 0$ and large enough control constraint $M > 0$, initially and recursively feasible and that it guarantees the evolution of the tracking error e and its derivative $\dot{e}$ within their respective performance funnels $\mathcal{F}_{\psi_i}$. Due to space limitations, we omit the proof.

Theorem 2. Consider system (3) with strict relative degree $r = 2$ and assume that there exists a diffeomorphism $\Phi : \mathbb{R}^n \to \mathbb{R}^n$ such that the coordination transformation in (2) puts the system (1) in the Byrnes-Isidori form (3) satisfying (4). Let $\psi = (\psi_0, \psi_1) \in \mathcal{G}^1$, $y_{\mathrm{ref}} \in W^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$, $t^0 \in \mathbb{R}_{\geq 0}$, $\delta > 0$, and $B \subset \mathcal{D}_{t^0}$ a compact set. Then there exist $T > \delta$ and $M > 0$ such that the FMPC Algorithm 1 is initially and recursively feasible for every $\Phi(x^0) \in B$, i.e. at time $\hat{t} = t^0$ and at each successor time $\hat{t} \in t^0 + \delta\mathbb{N}$ the OCP (6) has a solution. In particular, the closed-loop system consisting of (1) and the FMPC feedback (7) has a global solution $x : [t^0, \infty) \to \mathbb{R}^n$ and the corresponding input is given by

$$u_{\mathrm{FMPC}}(t) = \mu(t, x(\hat{t})), \quad t \in [\hat{t}, \hat{t}+\delta),\ \hat{t} \in t^0 + \delta\mathbb{N}_0.$$

Furthermore, each global solution x with corresponding input u_{FMPC} satisfies:

(i) $\forall\, t \geq t^0 :\ |u_{\mathrm{FMPC}}(t)| \leq M$.

(ii) $\forall\, t \geq t^0 :\ \big|e^{(i)}(t)\big| < \psi_i(t)$ for $i = 0, 1$; in particular the error $e = y - y_{\mathrm{ref}}$ evolves within the funnel $\mathcal{F}_{\psi_0}$ and $\dot{e}$ within $\mathcal{F}_{\psi_1}$.

4. SIMULATION

To demonstrate the application of the FMPC Algorithm 1, we consider the example of a mass-spring system mounted on a car from Seifried and Blajer (2013). The mass m_2 moves on a ramp inclined by the angle $\vartheta \in [0, \frac{\pi}{2})$ and mounted on a car with mass m_1 by a spring-damper system, see Figure 2. It is possible to control the force $F = u$ acting on the car. The system is described by the equations

$$\begin{bmatrix} m_1 + m_2 & m_2\cos(\vartheta) \\ m_2\cos(\vartheta) & m_2 \end{bmatrix} \begin{pmatrix} \ddot{z}(t) \\ \ddot{s}(t) \end{pmatrix} + \begin{pmatrix} 0 \\ ks(t) + d\dot{s}(t) \end{pmatrix} = \begin{pmatrix} u(t) \\ 0 \end{pmatrix}, \tag{8}$$

where $z(t)$ is the horizontal position of the car and $s(t)$ the relative position of the mass on the ramp at time t. The physical constants $k > 0$ and $d > 0$ are the coefficients of the spring and damper, resp. The horizontal position of the mass on the ramp is the output y of the system, i.e.

$$y(t) = z(t) + s(t)\cos(\vartheta). \tag{9}$$

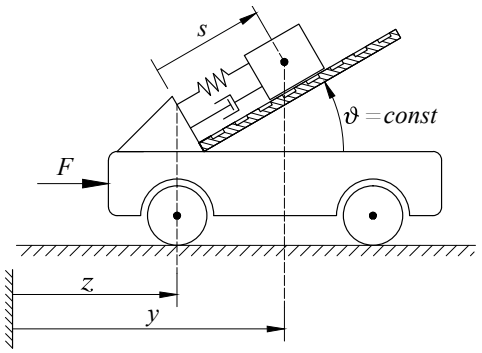

Fig. 2. Mass-on-car system.

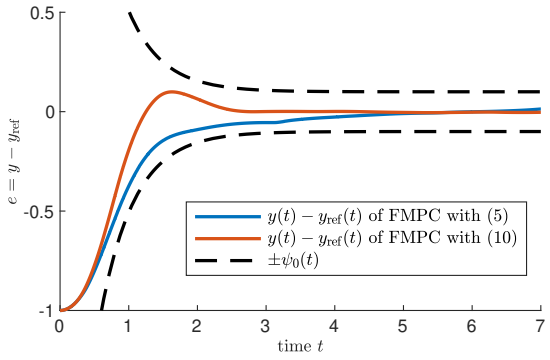
We choose the parameters $m_1 = 4$, $m_2 = 1$, $k = 2$, $d = 1$, $\vartheta = \frac{\pi}{4}$ and initial values $z(0) = s(0) = \dot{z}(0) = \dot{s}(0) = 0$ for the simulation. The objective is tracking of the reference signal $y_{\mathrm{ref}} : t \mapsto \cos(t)$ so that the error $t \mapsto e(t) := y(t) - y_{\mathrm{ref}}(t)$ satisfies $|e(t)| \leq \psi_0(t)$ and $|\dot{e}(t)| \leq \psi_1(t)$ for all $t \geq 0$ with $\psi_0(t) = 3\,\mathrm{e}^{-2t} + 0.1$ and $\psi_1(t) = 6e^{-t} + 0.1$. One can easily verify that $\psi = (\psi_0, \psi_1) \in \mathcal{G}^1$ and that the initial errors lie within their respective funnel boundaries. The system (8) with output (9) has relative degree $r = 2$ for the given parameters. We compare the FMPC Algorithm 1 with stage cost (5) to the FMPC scheme from Berger et al. (2021) which uses the stage cost function $\tilde{\ell} : \mathbb{R}_{\geq 0} \times \mathbb{R}^2 \times \mathbb{R} \to \mathbb{R} \cup \{\infty\}$ with

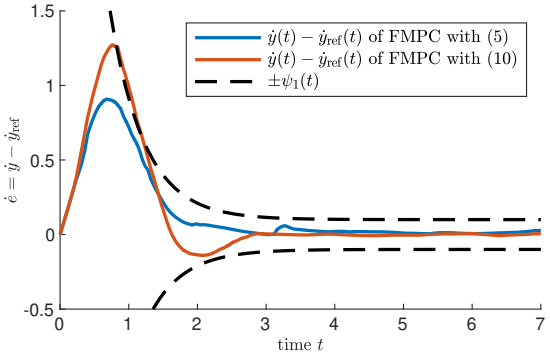
$$\tilde{\ell}(t, \zeta, u) = \begin{cases} \frac{1}{1 - \|e_0(t,\zeta)\|^2 / \psi_0(t)^2} + \lambda_u \|u\|^2, & \|e_0(t, \zeta)\| \neq \psi_0(t) \\ \infty, & \text{else.} \end{cases} \tag{10}$$

Contrary to the stage cost function (5), the function $\tilde{\ell}$ penalizes only the distance of the tracking error $e(t) = y(t) - y_{\mathrm{ref}}(t)$ to the funnel boundary ψ_0 but not derivative $\dot{e}(t) = \dot{y}(t) - \dot{y}_{\mathrm{ref}}(t)$ to the boundary ψ_1. For the FMPC Algorithm 1 the prediction horizon $T = 0.6$ and time shift $\delta = 0.04$. Due to discretisation, only step functions with constant step length 0.04 are considered for the OCP (6). We further choose for both stage cost functions the parameter $\lambda_u = 5 \cdot 10^{-3}$ and allow a maximal control value of $M = 30$. All simulations are performed on the time interval $[0, 7]$ with the MATLAB routine `ode45` and are depicted in Figure 3. Figure 3a shows the tracking error of the two different FMPC schemes evolving within the funnel boundaries given by ψ_0, while Figure 3b displays the derivative of the error within the boundaries given by ψ_1 The respective control signals generated by the controllers is displayed in Figure 3c.

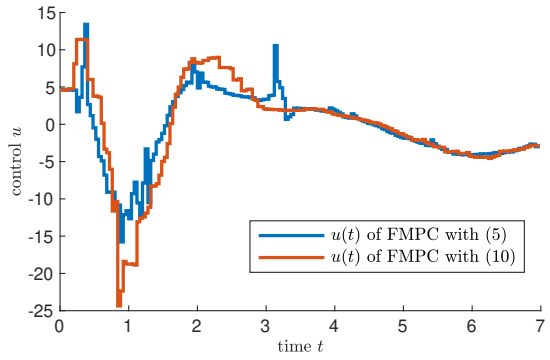
It is evident that both control schemes achieve the tracking of the reference signal within the performance boundaries given by ψ_0. While the FMPC Algorithm 1 with stage cost function (5) also ensures that the derivative of the tracking error evolves within funnel given by ψ_1, FMPC scheme with stage cost function $\tilde{\ell}$ as in (10) fails to do that and thus does not achieve the overall control objective. This is not surprising since the function $\tilde{\ell}$ does not penalize the distance of error's derivative to the funnel boundary.



(a) Funnel given by ψ_0 and tracking error e



(b) Funnel given by ψ_1 and tracking error derivative $\dot{e}$



(c) Control input

Fig. 3. Simulation of system (8) with output (9) under FMPC Algorithm 1 and FMPC from Berger et al. (2021)

Moreover, the FMPC Algorithm 1 with stage cost function (5) exhibits a smaller range of employed control values as the FMPC scheme from Berger et al. (2021).

5. CONCLUSION

In this note we outline a conceptual framework to extend the FMPC scheme proposed in Berger et al. (2021), which solves the problem of tracking a reference signal within a prescribed performance funnel, to systems with relative degree two. By exploiting concepts from funnel control and using a "funnel-like" stage cost, feasibility is achieved without the need for additional terminal or explicit output constraints while also being restricted to (a priori) bounded control values. In particular, additional output constraints in the OCP of FMPC as considered in Berger et al. (2020) and Berger and Dennstädt (2022) are not required to infer the feasibility results. However, contrary to previous results the prediction horizon has to be sufficiently long in order to guarantee recursive feasibility of the Funnel MPC algorithm. Extending these results to multi-input multi-output systems and systems with arbitrary relative degree $r > 2$ is subject of future work.

Abstract: A class of nonlinear, stochastic staticization control problems (including minimization problems with smooth, convex, coercive payoffs) driven by diffusion dynamics with constant diffusion coefficient is considered. The nonlinearities are addressed through staticization-based duality. The second-order Hamilton-Jacobi partial differential equations (HJ PDEs) are converted into associated control problems with higher-dimensional states. In these problems, one component of the state propagates by deterministic, nonlinear dynamics, while the other component is a scaled Brownian motion. These components interact only through a bilinear terminal cost. This structure will be exploited to generate an efficient solution approach.

Keywords: dynamic programming, Hamilton-Jacobi, partial differential equations, stochastic control, staticization.

1. INTRODUCTION

The results herein can be equivalently viewed as results regarding Hamilton-Jacobi partial differential equations (HJ PDEs), or as results regarding the optimal control of systems with dynamics defined by stochastic differential equations (SDEs). The second-order Hamilton-Jacobi partial differential equations (HJ PDEs) are converted into associated control problems with higher-dimensional states. In contrast to the original problems, in these associated problems, one component of the state propagates by deterministic, nonlinear dynamics, while the other component is a scaled Brownian motion. These components interact only through a bilinear terminal cost. This structure will be exploited to generate an efficient solution approach. It will be shown that numerical solutions of many nonlinear second-order HJ PDE problems may be obtained through numerical solutions of nonlinear first-order HJ PDE problems, along with associated finite-dimensional sets of differential Riccati equations (DREs). In more general cases, solution of steady-state second-order HJB PDEs in potentially much lower dimension may be required.

Consider the HJ PDE

$$0 = W_t + \underset{v\in\mathbb{R}^k}{\text{stat}} \left\{ f^T(x,v)W_x + L(x,v) \right\} + \tfrac{1}{2}\,\text{tr}[AW_{xx}], \quad (1)$$

for $(t,x) \in (0,T)\times\mathbb{R}^n$, where specific assumptions on the problem data appear further below. The "stat" operator is briefly discussed in Section 2.2, but it is useful to note here that in the case of a convex, coercive, C^1 argument, it is equivalent to the minimization operator, and hence the results herein typically subsume HJ PDEs of the form

$$0 = W_t + \min_{v\in\mathbb{R}^k} \left\{ f^T(x,v)W_x + L(x,v) \right\} + \tfrac{1}{2}\,\text{tr}[AW_{xx}].$$

Consider the following class of quadratic terminal costs. Let $\mathcal{M}_{2n}$ denote the set of matrices $\bar{\Pi}$ such that

$$\bar{\Pi} \doteq \begin{pmatrix} \bar{M} & -\bar{M} \\ -\bar{M} & \bar{M} \end{pmatrix},$$

where $\bar{M}$ is symmetric and nonsingular, and let

$$\begin{aligned} W(T,x) &= \psi(x; z, \bar{\pi}, \bar{\Pi}, \bar{\gamma}) \\ &\doteq \tfrac{1}{2} \begin{pmatrix} x \\ z \end{pmatrix}^T \bar{\Pi} \begin{pmatrix} x \\ z \end{pmatrix} + \bar{\pi}^T \begin{pmatrix} x \\ z \end{pmatrix} + \bar{\gamma}, \end{aligned} \quad (2)$$

where $\bar{\Pi} \in \mathcal{M}_{2n}$, $z \in \mathbb{R}^n$, $\bar{\pi} \in \mathbb{R}^{2n}$, $\bar{\gamma} \in \mathbb{R}$ are parameters.

It is well-known that for purposes of numerical solution, nonlinear stochastic control problems are typically converted into the second-order HJ PDE problems such as (1) with associated terminal data, and further, the dimension of the space over which these PDEs are defined is that of the state process of the control problem. Of course, realistic control problems typically have relatively high dimensional state processes, leading to PDEs over high dimensional spaces. The solution of such HJ PDE problems has long been hampered by the curse-of-dimensionality, which refers to the fact that with classical algorithms, the computational cost grows exponentially fast as a function of space dimension, and we note that this has limited the solvability of such problems by classical methods to state-space dimensions on the order of three to five, c.f. Falcone and Ferretti (2014). More recently, max-plus based curse-of-dimensionality-free methods (in addition to other notable new approaches) have demonstrated computational tractability for certain classes of problems in significantly

Bayreuth, Germany, 12-16 September 2022

higher space dimension, and this approach have been quite effective in the case of first-order HJ PDEs [Akian, Gaubert and Lakhoua (2008); Dower (2018); Gaubert et al (2011); McEneaney (2006); Qu (2014)].

2. PRELIMINARIES

2.1 Problem Class and Recollection of Results

We consider a nonlinear stochastic control problem with SDE dynamics and initial state are given by

$$d\xi(t) = f(\xi(t), \tilde{v}(t))\, dt + \bar{a}\, dB(t), \quad \xi(s) = x \in \mathbb{R}^n, \quad (3)$$

where the underlying probability space is denoted as $(\Omega, \mathcal{F}_\infty, P)$ with Ω denoting the sample space, $\mathcal{F}_\infty$ denoting the σ-algebra and P denoting the probability measure. Also, $B(t)$ denotes an n-dimensional Brownian motion adapted to filtration $\mathcal{F}_t$. Assumptions on f will be indicated further below. We suppose the controls take values in $V = \mathbb{R}^k$. Fix $T \in (0, \infty)$, and for $s \in [0, T]$, let

$$\mathcal{V}_{s,T} \doteq \{\tilde{v} : [s, T] \times \Omega \to \mathbb{R}^k | \tilde{v} \text{ is } \mathcal{F}_\cdot\text{-adapted, right-contin. and such that } \mathbb{E}\textstyle\int_s^T |\tilde{v}(t)|^m\, dt < \infty \ \forall m \in I\!N\},$$

$$\|\tilde{v}\| = \|\tilde{v}\|_{\mathcal{V}_{s,T}} \doteq \max_{m \le \breve{M}} \Big[\mathbb{E} \int_s^T |\tilde{v}(t)|^m\, dt\Big]^{1/m},$$

where $\breve{M} \doteq 8\breve{q}$ and $\breve{q}$ will be specified in Assumption ($\mathcal{A}$.1). The payoff will be given by

$$J(s, x, \tilde{v}; z, \bar{\Pi}, \bar{\pi}, \bar{\gamma}, T) \doteq \mathbb{E}\Big\{ \int_s^T L(\xi(t), \tilde{v}(t))\, dt + \psi(\xi(T); z)\Big\}$$

where ψ is as indicated in (2), $\bar{\pi} \in \mathbb{R}^{2n}$, $\bar{\gamma} \in \mathbb{R}$ and $z \in \mathbb{R}^n$. In the more general case, one takes a terminal cost form

$$\Psi(x) = \Psi(x; z) \doteq \operatorname*{stat}_{z \in \mathbb{R}^n} \Big\{ \tfrac{1}{2} \begin{pmatrix} x \\ z \end{pmatrix}^T \bar{\Pi} \begin{pmatrix} x \\ z \end{pmatrix} + a(z) \Big\}, \quad (4)$$

with some specified function, $a(\cdot)$, where the definition of operator stat follows in Section 2.2. The terminal cost in (4) is a "stat-quad" representation [Dower and McEneaney (2020); McEneaney and Dower (2018)], of a general class of terminal costs that may be represented as such. We will consider only the terminal cost form (2) here. For $(s, x) \in [0, T] \times \mathbb{R}^n$, the value function is given by

$$\bar{W}(s, x; z, \bar{\Pi}, \bar{\pi}, \bar{\gamma}, T) \doteq \operatorname*{stat}_{\tilde{v} \in \mathcal{V}_{s,T}} J(s, x, \tilde{v}; z, \bar{\Pi}, \bar{\pi}, \bar{\gamma}, T), \quad (5)$$

where $\bar{\pi} = 0$ here, but will be generalized below.

We will proceed through several steps. The first step is to obtain the equivalence between the value function and the solution of the associated HJ PDE problem. This equivalence is standard in the optimization and game cases, and less so in staticization cases that are not equivalent to these. We recall a result in the staticization case where the stationary value is given by (3)–(5). Specifically, letting $\mathcal{X}_0 \doteq (0, T) \times \mathbb{R}^n$, $\bar{\mathcal{X}}_0 \doteq (0, T] \times \mathbb{R}^n$, $z \in \mathbb{R}^n$, $\bar{\pi} \in \mathbb{R}^{2n}$, $\bar{\gamma} \in \mathbb{R}$ and $\bar{\Pi} \in \mathcal{M}_{2n}$, consider

$$0 = W_t + \operatorname*{stat}_{v \in \mathbb{R}^k} \big\{ f(x, v)^T W_x + L(x, v) \big\} + \tfrac{1}{2} \operatorname{tr}[A W_{xx}] \quad (6)$$

$$\doteq W_t + H_0(x, W_x) + \mathcal{Q}_0(x, W_x) + \tfrac{1}{2} \operatorname{tr}[A W_{xx}], \quad (7)$$

$$(s, x) \in \mathcal{X}_0,$$

$$W(T, x; z, \bar{\Pi}, \bar{\gamma}) = \psi(x; z, \bar{\pi}, \bar{\Pi}, \bar{\gamma}), \quad x \in \mathbb{R}^n, \quad (8)$$

where $A = \bar{a}\bar{a}^T$, $\mathcal{Q}_0$ is a quadratic function of its arguments, and the non-quadratic components of the Hamiltonian are isolated within H_0.

We make the following assumptions.

Assume that for $z \in \mathbb{R}^n$, there exists $W = W(\cdot, \cdot; z) \in C^{1,4}(\mathcal{X}_0) \cap C_p(\bar{\mathcal{X}}_0)$ satisfying (7)–(8) (where C_p denotes the space of continuous functions with at most quadratic growth), and that there exists $\bar{C}_0 < \infty$ and $\breve{q} \in I\!N$ such that $|W_x(s, x)| \le \bar{C}_0(1 + |x|^{2\breve{q}})$ and $|W_{xx}(s, x)| \le \bar{C}_0(1 + |x|^{2\breve{q}})$ for all $(s, x) \in \bar{\mathcal{X}}_0$. Assume $\bar{M}$ is positive definite, symmetric; $f, L \in C^3(\mathbb{R}^n \times \mathbb{R}^k)$; $\exists \bar{C}_1 < \infty$ such that for all $x, v \in \mathbb{R}^n$ $|f_x(x, v)|, |f_v(x, v)| \le \bar{C}_1$, $|f_{xx}(x, v)|, |f_{xv}(x, v)|, |f_{vv}(x, v)| \le \bar{C}_1$ and $|L_{xx}(x, v)|, |L_{xv}(x, v)|, |L_{vv}(x, v)|, \le \bar{C}_1$. Assume that for each $z \in \mathbb{R}^n$, there exists $v^* \in C(\bar{\mathcal{X}}_0)$ that is globally Lipschitz in x, and is such that $v^*(t, x) \in \operatorname{argstat}_{v \in \mathbb{R}^k}\{f(x, v)^T W_x(t, x) + L(x, v)\}$ for all $(t, x) \in \mathcal{X}_0$. ($\mathcal{A}$.1)

Theorem 1. Assume ($\mathcal{A}$.1). Then $W = \bar{W}$ on $\bar{\mathcal{Z}}$, and v^* is a stationary control yielding payoff $\bar{W}$. Further, with $\bar{\xi}^*$ denoting the trajectory generated by v^*, and letting $\tilde{v}^*(t) \doteq v^*(t, \bar{\xi}^*(t))$ for all t, $\tilde{v}^*$ is continuous with respect to t.

The proof of Theorem 1 may be found in McEneaney, Dower and Wang (2021). All results to follow are obtained under ($\mathcal{A}$.1).

2.2 Staticization and Stat-Quad Duality

Let $\mathcal{V}$ denote a Banach space over either the real or complex field, and suppose $\mathcal{U}$ is a [real or complex] normed vector space with $\mathcal{A} \subseteq \mathcal{U}$, and suppose $G : \mathcal{A} \to \mathcal{F}$. Let $\operatorname{argstat}_{u \in \mathcal{A}} G(u) \doteq \operatorname{argstat}\{G(u) \,|\, u \in \mathcal{A}\}$, $\operatorname{stat}^s{}_{u \in \mathcal{A}} G(u) \doteq \big\{G(\bar{u}) \,\big|\, \bar{u} \in \operatorname{argstat}\{G(u) \,|\, u \in \mathcal{A}\}\big\}$ and $\operatorname{stat}_{u \in \mathcal{A}} G(u) \doteq a$ be defined as in, for example, [McEneaney, Dower and Wang (2021); McEneaney and Zhao (2019); McEneaney and Dower (2018)].

Analogous to semiconvex duality, we have the following "stat-quad" duality (McEneaney and Dower, 2018, Th. 4). In the nondegenerate case, it is closely related to the Legendre-Fenchel transform. Let ϕ denote a generic function in $C^j(\mathbb{R}^n; \mathbb{R})$ with $j \ge 2$ such that there exists $\bar{c}_2 < \infty$ such that $|\phi_{uu}(u)| \le \bar{c}_2$ for all $u \in \mathbb{R}^n$. We let $\psi_0(u, w) \doteq \frac{\bar{m}}{2}|u - w|^2$ for all $u, w \in \mathbb{R}^n$, where $\bar{m} \in \mathbb{R} \setminus \{0\}$.

Lemma 2. Suppose $|\bar{m}| > \bar{c}_2$. We have

$$\phi(u) = \operatorname*{stat}_{w \in \mathbb{R}^n} [a(w) + \psi_0(u, w)] \quad \forall\, u \in \mathbb{R}^n, \quad (9)$$

$$a(w) = \operatorname*{stat}_{u \in \mathbb{R}^n} [\phi(u) - \psi_0(u, w)] \quad \forall\, w \in \mathbb{R}^n. \quad (10)$$

Further, there exists unique $u^* \in C^{j-1}(\mathbb{R}^n; \mathbb{R}^n)$ such that

$$a(w) = \phi(u^*(w)) - \psi_0(u^*(w), w), \quad \forall\, w \in \mathbb{R}^n, \quad (11)$$

$$a_w(w) = \bar{m}(u^*(w) - w) = \phi_u(u^*(w)) \quad \forall\, w \in \mathbb{R}^n, \quad (12)$$

where $a \in C^j(\mathbb{R}^n; \mathbb{R})$. Suppose $|\bar{m}| \in [2\bar{c}, \infty)$. Then, for each $u \in \mathbb{R}^n$, there exists unique argstat $w^*(u)$. Further, $w^* \in C^{j-1}(\mathbb{R}^n; \mathbb{R}^n)$, and one has

$$\phi(u) = a(w^*(u)) + \psi_0(u, w^*(u)), \quad w^* = (u^*)^{-1}.$$

Remark 3. For simplicity here, we are assuming that the condition $|\bar{m}| \in (\bar{c}_2, \infty)$ is satisfied, as it provides a simple sufficient condition. However, one should note that implies convexity or concavity, while stat-quad duality is employed so that we may cover a wider class of cases.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

3. A STATICIZATION-BASED REPRESENTATION OF THE NONLINEARITIES

For $x, p, \alpha, \beta \in \mathbb{R}^n$, let

$$\mathcal{Q}(x,p,\alpha,\beta) \doteq \tfrac{c_1}{2}|x-\alpha|^2 + \tfrac{c_2}{2}|p-\beta|^2, \tag{13}$$

where $c_1, c_2 \in \mathbb{R}$. We make the following assumption, which will be sufficient to guarantee existence of all the relevant duality objects to follow.

We assume that $H_0 \in C^{\hat{m}}(\mathbb{R}^{2n})$ with $\hat{m} \geq 4$, and that the second derivatives of H_0 are uniformly bounded. ($\mathcal{A}.2$)

As an aid in developing results further below, we recall the following from McEneaney, Dower and Wang (2021).

Lemma 4. Let $|c_1|, |c_2|$ be sufficiently large. Then,

$$H_0(x,p) = \operatorname*{stat}_{(\alpha,\beta)\in\mathbb{R}^{2n}} \big[G_0(\alpha,\beta) + \mathcal{Q}(x,p,\alpha,\beta)\big].$$

$$G_0(\alpha,\beta) = \operatorname*{stat}_{(x,p)\in\mathbb{R}^{2n}} \big[H_0(x,p) - \mathcal{Q}(x,p,\alpha,\beta)\big],$$

$\operatorname*{argstat}_{(x,p)\in\mathbb{R}^{2n}} \big[H_0(x,p) - \mathcal{Q}(x,p,\alpha,\beta)\big]$ is single-valued,

$\operatorname*{argstat}_{(\alpha,\beta)\in\mathbb{R}^{2n}} \big[G_0(\alpha,\beta) + \mathcal{Q}(x,p,\alpha,\beta)\big]$ is single-valued,

and $G_0 \in C^{\hat{m}}(\mathbb{R}^{2n})$ with bounded second derivatives.

Now, we let the coefficients in $\mathcal{Q}_0$ be specifically given by

$$\begin{aligned}\mathcal{Q}_0(x,p) &= \tfrac{1}{2}\begin{pmatrix}x\\p\end{pmatrix}^T D \begin{pmatrix}x\\p\end{pmatrix} + d^T\begin{pmatrix}x\\p\end{pmatrix}\\ &= \tfrac{1}{2}\begin{pmatrix}x\\p\end{pmatrix}^T\begin{pmatrix}D_{1,1} & D_{1,2}\\ D_{2,1} & D_{2,2}\end{pmatrix}\begin{pmatrix}x\\p\end{pmatrix} + \begin{pmatrix}d_1\\d_2\end{pmatrix}^T\begin{pmatrix}x\\p\end{pmatrix},\end{aligned}$$

where D is symmetric. Note that for $|c_2|$ sufficiently large,

$$\begin{aligned}&G_0(\alpha,\beta) + \mathcal{Q}_0(x,p) + \mathcal{Q}(x,p,\alpha,\beta) \\ &= \operatorname*{stat}_{v\in\mathbb{R}^n}\big\{[D_{1,2}x + d_2 - c_2\beta + v]^T p + H_1(x,\alpha,\beta,v)\big\},\end{aligned} \tag{14}$$

where

$$\begin{aligned}&H_1(x,\alpha,\beta,v) \doteq G_0(\alpha,\beta) + \tfrac{1}{2}x^T D_{1,1}x + \tfrac{c_1}{2}|x-\alpha|^2\\ &+ \tfrac{c_2}{2}|\beta|^2 + d_1^T x + \tfrac{1}{2}v^T\Gamma v,\\ &\Gamma \doteq -(c_2\mathcal{I}_n + D_{2,2})^{-1}.\end{aligned}$$

Consider the following stationarity control problem. Let the dynamics be given by

$$\begin{aligned}d\xi(t) &= f'(\xi(t),\bar{\beta}(t),\tilde{v}(t))\,dt + \bar{a}\,dB(t)\\ &\doteq (D_{1,2}\xi(t) + d_2 - c_2\bar{\beta}(t) + \tilde{v}(t))\,dt + \bar{a}\,dB(t)\end{aligned} \tag{15}$$

where $\tilde{v}, \bar{\beta} \in \mathcal{V}_{s,T}$. Let the payoff and stationary value be

$$\begin{aligned}J'(s,x,\tilde{v},\bar{\alpha},\bar{\beta};z,T) &\doteq \mathbb{E}\Big\{\int_s^T H_1(\xi(t),\bar{\alpha}^*(t),\bar{\beta}(t),\tilde{v}(t))\,dt\\ &\quad + \psi(\xi(T);z)\Big\},\\ W'(s,x;z,T) &\doteq \operatorname*{stat}_{(\tilde{v},\bar{\alpha},\bar{\beta})\in\mathcal{V}_{s,T}\times[\mathcal{O}_{s,T}]^2} J'(s,x,\tilde{v},\bar{\alpha},\bar{\beta};z,T),\end{aligned} \tag{16}$$

$$\begin{aligned}\mathcal{O}_{s,T} \doteq \{&\nu : [s,T]\times\Omega \to \mathbb{R}^k \,|\, \nu \text{ is } \mathcal{F}.\text{-adapted, contin.}\\ &\text{w.r.t. time, and s.t. } \mathbb{E}\textstyle\int_s^T |\nu(t)|^2\,dt < \infty\,\}.\end{aligned}$$

Also consider the iterated form of W' given by

$$\hat{W}'(s,x;z,T) \doteq \operatorname*{stat}_{(\bar{\alpha},\bar{\beta})\in[\mathcal{O}_{s,T}]^2} \operatorname*{stat}_{\tilde{v}\in\mathcal{V}_{s,T}} J'(s,x,\tilde{v},\bar{\alpha},\bar{\beta};z,T). \tag{17}$$

Theorem 5. Let $|c_1|, |c_2|$ be sufficiently large. For each $z \in \mathbb{R}^n$, value function W' is identical to the value function, $\bar{W}$ (given in (5)). Further, there exists unique (α^*, β^*, v^*) such that

$$\begin{aligned}[\alpha^*,\beta^*,v^*](t,x) \in \operatorname*{argstat}_{(\alpha,\beta,v)\in\mathbb{R}^{3n}} &\big\{[f'(x,\beta,v)]^T\bar{W}_x(t,x)\\ &+ H_1(x,\alpha,\beta,v)\big\},\end{aligned}$$

and $[\alpha^*,\beta^*,v^*](t,\xi(t))$ is a staticizing control. Lastly, for each $z \in \mathbb{R}^n$, value function $\hat{W}'$ is identical to value function $\bar{W}$.

4. SEPARATION

We now change the point of view to that of a control problem with state variables being both π and x. We will see that although in this case the dynamics are not purely deterministic, the nonlinear deterministic component and the linear stochastic component are separated in a very useful way, where in particular, the only interaction is through a bilinear terminal cost term. First, note that the inner staticization of (17) is a set of linear-quadratic Gaussian control problems, indexed by the $\bar{\alpha}, \bar{\beta}$. Consider the dynamics

$$\begin{aligned}\dot{\hat{\Pi}}(t) &= -\bar{F}_1(\hat{\Pi}(t))\\ &\doteq -\big\{\hat{\Pi}(t)K_2\hat{\Pi}(t) + K_3^T\hat{\Pi}(t) + \hat{\Pi}(t)K_3 + K_1\big\},\end{aligned} \tag{18}$$

$$\begin{aligned}\dot{\hat{\pi}}(t) &= -\bar{F}_2(\hat{\Pi}(t),\hat{\pi}(t),\bar{\alpha}(t),\bar{\beta}(t))\\ &\doteq -\big\{\hat{\Pi}(t)K_2\hat{\pi}(t) + \hat{\Pi}(t)\hat{\mathcal{I}}^{1,1}V^2(t) + K_3\hat{\pi}(t) + V^1(t)\big\},\end{aligned} \tag{19}$$

$$\begin{aligned}\dot{\hat{\gamma}}(t) &= -\bar{F}_3(\hat{\Pi}(t),\hat{\pi}(t),\bar{\alpha}(t),\bar{\beta}(t))\\ &\doteq -\big\{G_0(\bar{\alpha}(t),\bar{\beta}(t)) + \tfrac{c_1}{2}|\bar{\alpha}(t)|^2 + \tfrac{c_2}{2}|\bar{\beta}(t)|^2\\ &\quad + \tfrac{1}{2}\hat{\pi}(t)^T K_2\hat{\pi}(t) + (V^2(t))^T\hat{\pi}(t) + \tfrac{1}{2}\operatorname{tr}(K_4\hat{\Pi}(t)K_5)\big\},\end{aligned} \tag{20}$$

with terminal conditions, following from (2), given by

$$\hat{\Pi}(T) = \bar{\Pi} \doteq \begin{pmatrix}\bar{M} & -\bar{M}\\ -\bar{M} & \bar{M}\end{pmatrix},$$

$\hat{\pi}(T) = \bar{\pi} \doteq 0$, $\hat{\gamma}(T) = \bar{\gamma}$, where

$$K_1 \doteq \begin{pmatrix}k_1 & 0\\ 0 & 0\end{pmatrix},\ K_2 \doteq \begin{pmatrix}k_2 & 0\\ 0 & 0\end{pmatrix},\ K_3 \doteq \begin{pmatrix}D_{1,2}^T & 0\\ 0 & 0\end{pmatrix},$$

$$K_4 \doteq (A\ 0),\ K_5 \doteq \begin{pmatrix}\mathcal{I}_n\\ 0\end{pmatrix},\ \hat{\mathcal{I}}^{1,1} \doteq \begin{pmatrix}\mathcal{I}_n & 0\\ 0 & 0\end{pmatrix},$$

$$V^1(t) \doteq \begin{pmatrix}d_1 - c_1\bar{\alpha}(t)\\ 0\end{pmatrix},\ V^2(t) \doteq \begin{pmatrix}d_2 - c_2\bar{\beta}(t)\\ 0\end{pmatrix},$$

$k_1 \doteq c_1\mathcal{I}_n + D_{1,1}$ and $k_2 \doteq c_2\mathcal{I}_n + D_{2,2}$.

Let $(\hat{\Omega}, \hat{\mathcal{F}}_\infty, \hat{P})$ denote a probability space, and let $\hat{B}$ with $\hat{B}(\hat{s}) = 0$ a.s., be a Brownian motion on $(\hat{\Omega}, \hat{\mathcal{F}}_\infty, \hat{P})$, adapted to filtration $\hat{\mathcal{F}}.$. Finally, let

$$\begin{aligned}\hat{\mathcal{V}}_{\hat{s},\hat{t}} \doteq \big\{&\hat{v} : [\hat{s},\infty)\times\hat{\Omega} \to \mathbb{R}^k | \hat{v} \text{ is } \hat{\mathcal{F}}.\text{-adapted, rt.-contin.,}\\ &\text{s.t. } \hat{v}(r) = 0 \text{ a.s. } \forall r > \hat{t},\ \mathbb{E}\textstyle\int_{\hat{s}}^{\hat{t}} |\hat{v}(t)|^m\,dt < \infty\ \forall m \in I\!N\big\}.\end{aligned} \tag{21}$$

For $\hat{s} \in [0,\hat{t})$, consider the dynamics

$$\dot{\pi}(r) = \bar{F}_2(\Pi(r),\pi(r),\bar{\hat{\alpha}}(r),\bar{\hat{\beta}}(r)), \quad \pi(\hat{s}) = \bar{\pi}, \tag{22}$$

$$\dot{\gamma}(r) = \bar{F}_3(\Pi(r),\pi(r),\bar{\hat{\alpha}}(r),\bar{\hat{\beta}}(r)), \quad \gamma(\hat{s}) = \bar{\gamma}, \tag{23}$$

$$\xi(r) = x + \bar{a}\hat{B}(r), \tag{24}$$

where $(\bar{\hat{\alpha}}, \bar{\hat{\beta}}) \in \hat{\mathcal{V}}^2_{\hat{s},\hat{t}}$. We also let $\bar{\bar{\mu}} \doteq (\bar{\hat{\alpha}}, \bar{\hat{\beta}})$. Define the decomposition of π into $\rho, q \in \mathbb{R}^n$, by $(\rho^T, q^T) \doteq \pi^T$. Letting $y \doteq (x^T, z^T)^T$, consider

$$\hat{J}(\hat{s}, (\bar{\pi}, x), \bar{\bar{\mu}}; z, \bar{\Pi}, \hat{t}) \doteq \mathbb{E}\Big\{ \pi^T(\hat{t}) \begin{pmatrix} \xi(\hat{t}) \\ z \end{pmatrix} + \gamma(\hat{t}) \Big\}$$

$$= \mathbb{E}\Big\{ y^T \pi(\hat{t}) + \big(\bar{a}\hat{B}(\hat{t})\big)^T \rho(\hat{t}) + \int_{\hat{s}}^{\hat{t}} \bar{F}_3(\Pi(r), \pi(r), \bar{\bar{\mu}}(r))\, dr \Big\} + \bar{\gamma}, \tag{25}$$

$$\hat{W}(\hat{s}, (\bar{\pi}, x); z, \bar{\Pi}, \hat{t}) \doteq \operatorname*{stat}_{\bar{\bar{\mu}} \in \hat{\mathcal{V}}^2_{\hat{s},\hat{t}}} \hat{J}(\hat{s}, (\bar{\pi}, x), \bar{\bar{\mu}}; z, \bar{\Pi}, \hat{t}). \tag{26}$$

One should note that the only *direct* interaction between the nonlinear dynamics of π and the diffusion process is through the bilinear term in the terminal cost.

In order to map the results of Theorem 1 to the the case of HJ PDE problem (27)–(28) below and control problem (22)–(26), we make the following definitions. Let

$$\bar{\bar{x}} \doteq \begin{pmatrix} \bar{\pi} \\ x \end{pmatrix} = \begin{pmatrix} \bar{\rho} \\ \bar{q} \\ x \end{pmatrix}, \quad \bar{\bar{\xi}}(\cdot) \doteq \begin{pmatrix} \pi(\cdot) \\ \xi(\cdot) \end{pmatrix} = \begin{pmatrix} \rho(\cdot) \\ q(\cdot) \\ \xi(\cdot) \end{pmatrix},$$

$$\bar{\bar{f}}(\bar{\Pi}, \bar{\bar{\xi}}, \bar{\bar{\mu}}) \doteq \begin{pmatrix} \bar{F}_2(\bar{\Pi}, \pi, \bar{\bar{\mu}}) \\ 0 \end{pmatrix}, \quad \bar{\bar{A}} \doteq (0_{n\times 2n}, \bar{a}\mathcal{I}_n)^T,$$

$$\bar{\bar{L}}(\bar{\Pi}, \bar{\bar{\xi}}, \bar{\bar{\mu}}) \doteq \bar{F}_3(\bar{\Pi}, \pi, \bar{\bar{\mu}}), \quad \bar{\bar{\psi}}(\bar{\bar{\xi}}; z, \bar{\Pi}, \bar{\gamma}) \doteq \psi(\xi; z, \bar{\Pi}, \bar{\gamma}).$$

We implicitly invoke trivial congruences such as that between $(0, \hat{t}) \times \mathbb{R}^{2n} \times \mathbb{R}^n$ and $(0, \hat{t}) \times \mathbb{R}^{3n}$ without further mention, and let $\mathcal{X}^2_{0,\hat{t}} \doteq (0, \hat{t}) \times \mathbb{R}^{2n}$, $\bar{\mathcal{X}}^2_{0,\hat{t}} \doteq [0, \hat{t}] \times \mathbb{R}^{2n}$, $\mathcal{X}^3_{0,\hat{t}} \doteq (0, \hat{t}) \times \mathbb{R}^{3n}$ and $\bar{\mathcal{X}}^3_{0,\hat{t}} \doteq [0, \hat{t}] \times \mathbb{R}^{3n}$.

We also consider the HJ PDE problem

$$0 = W_{\hat{s}} + \operatorname*{stat}_{\bar{\bar{\mu}} \in \mathbb{R}^{2n}} \big\{ W^T_{\bar{\bar{x}}} \bar{\bar{f}}(\Pi(\hat{t} - \hat{s}), \bar{\bar{x}}, \bar{\bar{\mu}}) + \bar{\bar{L}}(\Pi(\hat{t} - \hat{s}), \bar{\bar{x}}, \bar{\bar{\mu}}) \big\} + \tfrac{1}{2} \operatorname{tr}[AW_{xx}], \quad (\hat{s}, \bar{\bar{x}}) \in (0, \hat{t}) \times \mathbb{R}^{3n}, \tag{27}$$

$$W(\hat{t}, \bar{\bar{x}}; \bar{\gamma}) = y^T \pi + \bar{\gamma}, \quad \bar{\bar{x}} \in \mathbb{R}^{2n}, \tag{28}$$

where Π satisfies $\dot{\Pi} = \bar{F}_1(\Pi)$. We make the following assumptions, which are similar to their analogues in ($\mathcal{A}$.1).

($\mathcal{A}$.3) Fix $z \in \mathbb{R}^n$, $\bar{\Pi} \in \mathbb{R}^{2n\times 2n}$, $\bar{\gamma} \in \mathbb{R}$ and $\hat{t} \in (0, T)$. Assume there exists a solution, $(\hat{s}, \bar{\pi}, x) \mapsto W(\hat{s}, \bar{\pi}, x; z, \bar{\Pi}, \bar{\gamma}, \hat{t})$, of (27)–(28) in $C^{1,4}(\mathcal{X}^3_{0,\hat{t}}) \cap C_p(\bar{\mathcal{X}}^3_{0,\hat{t}})$, such that there exist $\bar{c}_3, \bar{C}_0 < \infty$ and $\hat{q} \in I\!N$ such that $|W_{xxxx}(\hat{s}, \bar{\bar{x}})| \le \bar{c}_3$, $|W_{\bar{\bar{x}}}(\hat{s}, \bar{\bar{x}})| \le \bar{C}_0(1 + |\bar{\bar{x}}|^{2\hat{q}})$ and $|W_{\bar{\bar{x}}\bar{\bar{x}}}(\hat{s}, \bar{\bar{x}})| \le \bar{C}_0(1 + |\bar{\bar{x}}|^{2\hat{q}})$, for all $(\hat{s}, \bar{\bar{x}}) \in \bar{\mathcal{X}}^3_{0,\hat{t}}$. Assume $\bar{\bar{f}}, \bar{\bar{L}} \in C^3(\mathbb{R}^{2n\times 2n} \times \mathbb{R}^{3n} \times \mathbb{R}^{2n})$; $\exists \bar{C}_1 < \infty$ such that for all $(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}}) \in \mathbb{R}^{2n\times 2n} \times \mathbb{R}^{3n} \times \mathbb{R}^{2n}$, $|\bar{\bar{f}}_{\bar{\bar{x}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, |\bar{\bar{f}}_{\bar{\bar{\mu}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})| \le \bar{C}_1$, $|\bar{\bar{f}}_{\bar{\bar{x}}\bar{\bar{x}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, |\bar{\bar{f}}_{\bar{\bar{x}}\bar{\bar{\mu}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, |\bar{\bar{f}}_{\bar{\bar{\mu}}\bar{\bar{\mu}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})| \le \bar{C}_1$ and $|\bar{\bar{L}}_{\bar{\bar{x}}\bar{\bar{x}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, |\bar{\bar{L}}_{\bar{\bar{x}}\bar{\bar{\mu}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, |\bar{\bar{L}}_{\bar{\bar{\mu}}\bar{\bar{\mu}}}(\bar{\Pi}, \bar{\bar{x}}, \bar{\bar{\mu}})|, \le \bar{C}_1$. There exists $\bar{\mu}^* \in C(\bar{\mathcal{X}}^3_{0,\hat{t}})$ that is globally Lipschitz in $\bar{\bar{x}}$, and is such that $\bar{\mu}^*(r, \bar{\bar{x}}) \in \operatorname{argstat}_{\bar{\mu} \in \mathbb{R}^{2n}} \{ \bar{\bar{f}}(\Pi(r), \bar{\bar{x}}, \bar{\mu})^T W_{\bar{\bar{x}}}(r, \bar{\bar{x}}) + \bar{\bar{L}}(\Pi(r), \bar{\bar{x}}, \bar{\mu}) \}$ for all $(r, \bar{\bar{x}}) \in \bar{\mathcal{X}}^3_{0,\hat{t}}$.

Theorem 6. $W = \hat{W}$ on $[\hat{s}, \hat{t}] \times \mathbb{R}^{3n}$, and $\bar{\mu}^*$ is a staticizing feedback control yielding payoff $\hat{W}$. Further, with $\hat{v}^*(r) \doteq \bar{\mu}^*(r, \bar{\xi}^*(r))$ for all $r \in [\hat{s}, \hat{t}]$, $\hat{v}^*$ is a.s. continuous.

Fix $z \in \mathbb{R}^n$, $\bar{\Pi} \in \mathbb{R}^{2n\times 2n}$, $\bar{\gamma} \in \mathbb{R}$ and $\hat{t} \in (0, T)$, and let

$$\hat{W}^f(\hat{t}, (\pi, x); z, \bar{\Pi}, \bar{\gamma}) \doteq \bar{G}(0, x, z, \hat{t}; \bar{\Pi}) + \hat{W}(0, (\pi, x); z, \bar{\Pi}, \bar{\gamma}, \hat{t}) \quad \forall\, (\hat{t}, (\pi, x)) \in \bar{\mathcal{X}}^3_{0,T}.$$

Theorem 7. Let $T \in (0, \infty)$, $z \in \mathbb{R}^n$, $\bar{\Pi} \in \mathbb{R}^{2n\times 2n}$, $\bar{\gamma} \in \mathbb{R}$. Then, for all $(s, (\pi, x)) \in \bar{\mathcal{X}}^3_{0,T}$,

$$\hat{W}^f(T - s, (\pi, x); z, \bar{\Pi}, \bar{\gamma}) = \bar{W}(s, x; z, \bar{\Pi}, \pi, \bar{\gamma}, T),$$

where the latter is defined in (5).

Remark 8. Note that HJ PDE problem (27)–(28) is equivalently

$$0 = W_{\hat{s}} + \tfrac{1}{2} \operatorname{tr}[AW_{xx}] + \operatorname*{stat}_{\bar{\mu} \in \mathbb{R}^{2n}} \big\{ W^T_\pi \bar{F}_2(\Pi(\hat{t} - \hat{s}), \pi, \bar{\mu}) + \bar{F}_3(\Pi(\hat{t} - \hat{s}), \pi, \bar{\mu}) \big\}, \quad (\hat{s}, \pi, x) \in (0, \hat{t}) \times \mathbb{R}^{3n}, \tag{29}$$

$$W(\hat{t}, \pi, x; z, \bar{\gamma}) = y^T \pi + \bar{\gamma}, \quad (\pi, x) \in \mathbb{R}^{3n}. \tag{30}$$

Note that x does not appear inside the stat operation in (29). Alternatively, note that the stochastic component of control problem (22)–(26) interacts with the nonlinear component of the problem only through a bilinear expression in the terminal cost. This structure is greatly simplified over that of the original problem, and this will be exploited in the generation of efficient solutions.

Abstract: We extend the classical discrete-time bounded real lemma to the general case of systems that need not be controllable or observable, and its relationship to the related discrete-time optimal control problem. In the talk accompanying this extended abstract, we will further discuss the analogies in discrete time to the recent continuous time development of an assumption free theory of linear passive and non-expansive systems that draws on the behavioral framework of Jan Willems and collaborators.

Keywords: Dissipativity, Optimal Control, Discrete-time linear systems

1. INTRODUCTION

We present a new version of the discrete-time bounded real lemma (see Theorem 4). This new version addresses outstanding assumptions in existing literature, as discussed following that theorem statement.

1.1 Notation

A small amount of notation is in order for this work. Firstly, we let $\mathbb{R}$ denote the real numbers. We let $\mathbb{R}[z]$ denote the polynomials in the indeterminate z, and $\mathbb{R}(z)$ denote the rational functions in the indeterminate z. We denote matrices with entries in the real numbers as $\mathbb{R}^{m\times n}$, and equivalently for matrices with polynomial entries ($\mathbb{R}^{m\times n}[z]$) and entries in the rational functions ($\mathbb{R}^{m\times n}(z)$). If M is a real- or complex-valued matrix, then M^T denotes its transpose and M^* denotes its Hermitian transpose, while for a matrix of rational functions $M(z)$, $M^\sim(z) = (M(\frac{1}{z}))^T$. Finally, a matrix $M \in \mathbb{R}^{m\times m}$ is called non-negative definite if it is symmetric (i.e., $M = M^T$) and $\mathbf{z}^T M\mathbf{z} \geq 0$ for all real vectors $\mathbf{z} \in \mathbb{R}^m$, and positive definite if, in addition, $\mathbf{z}^T M\mathbf{z} = 0$ implies $\mathbf{z} = 0$.

1.2 Background

This work concerns discrete-time dissipativity of linear time-invariant systems, defined as follows:

Definition 1. (Discrete-time dissipative system). We consider the discrete-time state-space system

$$\Sigma \coloneqq \{\mathbf{x}(k{+}1) = A\mathbf{x}(k) + B\mathbf{u}(k) \text{ and } \mathbf{y}(k) = C\mathbf{x}(k) + D\mathbf{u}(k), \text{ for } k = 0, 1, 2, \dots \};$$

where A, B, C, D are appropriately dimensioned real-valued matrices, and we let d denote the dimension of the state $\mathbf{x}$. We refer to the solutions $(\mathbf{u}, \mathbf{y}, \mathbf{x})$ of this equation as trajectories of the system. We define the supply rate

$$s(\mathbf{u}, \mathbf{y}) \coloneqq \mathbf{u}^T\mathbf{u} - \mathbf{y}^T\mathbf{y},$$

and we say that the system Σ is dissipative with respect to the supply rate s if there exists a function $M : \mathbb{R}^d \to \mathbb{R}$ such that

$$-\sum_{i=0}^{N} s(\mathbf{u}, \mathbf{y})(i) \leq M(\mathbf{x}_0)$$

for all $N \geq 0$ and all trajectories $(\mathbf{u}, \mathbf{y}, \mathbf{x})$ of the system Σ with $\mathbf{x}(0) = \mathbf{x}_0$. We then define the available storage $S_a(\mathbf{x}_0)$ as the least such function M, i.e.,

$$S_a(\mathbf{x}_0) \coloneqq \sup_{(\mathbf{u},\mathbf{y},\mathbf{x})\in\Sigma, N\geq 0, \mathbf{x}(0)=\mathbf{x}_0} -\sum_{i=0}^{N} s(\mathbf{u}, \mathbf{y})(i).$$

This represents the discrete-time analogy to the definition of continuous-time dissipativity of Willems (1972a,b). The definition extends in a natural way to other supply functions. Such dissipative systems as outlined in the above definition correspond to the systems under consideration in the famous discrete-time bounded real lemma. The purpose of this extended abstract is to present a new version of the discrete-time bounded real lemma that completely characterises the conditions under which a system satisfies the dissipativity condition as defined above, in the absence of any assumptions whatsoever.

Firstly, we define a discrete bounded real function (hereafter denoted DBR):

Definition 2. (DBR). Let $G \in \mathbb{R}^{m\times n}(z)$. G is DBR if (i) G is analytic throughout the exterior of the unit circle; and (ii) $I - G(z)^*G(z) \geq 0$ for all complex numbers z whose magnitude is strictly greater than one.

Secondly, we define the observability matrix for the system Σ:

$$\mathcal{O} \coloneqq \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{d-1} \end{bmatrix}, \tag{1}$$

whose columns are linearly independent if and only if the system Σ is observable in the usual sense of the word.

We also recall a recent result on discrete-time spectral factors that will be useful in characterising the available storage. This result, from Baggio and Ferrante (2016), provides a relatively recent discrete-time version of the long-standing result in continuous-time by Youla (1961).

Lemma 3. Let $H \in \mathbb{R}^{n\times n}(z)$ and let $\max_{\lambda\in\mathbb{C}}(\text{rank}(H(\lambda)))$ $= r$. Further, suppose that $H(\lambda)$ is non-negative definite for all λ on the unit circle, with the exception of poles of H. Then there exists a rational matrix $Z \in \mathbb{R}^{r\times n}(z)$ such that (i) $H = Z^{\sim}Z$; (ii) Z is analytic throughout the exterior of the unit circle; (iii) the rows of $Z(\lambda)$ are independent for all λ outside of the unit circle; and (iv) $\lim_{\lambda\to\infty} Z(\lambda)$ exists and its rows are independent. If Z satisfies conditions (i)—(iv), then we call Z a discrete-time spectral factor of H, and if H has no poles on the unit circle then Z has no poles on the unit circle.

2. THEOREM STATEMENT

The new version of the discrete-time bounded real lemma, whose proof is the subject of a journal paper in preparation, is then as follows:

Theorem 4. Let Σ be as in Definition 1 and let $\mathcal{O}$ be as in equation (1). The following statements are equivalent

(1) Σ is dissipative with respect to the supply rate $s = \mathbf{u}^T\mathbf{u} - \mathbf{y}^T\mathbf{y}$, in accordance with Definition 1.
(2) Let $G(z) = D + C(zI - A)^{-1}B$ and let $U \in \mathbb{R}^{n\times n}[z]$ and $V \in \mathbb{R}^{n\times d}[z]$ be left coprime polynomial matrices that satisfy $U(z)B^T\mathcal{O}^T = V(z)(\frac{1}{z}I - A^T)\mathcal{O}^T$ (such matrices will always exist). The following three conditions all hold:
   (a) G is DBR, in accordance with Definition 2
   (b) If $\mathbf{z}$ is a complex-valued vector, λ is a complex number whose modulus is greater than or equal to one, and $\mathbf{z}^T\mathcal{O}[\lambda I - A \quad B] = 0$, then $\mathbf{z}^T\mathcal{O} = 0$.
   (c) If $\mathbf{b} \in \mathbb{R}^n[z]$ satisfies $\mathbf{b}^T(UU^{\sim} - (VC^T + UD^T)(VC^T + UD^T)^{\sim}) = 0$, then there exists a polynomial vector $X \in \mathbb{R}^d[z]$ such that $(\mathbf{b}^T(VC^T + UD^T))(z)C = X(z)^T(zI - A)$;
(3) There exists a real-valued non-negative definite matrix P such that the block matrix
$$\begin{bmatrix} P - A^TPA - C^TC & -C^TD - A^TPB \\ -D^TC - B^TPA & I - D^TD - B^TPB \end{bmatrix} \tag{2}$$
is non-negative definite.
(4) There exists a real-valued non-negative matrix P_-, and real-valued matrices L and W such that the following three conditions all hold:
   (a) $\begin{bmatrix} P_- - A^TP_-A - C^TC & -C^TD - A^TP_-B \\ -D^TC - B^TP_-A & I - D^TD - B^TP_-B \end{bmatrix}$
   $= \begin{bmatrix} L^T \\ W^T \end{bmatrix}[L \; W]$;
   (b) with the notation $Z(z) = W + L(zI - A)^{-1}B$, then Z is a discrete-time spectral factor of $I - G^{\sim}G$ in accordance with Definition 3;
   (c) if $\mathbf{z}$ is a real-valued vector satisfying $\mathcal{O}\mathbf{z} = 0$, then $P_-\mathbf{z} = 0$.

Moreover, if the above conditions hold, then $S_a(\mathbf{x}_0) = \mathbf{x}_0^TP_-\mathbf{x}_0$ for all $\mathbf{x}_0 \in \mathbb{R}^d$, where P_- is as in condition 4, and if P is a non-negative definite matrix satisfying condition 3, then $P \geq P_-$.

Together these conditions form a complete characterisation of the dissipativity of a general linear discrete-time system with respect to the supply rate s, the existence of non-negative definite solutions to the matrix inequality in condition 3, a characterisation of the spectral factorisation of the function $I - G^{\sim}G$, and a characterisation of the available storage whenever the system is dissipative. The equivalence of conditions 2–4 are analogous to results in the context of discrete-time positive-real systems by Branford and Hughes (2020). That paper did not consider the connection to dissipativity and the associated optimal control problem, and we note that a similar connection can also be made in the setting of discrete-time positive-real systems relating to dissipativity with respect to the supply rate $s_p(\mathbf{u}, \mathbf{y}) = \mathbf{u}^T\mathbf{y}$. Specifically, conditions (1)–(3) in Branford and Hughes (2020, Theorem 5) are equivalent to the system in Definition 1 being dissipative with respect to the supply rate s_p, and the available storage in this case takes the form $S_a(\mathbf{x}_0) = \frac{1}{2}\left(\mathbf{x}_0^T\tilde{P}_-\mathbf{x}_0\right)$ where (i) $\tilde{P}_-$ is as in Branford and Hughes (2020, Theorem 5, condition 3); and (ii) if $\mathbf{z}$ is a real-valued vector satisfying $\mathcal{O}\mathbf{z} = 0$, then $\tilde{P}_-\mathbf{z} = 0$.

The key distinction of the preceding theorem from existing results in the literature is the absence of any a-priori restrictions on the eigenvalues of the A matrix or the controllability or observability of the system. The consequence in terms of the second set of conditions in the theorem statement is that the familiar condition that $G(z)$ must be a discrete-time bounded real function (see, e.g., Vaidyanathan, 1985) must be augmented with two further conditions.

The first of these additional conditions, condition 2b, is equivalent to the requirement that the system be behaviorally stabilizable. In other words, for any given real k_0, any past input-output trajectory $(\mathbf{u}(k), \mathbf{k}(k))$, $k < k_0$, can be concatenated with a future trajectory $(\tilde{\mathbf{u}}(k), \tilde{\mathbf{y}}(k))$, $k \geq k_0$ with the property that $\tilde{\mathbf{u}}(k) \to 0$ and $\tilde{\mathbf{y}}(k) \to 0$ as $k \to \infty$. Note that this is not the same as state stabilizability, e.g., if D satisfies $I - D^TD \geq 0$ and $B = C = 0$ then the system is in fact dissipative for any given matrix A (indeed, $P = 0$ then satisfies condition 2 of Theorem 4).

Condition 2c is a coupling condition between lossless trajectories of the system (i.e., trajectories for which, were they returned to the same state at $k = N$ as their initial state at $k = 0$, would satisfy $\sum_{i=0}^{N} s(\mathbf{u}, \mathbf{y})(i) = 0$), and trajectories for which $\mathbf{u}(k) = 0$ for all k. This condition can be tested by first computing the left syzygy of $UU^{\sim} - (VC^T + UD^T)(VC^T + UD^T)^{\sim}$ (i.e., a polynomial matrix $H(z)$ with as many rows as the minimum dimension of the left kernel of $(UU^{\sim} - (VC^T + UD^T)(VC^T + UD^T)^{\sim})(\lambda)$ over all complex values of λ, and for which the rows of $H(\lambda)$ are always in this left kernel and are independent for all complex values of λ). Such a polynomial matrix can be obtained using standard symbolic algebra software. We note here that $UU^{\sim} - (VC^T + UD^T)(VC^T + UD^T)^{\sim}$ may be the ratio of a polynomial matrix and the monomial z^p for some integer p, whereby in order to compute the left syzygy using standard techniques for polynomial matrices it may be necessary to multiply this matrix by the monomial z^p to obtain a polynomial matrix whose left syzygy will be identical to that of $UU^{\sim} - (VC^T +$

$UD^T)(VC^T + UD^T)^\sim$. Next, compute the polynomial matrix $H(VC^T+UD^T)C$, which we shall denote K. Then, expand $K(z)$ in terms of z: $K(z) = K_0+K_1z+K_2z^2+\cdots$. Condition 2c is then equivalent to requiring $K_0 + K_1A + K_2A^2 + \cdots = 0$.

It is appropriate to recognise other notable contributions to generalise the applicability of the discrete-time bounded real lemma. For example, the paper by de Souza and Xie (1992), in which the assumption of controllability is removed, but the a-priori assumption is made that the eigenvalues of A are all strictly within the unit circle and, moreover, that $I - D^TD - B^TPB > 0$. In addition, Xiao and Hill (1999) present a necessary and sufficient condition for a transfer function $G(z) = D + C(zI - A)^{-1}B$ to be DBR in the absence of controllability and observability assumptions that involves the matrix in (2) and the controllability matrix

$$\mathcal{C} = \begin{bmatrix} B & AB & \cdots & A^{d-1}B \end{bmatrix}. \tag{3}$$

A simple example serves to illustrate the improvement in the version of the discrete-time bounded real lemma presented here. Consider a system Σ with $A = 0, B = 0, C = 1$ and $D = 1$. Then $D+C(zI-A)^{-1}B = 1$ which is a discrete bounded real function. But $I-D^TD-B^TPB = 0$, so if $I - D^TD - B^TPB = W^TW$ then we require $W = 0$. But this implies that $-1 = -C^TD - A^TPB = L^TW = 0$, a contradiction. Note also that in this case there does not exist a $P \geq 0$ such that $I - D^TD - B^TPB$ is non-singular. Hence, this case is not considered in the version of the discrete-time bounded real lemma presented in de Souza and Xie (1992). Moreover, the system satisfies the necessary and sufficient conditions outlined in Xiao and Hill (1999, Lemma 8) involving the matrix in (2) and the controllability matrix in equation (3), yet the system is not dissipative. It can further be verified using the method outlined in the previous paragraph that condition 2c does not hold for this example. In contrast, it can be shown that the system Σ with $A = 0, B = 1, C = 0$ and $D = 1$ does satisfy condition 2 and is in fact dissipative.

Finally, we note that Definition 1 and the results presented thereafter are specific to systems for which the difference equation stated in that definition is only required to hold for non-negative k. This implies that the initial state $\mathbf{x}(0)$ can be arbitratily specified. For the system Σ considered in the previous paragraph, in the case that $A = 0, B = 0, C = 1$ and $D = 1$, then if the difference equation in Definition 1 is instead required to hold for all k including negative values it follows that $\mathbf{y}(k) = \mathbf{u}(k)$ for all k, whereupon $-\sum_{i=0}^{N} s(\mathbf{u}, \mathbf{y})(i)$ is bounded above by zero. In contrast, when the difference equation only holds for non-negative k, then $-\sum_{i=0}^{N} s(\mathbf{u}, \mathbf{y})(i)$ can be made arbitrarily large for any given $\mathbf{x}(0) \neq 0$ by picking an initial input $\mathbf{u}(0)$ with the same sign as $\mathbf{x}(0)$ and a sufficiently large magnitude.

Simulating Mid-Air Interaction Trajectories via Model Predictive Control

Markus Klar * **Florian Fischer** * **Arthur Fleig** *
Miroslav Bachinski * **Jörg Müller** *

* *University of Bayreuth, 95440 Bayreuth, Germany*
(e-mail: markus.klar@uni-bayreuth.de)

Abstract: We investigate the ability of Model Predictive Control (MPC) to generate human-like movements during interaction with mid-air user interfaces, i.e., pointing in virtual or augmented reality, using a state-of-the-art biomechanical model. The model is partly a black box implemented in the MuJoCo physics engine, requiring either gradient-free optimization algorithms or gradient approximation. This makes it even more important to choose the objective function or the MPC horizon length wisely. We introduce three objective functions suggested in the literature and identify optimal cost weights such that the simulated trajectories best match real ones obtained from motion capturing, i.e., we tackle an inverse optimal control problem. For the best performing objective function, we then analyze the effects of the horizon length and of the cost weights. This model-based approach enables the analysis of interaction techniques, e.g., in terms of ergonomics and effort, without the need for extensive user studies.

1. INTRODUCTION

Recent achievements in virtual and augmented reality have brought up a variety of new interaction methods, ranging from typing in mid-air to complex manipulation of virtual objects. Naturally, such interaction techniques include a number of parameters (offsets, rotations, gains, etc.) that have a significant impact on the resulting interaction experience. As a result, careful tuning of these parameters is critical. Typically, this fine-tuning requires multiple user studies and therefore takes a considerable amount of time. These user studies could be partially replaced by simulations, where movement is calculated by solving Optimal Control Problems (OCPs).

This optimal control approach differs from traditional approaches in the field of Human Computer Interaction (HCI), which are rather evidence-based and focus on summary statistics such as Fitts' Law (Fitts, 1954) and phenomena like bell-shaped velocity profiles and corrective submovements. In contrast, we make use of recent models and methods from the fields of Control Theory and Optimal Feedback Control (OFC), which allows us to analyze the continuous development of any quantity of interest (e.g., end-effector position or muscle activations) (Müller et al., 2017). Building on such a control-theoretic forward simulation of interactive movement, we are able to identify optimal weights of a suitable objective function, i.e., solve an inverse optimal control problem (Albrecht, 2013). We thus have two layers of optimization: The inner layer calculates optimal movement trajectories w.r.t. a given objective function. The outer layer computes optimal weights of the objective function such that the simulated trajectories best match real ones obtained from motion capture. Combining this rigorous mathematical framework with an efficient implementation of a state-of-the-art biomechanical model has the potential to simulate and predict human mid-air trajectories during interaction – as we show in this work by applying Model Predictive Control (MPC) to a model of mid-air pointing.

2. MODELING

We consider a discrete-time MPC framework [1], i.e., we consider the following optimal control problem

$$\begin{aligned} &\min_{\mathbf{u}(\cdot)\in\mathbb{U}^N} \sum_{n=0}^{N-1} \ell(\mathbf{x}(n),\mathbf{u}(n)) \\ \text{s.t.}\quad &\mathbf{x}(n+1) = f(\mathbf{x}(n),\mathbf{u}(n)) \quad \forall n \in \{0,...,N-1\}, \\ &\mathbf{x}(0) = \mathring{\mathbf{x}} \end{aligned} \tag{1}$$

on a receding horizon of length $N \in \mathbb{N}$, only applying the first part of the optimal control sequence, $\mathbf{u}^*(0)$, in every MPC step. In the remainder of this section, we explain and motivate all variables appearing in (1).

2.1 System Dynamics

The components of the system dynamics f in (1) are illustrated in Figure 1. In addition to the "Interaction Technique" block, f encodes the human upper extremity body dynamics, which is split in the two blocks "Muscle Model" and "MuJoCo".

To simulate movement of the human body we use the fast physics simulation software MuJoCo (Todorov et al.,

[1] For more details on nonlinear MPC see Grüne and Pannek (2017).

2012). In our previous work (Fischer et al., 2021), we have derived a MuJoCo model from a state-of-the-art OpenSim (Seth et al., 2018) model of the upper extremity (Saul et al., 2014). This musculoskeletal model includes a shoulder, an elbow, and a wrist, with 7 independent joints, i.e., degrees of freedom (DOFs) (3 in the shoulder, 2 in the elbow, 2 in the wrist), and 13 coupled joints. To generate arm movements, MuJoCo applies torque at each independent joint. Since humans are not capable of producing torque instantaneously, we incorporate the following second-order muscle model.

Given a normalized control signal $\mathbf{u} \in \mathbb{U} := [-1,1]^7$ from the MPC block in Figure 1, we model basic muscle properties such as activation delays for each independent joint $i = 1, ..., 7$ via the second-order dynamics

$$\begin{bmatrix} \sigma_i(k+1) \\ \Delta\sigma_i(k+1) \end{bmatrix} = A \cdot \begin{bmatrix} \sigma_i(k) \\ \Delta\sigma_i(k) \end{bmatrix} + B \cdot u_i, \tag{2a}$$

$$\sigma_i(0) = \mathring{\sigma}_i, \quad \Delta\sigma_i(0) = \Delta\mathring{\sigma}_i, \quad k \in \{0, ..., K-1\}, \tag{2b}$$

with

$$A = \begin{bmatrix} 1 & \Delta t \\ \frac{-\Delta t}{(t_e t_a)} & 1 - \Delta t \frac{t_e + t_a}{t_e t_a} \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ \frac{\Delta t}{t_e t_a} \end{bmatrix}, \tag{3}$$

which yields the activation vector $\boldsymbol{\sigma} \in [-1,1]^7$ and its approximate derivative $\Delta\boldsymbol{\sigma} \in \mathbb{R}^7$. Here, $K \in \mathbb{N}$ denotes the number of steps, $\Delta t = 2$ ms is the sampling time, and $t_e = 30$ ms and $t_a = 40$ ms are the excitation and activation time constants, respectively, as in Van der Helm and Rozendaal (2000).

The biomechanical simulation in MuJoCo (cf. Figure 1) takes these activations $\boldsymbol{\sigma}$ as input and yields new joint angles $\mathbf{q} \in \mathbb{R}^7$ and velocities $\mathbf{v} \in \mathbb{R}^7$ as well as the position of the fingertip $\mathbf{y} \in \mathbb{R}^3$. The subsequent Interaction Technique block maps the fingertip $\mathbf{y}$ to the virtual cursor position $\mathbf{p} \in \mathbb{R}^3$. The mapping can be a simple translation by an offset $\boldsymbol{\omega} \in \mathbb{R}^3$, i.e., $\mathbf{p} = \mathbf{y} + \boldsymbol{\omega}$, as in the "Virtual Cursor" case that we consider, cf. Section 3. More generally, it could represent a dynamic system with its own internal state, e.g., for pointer acceleration techniques (Müller, 2017).

In summary, the state vector $\mathbf{x}$ consists of the joint angles $\mathbf{q}$ and velocities $\mathbf{v}$, the activations $\boldsymbol{\sigma}$ and their approximate derivatives $\Delta\boldsymbol{\sigma}$, and the cursor position $\mathbf{p}$:

$$\mathbf{x} = (\mathbf{q}, \mathbf{v}, \boldsymbol{\sigma}, \Delta\boldsymbol{\sigma}, \mathbf{p})^\top. \tag{4}$$

The initial state is denoted by $\mathring{\mathbf{x}}$.

As humans are known to change control behavior not continuously but only intermittently (Gawthrop et al., 2011), the control signal $\mathbf{u}$ is assumed to only change every 40 ms, while both MuJoCo and the Muscle Model update every 2 ms. Thus, evaluating $f(\mathbf{x}(n), \mathbf{u}(n))$ in (1) involves $K = 20$ forward steps of the muscle model (2) and the MuJoCo simulation starting from $\mathbf{x}(n)$, in which the control signal $\mathbf{u} = \mathbf{u}(n)$ is kept constant.

2.2 Objective Functions

In the following, we introduce three different stage costs ℓ that were proposed in HCI and movement science to explain human behavior (Berret et al., 2011). Unless stated otherwise, $\|\cdot\|$ denotes the Euclidean norm.

Distance and Control Cost (DC) A first approach is to penalize the remaining distance from the cursor to the target and adding quadratic control costs as regularization, i.e.,

$$\ell(\mathbf{x}, \mathbf{u}) = \|\mathbf{p} - \bar{\mathbf{p}}\| + r_1 \|\mathbf{u}\|^2, \tag{5}$$

where $\bar{\mathbf{p}} \in \mathbb{R}^3$ is the target center and $r_1 \geq 0$ can be interpreted as a weight for the trade-off between accuracy and effort. This was used in several works studying human movement, cf. Diedrichsen et al. (2010).

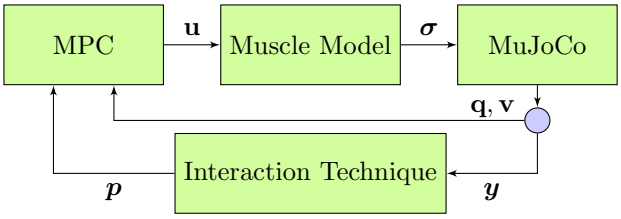

Fig. 1. High-level view on the closed feedback loop.

Joint Acceleration (JAC) The second approach is a simple extension of (5), where in addition high joint accelerations $\mathbf{a} = \dot{\mathbf{v}}$ are penalized:

$$\ell(\mathbf{x}, \mathbf{u}) = \|\mathbf{p} - \bar{\mathbf{p}}\| + r_1 \|\mathbf{u}\|^2 + r_2 \|\mathbf{a}\|^2, \tag{6}$$

where $r_1, r_2 \geq 0$ are weights. Since we cannot obtain joint accelerations $\mathbf{a}$ directly from MuJoCo, we use central differences of the velocities $\mathbf{v}$ (one-sided differences on the boundaries) to approximate them. From a biomechanical perspective, high joint acceleration leads to greater wear of the joints and should thus be avoided. Using inverse control, it could be shown that this cost term plays an important role in human movements (Berret et al., 2011).

Commanded Torque Change (CTC) As a third variant, we consider the commanded torque change cost from Nakano et al. (1999). In our case, CTC is directly proportional to $\Delta\boldsymbol{\sigma}$. Therefore, the stage cost reads

$$\ell(\mathbf{x}, \mathbf{u}) = \|\mathbf{p} - \bar{\mathbf{p}}\| + r_1 \|\mathbf{u}\|^2 + r_2 \|\Delta\boldsymbol{\sigma}\|^2, \tag{7}$$

where $r_1, r_2 \geq 0$ are weight parameters.

2.3 Numerical Solution

To solve OCP (1), we use direct single shooting to obtain a nonlinear program, which is solved with L-BFGS-B implemented in `scipy` [2]. Since gradient information is not available in closed-form due to partly blackbox dynamics, we approximate the gradients via central finite differences.

3. USER STUDY

We are interested in how well our model, with one of the stage costs (5)-(7), can synthesize human movement given different interaction techniques. To this end, we conducted a small user study with 6 participants (Mean Age=28.8, SD=6.6, 4 Male, all right-handed) from our local university campus. Participants wore a head mounted display [3] and a full-body suit to track their movements at 240Hz [4]. An LED marker was placed at the fingertip of the index finger to generate the virtual cursor position. Our experimental design involved two factors: interaction technique (Virtual Cursor vs. Virtual Pad) and specific

[2] https://scipy.org/
[3] HTC Vive Pro, https://vive.com/de/product/vive-pro/
[4] Phasespace X2E, https://phasespace.com/x2e-motion-capture/

setting (identity vs. ergonomic). Both factors were varied within subjects. The task was based on the discrete Fitts' Law paradigm, following the ISO 9241-9 standard: 13 virtual targets with a diameter of 5 cm were placed on a circle of 30 cm diameter, 50 cm in front of the right shoulder of the participant. Participants were instructed to move the cursor as fast as possible, only using their shoulder and arm. Each participant performed the complete ISO task consisting of 13 different targets 5 times per condition. After some preprocessing, where reaction times were removed as our model cannot account for them, we further removed 158 trials due to irregularities such as early starts or exceptionally long trials, leaving a total of 1402 movements, which we use in the following evaluation.

4. MODEL EVALUATION

In this section, we perform a pairwise comparison between simulated cursor trajectories to real user data. The simulated cursor trajectories, which we denote by $\boldsymbol{p}_{\text{sim}}$, are obtained by iteratively solving the OCP (1) on a receding horizon. This procedure is continued until the movement duration matches that of the user.

4.1 Quantitative Comparison of Cost Functions

To evaluate how well the simulated movement matches empirically observed user behavior, for each stage cost, we first perform a parameter optimization of r_1, r_2 for each user and condition separately, as follows. We choose five randomly selected trials per user and condition, and for each trial calculate the root mean squared error (RMSE)

$$\text{RMSE}(\boldsymbol{p}_{\text{sim}}, \boldsymbol{p}_{\text{real}})^2 = \frac{1}{M} \sum_{n=0}^{M-1} \|\boldsymbol{p}_{\text{sim}}(n) - \boldsymbol{p}_{\text{real}}(n)\|^2 . \quad (8)$$

Here, $\boldsymbol{p}_{\text{real}}(n) \in \mathbb{R}^3$ is the cursor position of the user at time step $n \in \mathbb{N}$, and $M \in \mathbb{N}$ is the number of time steps of the considered trial. We then use the *CMAES* (Hansen, 2016) to find cost weights that minimize the total RMSE between simulation and user position trajectories.[5] The identified cost weights are then used in the pairwise comparison of all 1402 movement trajectories.

To illustrate variability in human movement, we include both signal-dependent and constant control noise in the MPC closed-loop trajectory. That is, in every MPC step, after solving the OCP (1) (with no noise involved), we replace $\mathbf{u}^*(0)$ by a normally distributed random variable $\alpha(\mathbf{u}^*(0)) \sim \mathcal{N}(\mathbf{u}^*(0),\, 0.103^2 \cdot \mathbf{u}^*(0)^2 + 0.185^2)$, as suggested by van Beers et al. (2004). This illustrates a planned movement that, upon execution, is perturbed.

A box plot containing the RMSEs of all trials for each considered cost function is shown in Figure 2 (percentage of outliers: DC: 4.09%; CTC: 8.03%; JAC: 5.88%). Adding an additional cost term to the DC costs (5), as we have done for both the JAC (6) and the CTC costs (7), results in a significant (****, i.e., $p \leq 10^{-4}$) improvement of the RMSEs while also reducing variance. One has to keep in mind that both (6) and (7) introduce an additional weight parameter r_2, i.e., the observed better fit was to be

[5] To avoid the even more expensive gradient estimation at this point, we use the gradient-free evolutionary algorithm CMAES.

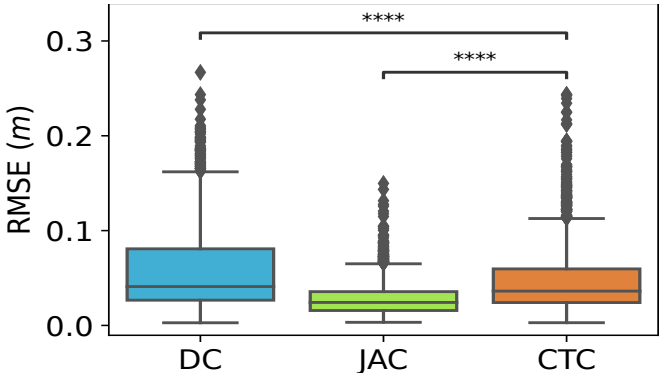

Fig. 2. Box plot for the RMSE on cursor position of all movements for the three considered cost functions.

expected. However, by far the best fit is obtained by joint acceleration costs (6), which we focus on in the following.

4.2 Effect of the MPC Horizon

Black box models like the one in our case suffer from the lack of efficiently available gradient information, resulting in considerably long optimization times. One way to handle extensive computation time is to reduce the MPC horizon. While this effectively reduces the number of control variables in each subproblem, the resulting MPC solution may further deviate from the (theoretic) optimal closed-loop trajectory for the infinite time-horizon problem (Grüne and Pannek, 2017). Therefore, the MPC horizon should be chosen carefully. To determine a suitable horizon length, we investigate our model with costs (6) and optimal cost weights r_1, r_2 from Section 4.1 by running a qualitative comparison for MPC horizons $N = 2, 4, 6, ..., 20$ on a representative trial of a single user.

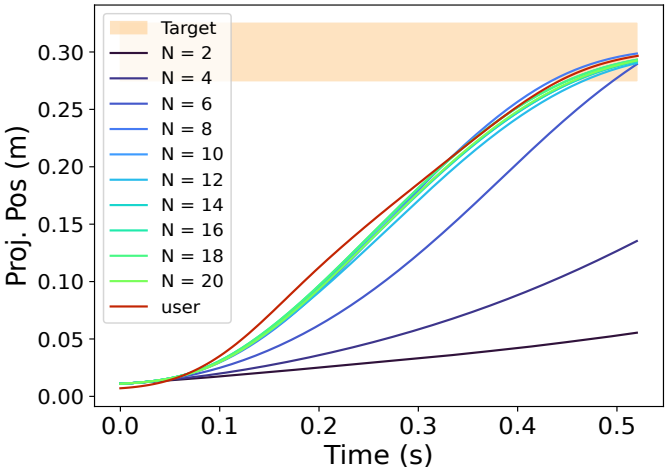

Fig. 3. Projected cursor position profiles of one trial for varying MPC horizon N, using JAC.

The resulting projected cursor trajectories[6] for the different MPC horizons are shown in Figure 3. As expected, a too short MPC horizon of $N = 2$ (80 ms) or $N = 4$ (160 ms) is not sufficient to reach the target. For $N = 6$ (200 ms), the controller manages to identify a control sequence that reaches the target, however, the simulation

[6] We orthogonally project the 3D trajectories onto the direct path between initial position and target.

clearly deviates from the user behavior (red line). For horizons starting from $N = 8$ (320 ms), trajectories hardly differ and visually match the user trajectory quite well.

4.3 Cost Function Sensitivity Analysis

To get insight in the individual effect of each cost weight r_1, r_2 in (6), we performed a numerical sensitivity analysis. For several combinations of the control weight r_1 and the joint acceleration weight r_2, we simulated all trials of a single participant in a single condition (61 in total) [7] and calculated the average RMSE between the corresponding simulation and user cursor position trajectories, analogous to (8).

Figure 4 shows an almost convex surface, indicating a local minimum close to $(r_1, r_2) = (0.01, 0.0001)$. This clearly shows that both too high control costs and too low joint acceleration costs result in large RMSE values. However, it is also visible that removing control costs completely, i.e., setting $r_1 = 0$, leads to a (slight) increase in RMSE values. This reflects that moving the human body does require some muscle control effort.

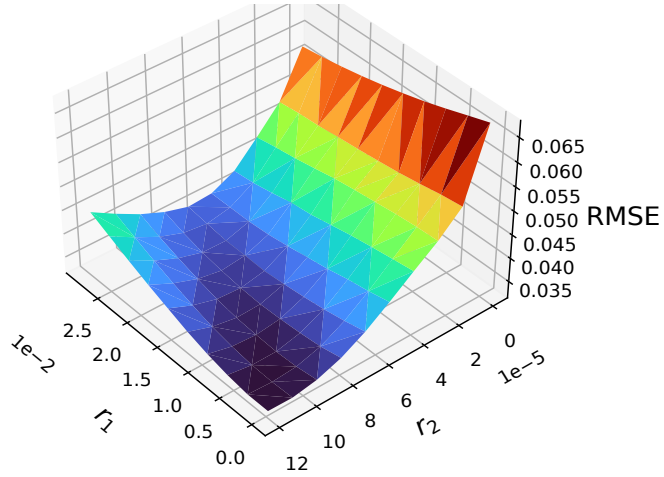

Fig. 4. Average RMSE for one representative participant and condition for different cost weights of JAC.

5. CONCLUSION

In this work, we demonstrated the application of Model Predictive Control to the HCI problem of evaluating interaction techniques through simulation. From the three considered cost functions, the combination of distance, control and joint acceleration cost showed the most promising results in terms of matching human pointing behavior. Our analysis of the MPC horizon showed that for the considered pointing task, a horizon of at least 320 ms (or $\approx 60\%$ of the total movement duration) is required to reliably reach the target. The subsequent sensitivity analysis brought novel insights in the choice of cost weights, showing a clear valley towards a (local) minimum, suggesting that large control costs should be avoided. With this work, we have established a sound basis for evaluating interaction techniques through simulation and have thus taken a first step towards being able to partially replace user studies in the future.

[7] We exemplarily chose participant U1 and the Virtual Cursor identity, i.e., the fingertip corresponds to the cursor position.

Abstract: We study the optimal landing problem for aerial vehicles under (1) a fixed landing time horizon or (2) the minimum time horizon. Both problems can be framed into solving the corresponding two-point boundary value problems. However, solving the boundary value problem in numerics is challenging, primarily due to the lack of good initial conditions. We present a space-marching scheme combined with machine learning techniques to provide good initial conditions for the boundary value problem solver. The algorithm greatly improves the solver's performance by increasing the success rate and reducing the computation time.

Keywords: optimal control, deep neural networks, Pontryagin minimum principle, quadrotors, landing problem

1. INTRODUCTION

The optimal landing problem concerns optimally controlling the aerial vehicles to land on the target position. Due to the high dimensionality of the state space and nonlinearity of the dynamics, solving the optimal landing problem has been a numerically challenging task for a long time. There has been a lot of work (Hu and Mishra, 2017; Zhu et al., 2019) focusing on solving the optimal landing problem. However, the exsiting methods still have some limitations such as simplified model, sub-optimal trajectory, reliance on good initial guesses, and long computation time.

In recent years, deep neural networks (DNN) have been widely used to solve challenging optimal control problems. For example, Zhu et al. (2019) use DNNs to learn the optimal action to improve the efficiency for the fuel-optimum lunar landing problem. Nakamura-Zimmerer et al. (2021) propose to learn the value function via DNN adaptively and predict the optimal feedback control.

This paper proposes a new numerical method enhanced by DNNs to solve the optimal landing problems and tackle the aforementioned difficulties. We will take the quadrotor unmanned aerial vehicles (UAVs) as an example to demonstrate our methodology. Quadrotor UAVs have received widespread attention in recent years due to their wide range of application scenarios. Our considered problem deals with the full quadrotor dynamic model and aims to achieve an optimal landing path with minimum time and control effort. We use the Pontryagin minimum principle to transform the original optimal landing problem into a two-point boundary value problem (TPBVP). One critical difficulty of TPBVP-based algorithms is to find good initial guesses. To overcome this difficulty, we design a DNN-based algorithm to provide an initial guess of the optimal landing time and a space-marching scheme to provide an initial guess of the control. Compared to the baseline methods, the proposed algorithm obtains the optimal landing trajectory with a much higher success rate and less computation time.

2. FORMULATION OF THE OPTIMAL CONTROL PROBLEM

We consider a deterministic system defined by the following ordinary differential equation

$$\begin{cases} \dot{\boldsymbol{x}}(t) = f(\boldsymbol{x}(t), \boldsymbol{u}(t)), \quad t \in [0, t_f] \\ \boldsymbol{x}_0 = x_0, \ \boldsymbol{g}(\boldsymbol{x}(t_f)) = \boldsymbol{0}. \end{cases} \tag{1}$$

where $\boldsymbol{x}(t) \in \mathbb{R}^n$ indicates the states, $\boldsymbol{u}(t) \in \mathcal{U} \subset \mathbb{R}^m$ represents the controls with $\mathcal{U}$ being the admissible set of the controls, $\boldsymbol{f} : \mathbb{R}^n \times \mathcal{U} \mapsto \mathbb{R}^n$ and $\boldsymbol{g} : \mathbb{R}^n \mapsto \mathbb{R}^k$ are smooth functions describing the dynamics and terminal condition. We call $\{\boldsymbol{x}, \boldsymbol{u}, t_f\}$ a feasible path if (1) is satisfied and use $\mathcal{P}$ to denote the set of all feasible paths. The *performance function* is defined by

$$J[\boldsymbol{x}, \boldsymbol{u}, t_f] = \int_0^{t_f} L(\boldsymbol{x}(t), \boldsymbol{u}(t))dt, \tag{2}$$

where $L : \mathbb{R}^n \times \mathcal{U} \mapsto \mathbb{R}^+$ is the nonnegative running cost.

We will consider two different but closely related problems. In the first problem, t_f is a given positive constant and we aim to minimize the performance function over all feasible paths with a fixed terminal time t_f:

$$\min_{(\boldsymbol{x}, \boldsymbol{u}) : \{\boldsymbol{x}, \boldsymbol{u}, t_f\} \in \mathcal{P}} J[\boldsymbol{x}, \boldsymbol{u}, t_f]. \tag{3}$$

We call this problem a *fixed terminal time problem*. Another problem is called *free terminal time problem*, where

we aim to minimize the performance function over all feasible paths:

$$\min_{\{\boldsymbol{x},\boldsymbol{u},t_f\}\in\mathcal{P}} J[\boldsymbol{x},\boldsymbol{u},t_f]. \tag{4}$$

2.1 Pontryagin's Minimum Principle

Pontryagin's minimum principle (PMP) derives the necessary conditions for optimality, which converts the optimal control problems (3) or (4) to two-point boundary value problems (TPBVPs). In this paper, we assume the solutions of the TPBVP are optimal. Then one can solve the TPBVPs to obtain the solution to the original control problem. To state the PMP, we introduce the costate variable $\lambda \in \mathbb{R}^n$ and define the Hamiltonian function

$$H(\boldsymbol{x},\boldsymbol{\lambda},\boldsymbol{u}) = L(\boldsymbol{x},\boldsymbol{u}) + \boldsymbol{\lambda}\cdot f(\boldsymbol{x},\boldsymbol{u}). \tag{5}$$

The PMP reduces the fixed terminal time problem (3) to a system of $2n$ equations in the form of a TPBVP

$$\begin{cases} \dot{\boldsymbol{x}}(t) = \partial^T_{\boldsymbol{\lambda}} H(\boldsymbol{x}(t),\boldsymbol{\lambda}(t),\boldsymbol{u}^*(t)), \\ \dot{\boldsymbol{\lambda}}(t) = \partial^T_{\boldsymbol{x}} H(\boldsymbol{x}(t),\boldsymbol{\lambda}(t),\boldsymbol{u}^*(t)), \end{cases} \tag{6}$$

with the boundary conditions given by the original boundary conditions augmented with the transversality conditions:

$$\begin{cases} \boldsymbol{g}(\boldsymbol{x}(t_f)) = \boldsymbol{0}, \\ \mathcal{A}\nabla\boldsymbol{g}(\boldsymbol{x}(t_f)) = \boldsymbol{\lambda}(t_f). \end{cases} \tag{7}$$

Here $\mathcal{A} \in \mathbb{R}^{n\times k}$ is a matrix multiplier. The optimal control $\boldsymbol{u}^*(t)$ should satisfy the minimization of the Hamiltonian at each t:

$$\boldsymbol{u}^*(t) = \arg\min_{\boldsymbol{u}\in\mathcal{U}} H(\boldsymbol{x},\boldsymbol{\lambda},\boldsymbol{u}). \tag{8}$$

Equations (6), (7) and (8) together complete the PMP for the fixed terminal time problem (3). For the free terminal time problem (4), besides (6), (7) and (8), we need the following condition to determinate the optimal terminal time t_f:

$$H(\boldsymbol{x}(t_f),\boldsymbol{\lambda}(t_f),\boldsymbol{u}^*(t_f)) = 0. \tag{9}$$

2.2 Optiaml landing problem

The dynamics of the quadrotor UAV is modeled as follows

$$\begin{cases} \dot{\boldsymbol{p}} = \boldsymbol{R}^T(\boldsymbol{\eta})\boldsymbol{v}_b \\ \dot{\boldsymbol{v}}_b = -\boldsymbol{w}_b\times\boldsymbol{v}_b - \boldsymbol{R}(\boldsymbol{\eta})\boldsymbol{g} + \dfrac{1}{m}\boldsymbol{f}_u \\ \dot{\boldsymbol{\eta}} = \boldsymbol{K}(\boldsymbol{\eta})\boldsymbol{w}_b \\ \dot{\boldsymbol{w}}_b = -\boldsymbol{J}^{-1}\boldsymbol{w}_b\times\boldsymbol{J}\boldsymbol{w}_b + \boldsymbol{J}^{-1}\boldsymbol{\tau}_u, \end{cases} \tag{10}$$

where $\boldsymbol{p} = (x,y,z)^T$ is the inertial position in the earth frame and $\boldsymbol{v}_b = (v_x,v_y,v_z)$ is the inertial velocity of the quadrotor in the body frame. $\boldsymbol{\eta} = (\phi,\theta,\psi)$ is the attitude of the quadrotor in the earth frame defined by the Euler angles: roll(ϕ), pitch(θ) and yaw(ψ). $\boldsymbol{w}_b = (p,q,r)^T$ denotes the angular velocity in the body frame. $\boldsymbol{f}_u = (0,0,T)^T$ and $\boldsymbol{\tau}_u = (\tau_x,\tau_y,\tau_z)^T$ are the total thrust and body torques from four rotors, which are forces applied by the control variables to adjust the quadrotor's dynamics. The constants m and $\boldsymbol{g} = (0,0,g)^T$ denote the mass and the gravity vector, respectively. $\boldsymbol{R}(\boldsymbol{\eta}) \in SO(3)$ and $\boldsymbol{K}(\boldsymbol{\eta})$ are given matrix functions denoting the direction cosine matrix and attitude kinematic matrix. $\boldsymbol{J}$ denotes the constant inertia matrix. We let $\boldsymbol{x} = (\boldsymbol{p}^T,\boldsymbol{v}_b^T,\boldsymbol{\eta}^T,\boldsymbol{w}_b^T)^T \in \mathbb{R}^{12}$ so that $\boldsymbol{x}$ denotes the state variable of our optimal landing problem. Meanwhile, we denote the control as $\boldsymbol{u} = (T,\tau_x,\tau_y,\tau_z)^T$. Then we have $\boldsymbol{f}_u = A\boldsymbol{u}$ and $\boldsymbol{\tau}_u = B\boldsymbol{u}$ with A and B are two constant matrices.

We aim to solve the quadrotor landing problem with minimum time and control effort under the dynamics described above. That is, to find the optimal controls to steer the UAVs from some initial states $\boldsymbol{x}_0 \in \mathcal{S}_0$ to a given target $\boldsymbol{x}_{t_f} \in \mathcal{S}_{t_f}$ satisfying $\boldsymbol{g}(\boldsymbol{x}_{t_f}) = \boldsymbol{0}$. For the landing problem, $\mathcal{S}_{t_f}$ has the form $\{\boldsymbol{x}_{t_f} \mid \boldsymbol{p}(t_f) = \boldsymbol{v}(t_f) = \boldsymbol{w}(t_f) = \boldsymbol{0}; \phi(t_f) = \theta(t_f) = 0\}$. The running cost L is defined as

$$L(\boldsymbol{x},\boldsymbol{u}) = 1 + (\boldsymbol{u}-\boldsymbol{u}_d)^T Q_u(\boldsymbol{u}-\boldsymbol{u}_d),$$

where $\boldsymbol{u}_d = (mg,0,0,0)$ represents the reference control that balances with gravity and $Q_u = \mathrm{diag}(1,1,1,1)$ represents the weight matrix characterizing the cost of deviating from the reference control. Then the description of the optimal landing problem is complete. With the aforementioned Pontryagin's minimum principle, we can transform both optimal landing problems with fixed terminal time and free terminal time to the corresponding TPBVPs.

3. MACHINE LEARNING ENHANCED METHOD FOR SOLVING OPTIMAL LANDING PROBLEM

This section presents our machine learning enhanced algorithm for solving the optimal landing problem, accompanied by the numerical results on the optimal landing problem of the quadrotor UAVs. The same system parameters as in Madani and Benallegue (2006) are used in this paper: the mass $m = 2kg$, the gravity $g = 9.81m/s^2$, the moment of of inertia $J_x = J_y = J_z/2 = 1.2416kg\cdot m^2$. We specify the domain of initial state as $\mathcal{S}_0 = \{x,y \in [-10,10], z \in [5,100], v_x,v_y,v_z \in [-0.5,0.5], \theta,\phi \in [-\pi/4,\pi/4], \psi \in [-\pi,\pi]; \boldsymbol{w} = \boldsymbol{0}\}$. We always uniformly sample 100 initial positions $\boldsymbol{x}_0$ from $\mathcal{S}_0$ to estimate the success rate and average computation time of the algorithm. Throughout the paper, we will use the BVP solver in Kierzenka and Shampine (2001) to solve the TPBVP. Figure 1 presents an example of the optimal landing path of the quadrotor UAV from the starting position $\boldsymbol{x}_0$ to the origin.

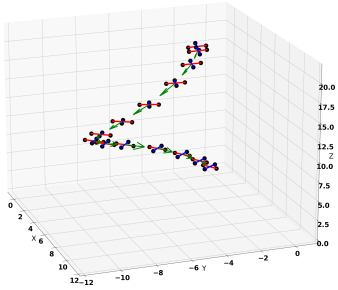

Fig. 1. An example of the optimal trajectory for the landing problem

3.1 Use Solution to the fixed terminal time as initial guess

Although we have the PMP (6)–(9) characterizing the solution of the optimal landing problem with free terminal time, we observe that the associated TPBVP is numerically challenging to solve. The main reason is the lack of a good initial guess for t_f and the paths of $\boldsymbol{x}(t),\boldsymbol{\lambda}(t)$. Without any prior knowledge, the simplest choice is to

initialize t_f with a reasonable scalar and $\boldsymbol{x}(t), \boldsymbol{\lambda}(t)$ with constant zero. However, the BVP solver hardly converges under this choice. Table 1 reports its success rate with a few different initial guesses of t_f. We can see that, with zero initialization of the path, the success rate of solving free terminal time TPBVP is always extremely low, regardless of the initial guess of t_f.

Table 1. Solving TPBVP corresponding to the free terminal time problems with zero initialization

initial guess $\tilde{t}_f^*$	4	8	12	16	20	24
success rate	3%	4%	0%	0%	1%	1%

Table 1 suggests that the initial guess of $\boldsymbol{x}(t)$ and $\boldsymbol{\lambda}(t)$ plays an important role in the convergence of the BVP solver when solving the free terminal time problem. To address this issue, we notice that the solution of the free terminal time problem is also the solution of a corresponding fixed terminal time problem if the fixed terminal time t_f equals the optimal terminal time t_f^*. In other words, if we have a reasonable guess of t_f^*, the solution of the fixed terminal time problem can provide us a good initial guess to the free terminal time problem. Moreover, the fixed terminal time problem is easier to solve with many efficient techniques, such as marching methods introduced in the next subsection. Therefore, we can first guess a value of the optimal terminal time $\tilde{t}_f^*$ and solve the fixed terminal time problem with $t_f = \tilde{t}_f^*$. Then we use its solution as the initial guess to solve the free terminal time problem. This approach can be viewed as a warm start method for solving the optimization problem. The corresponding algorithm is summarized in Algorithm 1, in which we again use zero to initialize the paths. The corresponding numerical results are presented in Figure 2. In Figure 2, the label "free" means the success rate of the free terminal time problem while the label "fix/free" means the success rate of problems that the fix terminal time problem has been solved while the corresponding free terminal time problem failed. Because we will not solve the free terminal time problem when the fixed terminal time problem fails, the success rate of the free terminal time problem is always lower than the success rate of the fixed terminal time problem. Comparing Figure 2 with Table 1, we can see that warming start with the solution to the fixed terminal time problem significantly improves the success rate, although the rate is still not high enough for practical applications.

Algorithm 1 Warm start with fixed terminal time solution

1: **Input:** The initial state x_0; the guess value of the optimal terminal time $\tilde{t}_f^*$.
2: Solve the fixed time problem with $t_f = \tilde{t}_f^*$ using zero initialization.
3: Solve the free time problem by using the solution of the corresponding fixed time problem as initial guess.
4: **Output:** The solution of the free time problem.

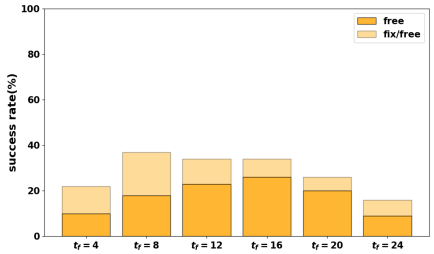

Fig. 2. Sucess rate of Algoriuthm 1: warm start with fixed terminal time solution.

3.2 Space-marching for solving the fixed terminal time problem

To further improve the success rate of solving the TPBVP corresponding to the fixed terminal time problem, we propose a space-marching method (Murio, 2002) tailored to the optimal landing problem. Its intuition is as follows. Solving the fixed time problem is still difficult since the initial state $\boldsymbol{x}_0$ is far away from the terminal set $\mathcal{S}_{t_f}$. We can solve a simpler fixed time problem in which the initial state is closer to the terminal state, while the solution is not far from the original fixed time problem. After the simpler fixed time problem is solved, we can use its solution as the initial guess to solve the original harder one. To present this method in a more general and systematic way, we say $\boldsymbol{x}_{end}$ is a terminal state if there exists $\boldsymbol{u} \in \mathcal{U}$ such that for any $t_f \geq 0$, the path

$$\boldsymbol{x}(t) \equiv \boldsymbol{x}_{end},\ \boldsymbol{u}(t) \equiv \boldsymbol{u},\ 0 \leq t \leq t_f$$

is the optimal path for the fixed-time problem with t_f as terminal time and $\boldsymbol{x}_0 = \boldsymbol{x}_{end}$. We always assume such a terminal state exists for the optimal landing problem. In this paper, we choose the origin point (of the 12-dimensional state space) as the terminal state. Then we evenly select K points in the line segment from $\boldsymbol{x}_{end}$ to $\boldsymbol{x}_0$, and denote them as $\{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \cdots, \boldsymbol{x}_0^K\}$ according to their increasing distances to $\boldsymbol{x}_{end}$ ($\boldsymbol{x}_0^K = \boldsymbol{x}_0$). In each marching step, we solve the fixed time problem with the initial state $\boldsymbol{x}_0^k$ by using the solution obtained from the fixed time problem with the initial state $\boldsymbol{x}_0^{k-1}$ as the initial guess. The process repeats until $k = K$. This algorithm is called warm start with fixed terminal time solution through space-marching, as summarized in Algorithm 2.

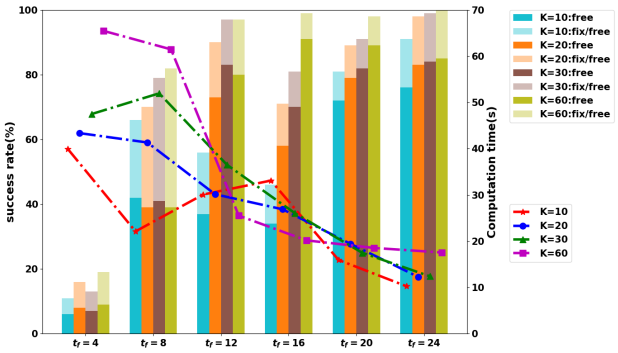

Fig. 3. Success rate and computation time of Algorithm 2: warm start with fix terminal time solution through space-marching with different K.

Algorithm 2 Warm start with fixed terminal time solution through space-marching

1: **Input:** The initial state $\boldsymbol{x}_0$; the guess value of the optimal terminal time $\tilde{t}_f^*$; the marching number K.
2: Evenly select K points in the line segment from $\boldsymbol{x}_{end}$ to $\boldsymbol{x}_0$, and denotes them as $\{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \cdots, \boldsymbol{x}_0^K\}$.
3: Set the initial guess $\boldsymbol{x}_{aug}$ as the zero initial guess.
4: **for** $k = 1, 2, \cdots, K$ **do**
5: Solve the fixed terminal time problem with initial state $\boldsymbol{x}_0^k$ by using the initial guess $\boldsymbol{x}_{aug}$.
6: replace the initial guess $\boldsymbol{x}_{aug}$ with the solution.
7: **end for**
Solving the free time problem with $\boldsymbol{x}_{aug}$ as the initial guess of the path and $\tilde{t}_f^*$ as the initial guess of terminal time.
8: **Output:** The solution of the free terminal time problem with initial state $\boldsymbol{x}_0$.

Figure 3 shows the success rate and computation time of Algorithm 2 with different choices of the initial guess $\tilde{t}_f^*$ and K. We can see that most fixed terminal time problems can be solved with a high success rate if the predicted terminal time $\tilde{t}_f^*$ is not too small and the marching number K is large enough. However, the free terminal time problem may not be solved successfully if the guessed terminal time is not close enough to the real terminal time. To further improve the success rate of the free terminal time problem, we need a more accurate prediction of the optimal terminal time.

3.3 Predict the Optimal Terminal Time

Now we consider empowering Algorithm 2 by predicting the optimal terminal time as a function of the initial state $\boldsymbol{x}_0$ through a linear model or a neural network. To do so, we first prepare a dataset for supervised learning. We randomly select 300 initial positions $\boldsymbol{x}_0$ and use Algorithm 3 with $K = 60, \tilde{t}_f^* = 24$ to collect 300 optimal landing paths. We select 100 positions (uniformly in time) on each optimal landing path and store the corresponding optimal landing time to obtain the training data. We have 30000 pairs of starting positions and optimal ending times for training in total. We then use them to optimize a linear model and a neural network model (3 three hidden layers and 64 neurons in each layer) based on the objective being the squared difference between the predicted $\tilde{t}_f^*$ and the truth optimal terminal time. Then, when we need to solve a free terminal time problem with a new initial state $\boldsymbol{x}_0$, we first use the linear model or the neural network to predict the optimal terminal time $\tilde{t}_f^*$ associated with $\boldsymbol{x}_0$ and use Algorithm 2 to solve the free terminal time problem.

The success rates of using a linear model or a neural network to predict the optimal terminal time with different space-marching numbers are presented in Figure 4. Comparing the results with those using the guessed constant optimal terminal time independent of the initial state in Figure 3, we can see that both the linear model and neural network model achieves much higher success rates. Using a neural network attains higher success rates and takes less computation time because it can more accurately predict the optimal terminal time. With the help of neural networks and the space-marching with $K = 60$, we achieve a 99% successful rate and the average computational time is about 17 seconds, which performs the best among the methods considered in this paper.

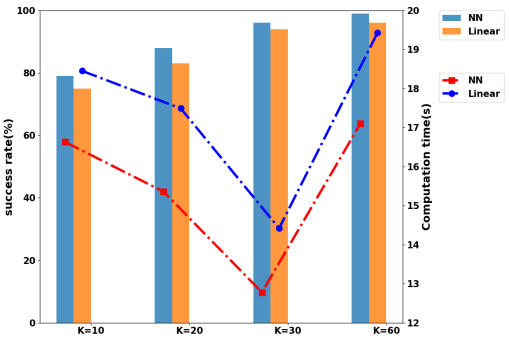

Fig. 4. NN prediction of t_f as the input to Algorithm 2 vs. Linear prediction of t_f as the input to Algorithm 2.

4. SUMMARY AND DISCUSSION

In this paper, we propose a machine learning enhanced method to solve the optimal control problem of quadrotor landing. To solve the free terminal TPBVP, we first solve a fixed terminal time TPBVP and then use its solution as an initial guess. The initial guess for the optimal landing time is predicted by a neural network that is trained in advance. A space-marching method is proposed to improve the efficiency of solving the fixed terminal time problem. We demonstrate the effectiveness of the proposed method through a series of experiments.

When solving the optimal landing problem, we have observed that directly learning the mapping from states to controls or value functions with a DNN and using its prediction as an initial guess for the TPBVP leads to divergence. Improving the stability of neural network-based control is an important future direction of research.

Abstract: We consider mobile robots described through unicycle dynamics equipped with range sensors and cameras, one in the front and one in the back providing measurements of the distance and misalignment to a target. We derive locally asymptotically stabilizing control laws driving the robot to the target position and orientation. The local control laws are combined into a hybrid global stabilizer, switching between control laws relying on the measurements from the front and rear sensors. Using Lyapunov arguments in the local setting as well as in the hybrid systems formulation, we prove global asymptotic stability of the target set for the hybrid closed-loop system. The results are illustrated on numerical examples.

1. INTRODUCTION & MOTIVATION

Driving a robot described through unicycle dynamics to a target set with a particular fixed final orientation is a difficult task due to nonholonomic constraints. In particular, the origin of the unicycle dynamics cannot be globally asymptotically stabilized through a static state feedback Brockett (1983). Indeed unicycle dynamics do not satisfy the so-called Brockett conditions. Control laws guaranteeing convergence to the origin, thus imply the necessity to combine the controller designs with reference tracking or path following approaches or to rely on discontinuous feedback laws instead. We refer to Tzafestas (2013) as a general reference for mobile robots and control.

In this work, we follow the second path, i.e., we consider discontinuous feedback laws. While Lipschitz-continuous feedback laws guarantee some intrinsic robustness properties with respect to stability and with respect to existence and uniqueness of solutions, well-posedness and robustness is more difficult to achieve with discontinuous feedback laws (Sontag (1999)). To define a globally asymptotically stabilizing feedback we use a hybrid systems formalism and borrow results from hybrid Lyapunov theory (Goebel et al. (2012)). We define locally stabilizing control laws and orchestrate them through a switching mechanism to obtain global results. The local controller design is motivated through the results and derivations in Aicardi et al. (1995), whereas the global design and the setup are motivated and derived differently.

We consider mobile robots, which in Cartesian coordinates are described through the dynamics

$$\dot{x} = \begin{bmatrix} \dot{p}_1 \\ \dot{p}_2 \\ \dot{\phi} \end{bmatrix} = f(x,u) = \begin{bmatrix} u_1 \cos(\phi) \\ u_1 \sin(\phi) \\ u_2 \end{bmatrix}, \tag{1}$$

where $p = [p_1 \ p_2]^T \in \mathbb{R}^2$ captures the unicycle position in the plane, $\phi \in \mathbb{R}$ captures its orientation and the input $u = [u_1 \ u_2]^T \in \mathbb{R}^2$ captures the velocity and angular velocity.

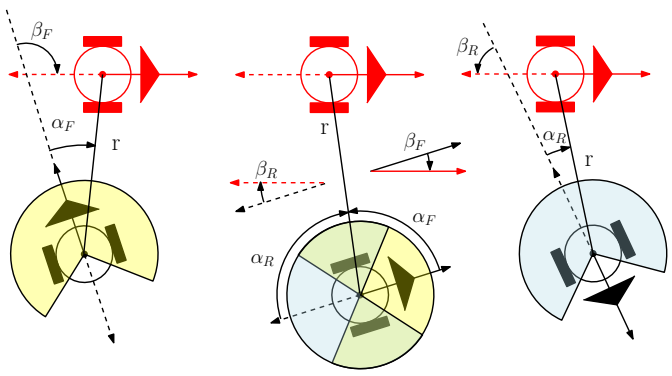

Fig. 1. The robot is equipped with range sensors and cameras (a front and a rear camera) with overlapping fields of view, providing measurements $(r, \alpha_\mathrm{F}, \beta_\mathrm{F})$ and $(r, \alpha_\mathrm{R}, \beta_\mathrm{R})$, respectively. Each measurement is only available when the target is in the camera's field of view $\alpha_i \in [-\frac{\pi}{2} - \delta, \frac{\pi}{2} + \delta]$, $i \in \{\mathrm{F}, \mathrm{R}\}$.

We assume that the mobile robot is equipped with various sensors, including a range sensor, measuring the distance $r \in \mathbb{R}_{\geq 0}$ to the target position, and two cameras (a front and a rear camera). The cameras provide measurements of the misalignment of the heading of the robot in terms of angles α_F and α_R corresponding to measurements from the front and the rear camera. In addition, the cameras provide measurements of the angles β_F and β_R, as represented in Figure 1. By combining α_i and β_i, $i \in \{\mathrm{F}, \mathrm{R}\}$, the mismatch of the robot orientation and the target orientation is defined. The setting is visualized in Figure 1, where it is apparent that, the field of view of both front and rear cameras are as follows

$$\alpha_\mathrm{F}, \alpha_\mathrm{R} \in [-\tfrac{\pi}{2} - \delta, \tfrac{\pi}{2} + \delta], \tag{2}$$

where $\delta \in (0, \frac{\pi}{2})$ induces some overlap and ensures that the combined fields of view are covering an area of 360°. While in certain configurations only one camera is available (left and right cases in Figure 1), in some configurations the target is in the field of view of both cameras. This motivates the use of a hybrid controller, which switches between measurements from the two cameras and makes

Bayreuth, Germany, 12-16 September 2022

use of different error dynamics describing the mismatch of the robot and the target position and orientation.

2. ROBOT DYNAMICS

In this section we derive dynamics in local coordinates defined as $z_i = [r_i \ \beta_i \ \alpha_i]^T$, $i \in \{\mathrm{R}, \mathrm{F}\}$. The relation between the mobile robot in Cartesian coordinates and the local coordinates related to the sensor measurements, is described through the coordinate transformations

$$\begin{bmatrix} p_1 \\ p_2 \\ \phi \end{bmatrix} = \begin{bmatrix} r\cos(\alpha_\mathrm{R} - \beta_\mathrm{R}) \\ r\sin(\alpha_\mathrm{R} - \beta_\mathrm{R}) \\ -\beta_\mathrm{R} \end{bmatrix}, \quad \begin{bmatrix} p_1 \\ p_2 \\ \phi \end{bmatrix} = \begin{bmatrix} r\cos(\alpha_\mathrm{F} - \beta_\mathrm{F} - \pi) \\ r\sin(\alpha_\mathrm{F} - \beta_\mathrm{F} - \pi) \\ -\beta_\mathrm{F} \end{bmatrix} \tag{3}$$

where F and R again correspond to the front and rear cameras. The coordinate transformations (3) follow from trigonometric arguments applied to the variables defined and illustrated through Figure 2.

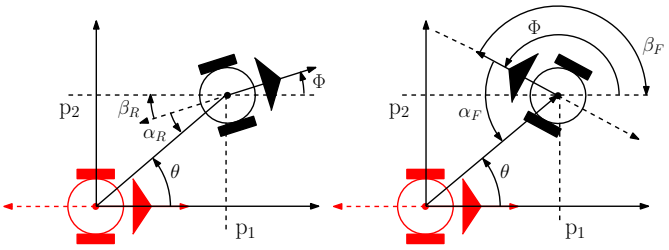

Fig. 2. Coordinate transformation from global Cartesian coordinates to local coordinates depending on the robot orientation.

The local coordinates are defined on the domain

$$z_i \in \mathcal{Z} := \mathbb{R}_{\geq 0} \times \mathbb{R} \times [-\tfrac{\pi}{2} - \delta, \tfrac{\pi}{2} + \delta], \quad i \in \{\mathrm{F}, \mathrm{R}\}, \tag{4}$$

for $\delta \in (0, \frac{\pi}{2})$, where the third component of z_i evolves in a bounded set as defined in (2). Whenever the target is in the field of view of both cameras (see the middle sketch in Figure 1), by simple geometric considerations we obtain

$$\begin{aligned} \alpha_\mathrm{F} &= \alpha_\mathrm{R} - \pi\,\mathrm{sign}(\alpha_\mathrm{R}), \qquad \beta_\mathrm{F} = \beta_\mathrm{R}, \\ \alpha_\mathrm{R} &= \alpha_\mathrm{F} - \pi\,\mathrm{sign}(\alpha_\mathrm{F}), \qquad \beta_\mathrm{R} = \beta_\mathrm{F}. \end{aligned} \tag{5}$$

Moreover, again due to the fact that $\delta > 0$ by assumption, for $r \neq 0$, i.e., $|p| \neq 0$, we can equivalently represent the robot through Cartesian coordinates x or through at least one of the local coordinates z_i, $i \in \{\mathrm{F}, \mathrm{R}\}$.

As a next step, we derive from (1) and (3) the dynamics in the local coordinates

$$\dot{z}_\mathrm{R} = f_\mathrm{R}(z_\mathrm{R}, v) \qquad \text{and} \qquad \dot{z}_\mathrm{F} = f_\mathrm{F}(z_\mathrm{F}, v), \tag{6}$$

with a transformed input $v \in \mathbb{R}^2$.

Lemma 1. Whenever $r \neq 0$, the dynamics (1) can be equivalently represented through (6) where

$$f_\mathrm{R}(z_\mathrm{R}, v) = \begin{bmatrix} v_1 r\cos(\alpha_\mathrm{R}) \\ -v_2 \\ -v_1\sin(\alpha_\mathrm{R}) - v_2 \end{bmatrix}, f_\mathrm{F}(z_\mathrm{F}, v) = \begin{bmatrix} -v_1 r\cos(\alpha_\mathrm{F}) \\ -v_2 \\ v_1\sin(\alpha_\mathrm{F}) - v_2 \end{bmatrix} \tag{7}$$

with transformed input $v_1 r = u_1$ and $v_2 = u_2$. ⌟

Proof. We start with a derivation of f_R. Let $r \neq 0$ for the remainder of the proof and define the angle $\theta = \alpha_\mathrm{R} - \beta_\mathrm{R}$.

Proceeding as in (Nešić et al., 2011, eq. (41)), we provide an alternative expression of the Jacobian $\frac{\partial p}{\partial p} = I$. In particular, using the definition of θ as well as (3), the matrix can be rewritten as

$$\begin{aligned} \frac{\partial p}{\partial p} &= \begin{bmatrix} \frac{\partial r}{\partial p_1}\cos(\theta) & \frac{\partial r}{\partial p_2}\cos(\theta) \\ \frac{\partial r}{\partial p_1}\sin(\theta) & \frac{\partial r}{\partial p_2}\sin(\theta) \end{bmatrix} + r \begin{bmatrix} -\sin(\theta)\frac{\partial \theta}{\partial p_1} & -\sin(\theta)\frac{\partial \theta}{\partial p_2} \\ \cos(\theta)\frac{\partial \theta}{\partial p_1} & \cos(\theta)\frac{\partial \theta}{\partial p_2} \end{bmatrix} \\ &= \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix} \begin{bmatrix} \frac{\partial r}{\partial p_1} & \frac{\partial r}{\partial p_2} \end{bmatrix} + r \begin{bmatrix} -\sin(\theta) \\ \cos(\theta) \end{bmatrix} \begin{bmatrix} \frac{\partial \theta}{\partial p_1} & \frac{\partial \theta}{\partial p_2} \end{bmatrix} \\ &= \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix} \frac{\partial r}{\partial p} + r \begin{bmatrix} -\sin(\theta) \\ \cos(\theta) \end{bmatrix} \frac{\partial \theta}{\partial p}. \end{aligned}$$

With the definition $J = \left[\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right]$ and the observations that

$$\frac{p}{r} = \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix} \quad \text{and} \quad Jp = r \begin{bmatrix} -\sin(\theta) \\ \cos(\theta) \end{bmatrix}, \tag{8}$$

for $r \neq 0$, the calculations above can be further simplified and summarized as

$$I = \frac{\partial p}{\partial p} = \frac{\partial}{\partial p}\left(r \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix}\right) = \frac{1}{r} p \frac{\partial r}{\partial p} + Jp \frac{\partial \theta}{\partial p}. \tag{9}$$

Note that $p^T J p = 0$ follows from the definition of J. Hence, left-multiplying (9) by p^T gives

$$p^T = \tfrac{1}{r} p^T p \tfrac{\partial r}{\partial p} + p^T J p \tfrac{\partial \theta}{\partial p} = \tfrac{r^2}{r} \tfrac{\partial r}{\partial p} = r \tfrac{\partial r}{\partial p}.$$

Similarly, the following equations hold

$$(Jp)^T I = \tfrac{1}{r} p^T J^T p \tfrac{\partial r}{\partial p} + p^T p \tfrac{\partial \theta}{\partial p} = r^2 \tfrac{\partial \theta}{\partial p},$$

which leads to the partial derivatives

$$\frac{\partial r}{\partial p} = \tfrac{1}{r} p^T \quad \text{and} \quad \frac{\partial \theta}{\partial p} = \tfrac{1}{r^2} (Jp)^T. \tag{10}$$

With these calculations, the definition of the function f_B follows from (1):

$$\begin{aligned} \dot{r} &= \tfrac{\partial r}{\partial p}\dot{p} = \tfrac{1}{r} p^T \dot{p} = \tfrac{1}{r} \begin{bmatrix} r\cos(\theta) & r\sin(\theta) \end{bmatrix} \begin{bmatrix} u_1\cos(\phi) \\ u_2\sin(\phi) \end{bmatrix} \\ &= u_1[\cos(\theta)\cos(\phi) - \sin(\theta)\sin(\phi)] = v_1 r\cos(\phi - \theta) \\ &= v_1 r\cos(-\beta_\mathrm{R} - \alpha_\mathrm{R} + \beta_\mathrm{R}) = v_1 r\cos(\alpha_\mathrm{R}) \\ \dot{\theta} &= \tfrac{\partial \theta}{\partial p}\dot{p} = \tfrac{1}{r^2} p^T J^T \dot{p} = \tfrac{1}{r^2} \begin{bmatrix} r\cos(\theta) & r\sin(\theta) \end{bmatrix} \begin{bmatrix} u_1\sin(\phi) \\ -u_1\cos(\phi) \end{bmatrix} \\ &= u_1(\cos(\theta)\sin(\phi) - \sin(\theta)\cos(\phi)) = v_1\sin(\phi - \theta)\alpha_\mathrm{R}) \\ &= -v_1\sin(\alpha_\mathrm{R}) \\ \dot{\beta}_\mathrm{R} &= -\dot{\phi} = -v_2 \\ \dot{\alpha}_\mathrm{R} &= \dot{\beta}_\mathrm{R} + \dot{\theta} = -v_2 - v_1\sin(\alpha_\mathrm{R}). \end{aligned}$$

Observe that for f_F we need to consider the relation $\alpha_\mathrm{R} = \alpha_\mathrm{F} - \pi$ and thus the representation f_F follows. □

While Lemma 1 excludes the case $r = 0$, note that the functions f_R and f_F are well-defined for $r = 0$.

3. LOCAL CONTROLLER DESIGN

In this section, we derive control laws locally asymptotically stabilizing the set

$$\mathcal{A} = \{0\} \times \mathbb{R} \times \{0\} \tag{11}$$

as well as the origin of the dynamical system (6). The Lyapunov construction is inspired by Aicardi et al. (1995).

Lemma 2. Let the feedback gains $k_r, k_\alpha \in \mathbb{R}_{>0}$ be arbitrary. Consider the dynamics (6) with $z_\mathrm{R} \in \mathcal{Z}$. Then

$$v_\mathrm{R} = \begin{bmatrix} -k_r\cos(\alpha_\mathrm{R}) \\ k_r\cos(\alpha_\mathrm{R})\sin(\alpha_\mathrm{R}) + k_\alpha\alpha_\mathrm{R} \end{bmatrix} \tag{12}$$

locally asymptotically stabilizes the set $\mathcal{A}$ in (11). Moreover, $V(z_\mathrm{R}) = \frac{1}{2}(r^2 + \alpha_\mathrm{R}^2)$ is a Lyapunov function for the closed-loop dynamics with respect to $\mathcal{A}$. ⌟

Proof. First observe that $\frac{1}{2}|z_\mathrm{R}|_\mathcal{A}^2 \leq V(z_\mathrm{R}) \leq \frac{1}{2}|z_\mathrm{R}|_\mathcal{A}^2$, i.e., V radially unbounded. Moreover, the directional derivative of V along the dynamics satisfies

$$\begin{aligned}\langle \nabla V(z_{\mathrm{R}}), & f_{\mathrm{R}}(z_{\mathrm{R}}, v_{\mathrm{R}})\rangle \\ &= r^2 v_{\mathrm{R}_1}\cos(\alpha_{\mathrm{R}}) + \alpha(-v_{\mathrm{R}_2} - v_{\mathrm{R}_1}\sin(\alpha_{\mathrm{R}})) \\ &= -k_r r^2\cos^2(\alpha_{\mathrm{R}}) - k_\alpha \alpha_{\mathrm{R}}^2 < 0,\end{aligned}$$

and thus $\frac{d}{dt}V(z_{\mathrm{R}}(t)) < 0$ for all $z_{\mathrm{R}} \in \mathbb{R}^3 \backslash \mathcal{A}$ which implies asymptotic stability of $\mathcal{A}$. □

To additionally ensure that $\beta_{\mathrm{R}}(t) \to 0$ for $t \to \infty$, we may include an additional term in the feedback law v_{R} and in the Lyapunov function.

Lemma 3. Let $k_r, k_\alpha, k_\beta \in \mathbb{R}_{>0}$ be arbitrary. Consider the dynamics (6) with $z_{\mathrm{R}} \in \mathcal{Z}$. Then the control law

$$v_{\mathrm{R}} = \begin{bmatrix} -k_r\cos(\alpha_{\mathrm{R}}) \\ k_r\cos(\alpha_{\mathrm{R}})\sin(\alpha_{\mathrm{R}}) + k_\alpha\alpha_{\mathrm{R}} + k_\beta(\alpha_{\mathrm{R}} - \beta_{\mathrm{R}})\frac{\cos(\alpha_{\mathrm{R}})\sin(\alpha_{\mathrm{R}})}{\alpha_{\mathrm{R}}} \end{bmatrix} \tag{13}$$

is well-defined for all $z_{\mathrm{R}} \in \mathcal{Z}$, locally asymptotically stabilizes the origin $0 \in \mathbb{R}^3$ and $V(z_{\mathrm{R}}) = \frac{1}{2}(r^2 + \frac{k_\beta}{k_r}(\alpha_{\mathrm{R}} - \beta_{\mathrm{R}})^2 + \alpha_{\mathrm{R}}^2)$ is monotonically decreasing for all $z_{\mathrm{R}} \in \mathcal{Z}$. ⌟

Proof. First note that $\lim_{\alpha_{\mathrm{R}}\to 0}\frac{\sin(\alpha_{\mathrm{R}})}{\alpha_{\mathrm{R}}} = 1$ and thus the feedback law is well-defined. Moreover, since the matrix $\begin{bmatrix} k_\beta + k_r & -k_\beta \\ -k_\beta & k_\beta \end{bmatrix}$ is positive definite, V is radially unbounded. Extending the derivations in Lemma 2, it holds that

$$\begin{aligned}&\langle \nabla V(z_{\mathrm{R}}), f_{\mathrm{R}}(z_{\mathrm{R}}, v_{\mathrm{R}})\rangle \\ &= r^2 v_{\mathrm{R}_1}\cos(\alpha_{\mathrm{R}}) + \tfrac{k_\beta}{k_r}(-v_{\mathrm{R}_2} - v_{\mathrm{R}_1}\sin(\alpha_{\mathrm{R}}) + v_{\mathrm{R}_2})(\alpha_{\mathrm{R}} - \beta_{\mathrm{R}}) \\ &\quad + \alpha_{\mathrm{R}}(-v_{\mathrm{R}_2} - v_{\mathrm{R}_1}\sin(\alpha_{\mathrm{R}})) \\ &= -k_r r^2\cos^2(\alpha_{\mathrm{R}}) - k_\alpha\alpha_{\mathrm{R}}^2 + k_\beta(\alpha_{\mathrm{R}} - \beta_{\mathrm{R}})\cos(\alpha_{\mathrm{R}})\sin(\alpha_{\mathrm{R}}) \\ &\quad - \alpha_{\mathrm{R}} k_\beta(\alpha_{\mathrm{R}} - \beta_{\mathrm{R}})\left(\cos(\alpha_{\mathrm{R}})\tfrac{\sin(\alpha_{\mathrm{R}})}{\alpha_{\mathrm{R}}}\right) \\ &= -k_r r^2\cos^2(\alpha_{\mathrm{R}}) - k_\alpha\alpha_{\mathrm{R}}^2 \le 0 \quad \forall\, z_{\mathrm{R}} \in \mathcal{Z}\end{aligned}$$

and thus, local stability of the origin follows. Moreover, for all $z_{\mathrm{R}} \in \mathcal{Z}$ for which V is not strictly decreasing it holds that $\dot{z}_{\mathrm{R}}^T = [\,0\ k_\beta\beta_{\mathrm{R}}\ k_\beta\beta_{\mathrm{R}}\,]$, whose right-hand side is unequal to zero for all $\beta_{\mathrm{R}} \neq 0$. Hence, local asymptotic stability follows from the Krasovskii-LaSalle invariance theorem (Vidyasagar, 1993, Theorem 5.3.77). □

Observe that through $k_\beta = 0$, Lemma 3 covers the result of Lemma 2 as a special case because (13) reduces to (12). For the z_{F}-dynamics in (6), using the same ideas, a result equivalent to Lemma 3 can be derived. We summarize this result in the following corollary.

Corollary 1. Let $k_r, k_\alpha, k_\beta \in \mathbb{R}_{>0}$ be arbitrary. Consider the dynamics (6) with $z_{\mathrm{F}} \in \mathcal{Z}$. Then the control law

$$v_{\mathrm{F}} = \begin{bmatrix} k_r\cos(\alpha_{\mathrm{F}}) \\ k_r\cos(\alpha_{\mathrm{F}})\sin(\alpha_{\mathrm{F}}) + k_\alpha\alpha_{\mathrm{F}} + k_\beta(\alpha_{\mathrm{F}} - \beta_{\mathrm{F}})\frac{\cos(\alpha_{\mathrm{F}})\sin(\alpha_{\mathrm{F}})}{\alpha_{\mathrm{F}}} \end{bmatrix} \tag{14}$$

is well-defined for all $z_{\mathrm{F}} \in \mathcal{Z}$, locally asymptotically stabilizes the origin $0 \in \mathbb{R}^3$ and $V(z_{\mathrm{F}}) = \frac{1}{2}(r^2 + \frac{k_\beta}{k_r}(\alpha_{\mathrm{F}} - \beta_{\mathrm{F}})^2 + \alpha_{\mathrm{F}}^2)$ is monotonically decreasing for all $z_{\mathrm{F}} \in \mathcal{Z}$. ⌟

4. A GLOBAL HYBRID STABILIZER

In this section we combine the two local control laws introduced in the preceding section in a hybrid systems formulation. As a first step, we introduce an additional discrete variable $q \in \{-1, 1\}$ where $q = -1$ represents the rear camera R and $q = 1$ represents the front camera F. In the overall system representation we consider the state

$$\xi = [r\ \beta\ \alpha\ q]^T \in \Xi \tag{15a}$$

where the pair (α, β) can either represent $(\alpha_{\mathrm{R}}, \beta_{\mathrm{R}})$ when $q = -1$ or $(\alpha_{\mathrm{F}}, \beta_{\mathrm{F}})$ when $q = 1$ and where the domain Ξ is defined as

$$\Xi := \mathbb{R}_{\ge 0} \times \mathbb{R} \times [-\tfrac{\pi}{2} - \delta, \tfrac{\pi}{2} + \delta] \times \{-1, 1\} \tag{15b}$$

for $\delta \in (0, \frac{\pi}{2})$. With this definition, the dynamics (6) can be summarized through the flow map

$$\dot{\xi} = \begin{bmatrix} \dot{r} \\ \dot{\beta} \\ \dot{\alpha} \\ \dot{q} \end{bmatrix} = \begin{bmatrix} -qv_1 r\cos(\alpha) \\ -v_2 \\ -v_2 + qv_1\sin(\alpha) \\ 0 \end{bmatrix}, \quad \xi \in \mathcal{C} \tag{15c}$$

and the feedback laws (13) and (14) are captured through

$$v = \begin{bmatrix} qk_r\cos(\alpha) \\ k_r\cos(\alpha)\sin(\alpha) + k_\alpha\alpha + k_\beta(\alpha - \beta)\cos(\alpha)\frac{\sin(\alpha)}{\alpha} \end{bmatrix} \tag{15d}$$

The set $\mathcal{C}$, denoting the flow set, is defined as

$$\mathcal{C} := \{\xi \in \Xi : |\alpha| \le \tfrac{\pi}{2} + \delta, |\beta| \le \tfrac{3}{2}\pi + \delta\}.$$

For the jump map and the jump set, we first define the functions

$$g_\beta(\xi) = \begin{bmatrix} r \\ \beta - 2\pi\,\mathrm{sign}(\beta) \\ \alpha \\ q \end{bmatrix},\ g_\alpha(\xi) = \begin{bmatrix} r \\ \beta \\ \alpha - \pi\,\mathrm{sign}(\alpha) \\ -q \end{bmatrix}$$

and the sets

$$\begin{aligned}\mathcal{D}_\alpha &:= \{\xi \in \Xi : |\alpha| \ge \tfrac{\pi}{2} + \delta \ \wedge\ |\beta| \le \tfrac{3}{2}\pi + \delta\}, \\ \mathcal{D}_\beta &:= \{\xi \in \Xi : |\beta| \ge \tfrac{3}{2}\pi + \delta\}.\end{aligned}$$

Then the jump map is defined as

$$\xi^+ \in G(\xi) = \begin{cases} \{g_\beta(\xi)\} & \text{if } \xi \in \mathcal{D}_\beta \backslash \mathcal{D}_\alpha, \\ \{g_\alpha(\xi)\} & \text{if } \xi \in \mathcal{D}_\alpha \backslash \mathcal{D}_\beta, \\ \{g_\alpha(\xi)\} \cup \{g_\beta(\xi)\} & \text{if } \xi \in \mathcal{D}_\alpha \cap \mathcal{D}_\beta, \end{cases} \tag{15e}$$

and the jump set is defined as the union

$$\mathcal{D} := \mathcal{D}_\beta \cup \mathcal{D}_\alpha. \tag{15f}$$

Note that $\beta^+ = \beta - 2\pi\,\mathrm{sign}(\beta)$ defined through g_β guarantees that β^+ and β differ by a multiple of 2π and $|\beta^+| < |\beta|$ for all $\xi \in \mathcal{D}_\beta$ (wherein $|\beta| \ge \frac{3}{2}\pi + \delta$). Thus, β^+ and β describe the same information with respect to the position of the robot but β^+ is closer to the target orientation $\beta = 0$. Similarly, $\alpha^+ = \alpha - \pi\,\mathrm{sign}(\alpha)$ defined through g_α captures the properties in (5) when the perspective of the cameras is switched. Additionally, from the definition of the hybrid system it is clear that multiple consecutive jumps are possible, but, due to the selection of the parameter δ, Zeno behavior is not possible. Finally, since (15) satisfies (Goebel et al., 2012, As. 6.5), then asymptotic stability is robust in the sense of (Goebel et al., 2012, Ch. 7).

Theorem 1. Let $\delta \in (0, \frac{\pi}{2})$, $k_r, k_\alpha \in \mathbb{R}_{>0}$ and $k_\beta \in (0, \frac{2\delta k_r}{3\pi}]$ be arbitrary. Then, the set $\mathcal{A}_q = \{0\} \times \{0\} \times \{0\} \times \{-1, 1\}$ is globally robustly asymptotically stable for the hybrid closed-loop system dynamics (15). Moreover, $V(\xi) = \frac{1}{2}(r^2 + \frac{k_\beta}{k_r}(\alpha - \beta)^2 + \alpha^2)$ is monotonically decreasing along solutions $\xi : \mathrm{dom}(\xi) \to \Xi$. ⌟

Proof. We have established local properties of the closed-loop dynamics in Lemma 3 and in Corollary 1. What is left to show, is that the function V is decreasing at discrete time updates. Let $\xi \in \mathcal{D}_\beta$. Then it holds that

$$\begin{aligned}V(\xi^+) - V(\xi) &= \tfrac{k_\beta}{2k_r}(\alpha^+ - \beta^+)^2 - \tfrac{k_\beta}{2k_r}(\alpha - \beta)^2 \\ &= \tfrac{k_\beta}{2k_r}\left[4(\alpha - \beta)\,\mathrm{sign}(\beta)\pi + 4\pi^2\right] \\ &= 2\tfrac{k_\beta}{k_r}\left[\alpha\,\mathrm{sign}(\beta)\pi - \beta\,\mathrm{sign}(\beta)\pi + \pi^2\right]\end{aligned}$$

$$\leq 2\tfrac{k_\beta}{k_r}\left[(\tfrac{\pi}{2}+\delta)\pi-(\tfrac{3}{2}\pi+\delta)\pi+\pi^2\right]=0.$$

Similarly, for $\xi \in \mathcal{D}_\alpha$ it holds that

$$\begin{aligned}
V(\xi^+)-V(\xi) &= \tfrac{k_\beta}{2k_r}(\alpha^+-\beta^+)^2+\tfrac{1}{2}(\alpha^+)^2-\tfrac{k_\beta}{2k_r}(\alpha-\beta)^2-\tfrac{1}{2}\alpha^2\\
&= \tfrac{k_\beta}{k_r}(\alpha-\beta)\operatorname{sign}(\alpha)\pi+\tfrac{k_\beta}{2k_r}\pi^2-|\alpha|\pi+\tfrac{1}{2}\pi^2\\
&= -\tfrac{k_\beta}{k_r}|\alpha|\pi+\tfrac{k_\beta}{k_r}\beta\operatorname{sign}(\alpha)\pi+\tfrac{k_\beta}{2k_r}\pi^2-|\alpha|\pi+\tfrac{1}{2}\pi^2\\
&= -\tfrac{k_\beta}{k_r}|\alpha|\pi+\beta\operatorname{sign}(\alpha)\pi+\tfrac{k_\beta}{2k_r}\pi^2-|\alpha|\pi+\tfrac{1}{2}\pi^2\\
&\leq -\tfrac{k_\beta}{k_r}(\tfrac{\pi}{2}+\delta)\pi+\tfrac{k_\beta}{k_r}(\tfrac{3\pi}{2}+\delta)\pi+\tfrac{k_\beta}{2k_r}\pi^2-(\tfrac{\pi}{2}+\delta)\pi+\tfrac{1}{2}\pi^2\\
&\leq -\delta\pi+\tfrac{3}{2}\tfrac{k_\beta}{k_r}\pi^2\leq 0
\end{aligned}$$

and where the last inequality follows from the assumption $k_\beta \leq \frac{2\delta k_r}{3\pi}$. Thus, V is monotonically decreasing and we can conclude global asymptotic stability. Finally, robustness follows from (Goebel et al., 2012, Thm 7.21). □

5. NUMERICAL SIMULATIONS

We illustrate the results derived in the preceding section based on numerical simulations. Figure 3 shows closed-loop solutions using the feedback law (15d) with $k_\beta = 0$, i.e., the final orientation ϕ (or β) is not penalized. In particular, closed-loop solutions for various initial conditions in the (p_1, p_2)-plane, as well as the evolution over time in the x and z coordinates are shown. The remaining gains are defined as $k_r = 2$ and $k_\alpha = 1$, respectively. Additionally, the parameter $\delta = \frac{\pi}{10}$ is used for the simulations. To illustrate robustness properties of the controller, ξ is replaced by $\xi + [\varepsilon_r\ \varepsilon_\beta\ \varepsilon_\alpha\ 0]^T$ in the right-hand side of (15c) in the simulations, where ε_r, ε_β and ε_α represent white Gaussian noise with zero mean and standard deviations $\sigma_r = 0.05$, $\sigma_\beta = \sigma_\alpha = \frac{3\pi}{180}$. As expected from the theoretical results, r and α converge to to origin, while the angle β does not necessarily converge to zero.

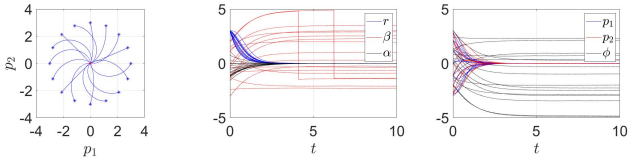

Fig. 3. Closed-loop solutions of the hybrid system (15) with controller gain $k_\beta = 0$.

For the simulations in Figure 4 the gain $k_\beta = 0$ has been replaced by $k_\beta = \frac{2\delta k_r}{3\pi}$. As expected, the controller ensures that additionally the orientation in terms of β or ϕ, respectively converges to zero for $t \to \infty$ according to Theorem 1. Figure 4 additionally shows the decrease of the function V defined in Theorem 1.

6. CONCLUSIONS

Inspired by the controller design in Aicardi et al. (1995), in this work we have proposed a globally stabilizing controller for unicycle dynamics relying on a hybrid systems formulation. The controller is motivated through mobile robots equipped with range sensors and front and rear cameras with overlapping fields of view.

While the control law derived in Theorem 1 is unbounded, a bounded globally stabilizing control law can be obtained by appropriately scaling v in (15d) (see (Braun et al., 2021, Theorem 2.3), for example). Such a scaling

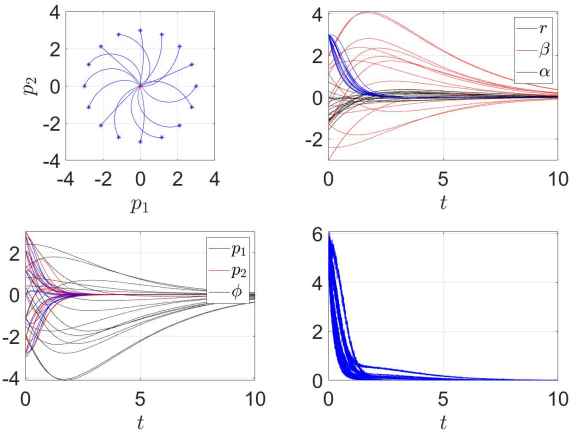

Fig. 4. Closed loop solutions of the hybrid system (15).

can also be used to handle unknown input gains, which have been encountered for example in Vinco et al. (2021), where the input gain depends on the (unknown) state of charge of the battery. Future work will focus on the analysis of robustness properties of the controller and will incorporate obstacle avoidance properties in the overall controller design. In this context we will take inspiration from Braun and Zaccarian (2021) and Marley et al. (2021).

Abstract: Given a C^1 function over a potentially high dimensional domain, the active subspace method seeks an affine subspace inside which the functions changes the most on average. This is done by finding the eigenvectors of a covariance matrix incorporating gradient information. In a similar vein, the active manifold method finds a manifold γ and if information on f is recovered along γ then f can be recovered on the connected component of a level set touching γ. An inherent limitation of the Active subspace technique is that it only considers affine subspaces (which may still be high dimensional). Inspired by methods in occupation kernel dynamic mode decomposition, we develop a notion of active subspace taking place in a Hilbert space which contains sufficient complexity to describe highly nonlinear level sets. In this learning problem, only function values along trajectories following the gradient direction of the function are required to determine this decomposition.

Keywords: active manifolds, occupation kernels, Liouville operators, reproducing kernels.

1. INTRODUCTION

Active subspaces is a dimension reduction technique originated by (Russi (2010)) and developed extensively by (Constantine (2015)). Current implementations of the active subspace method can capture "active" subspaces for functions whose level sets are subspaces of $\mathbb{R}^n$. However, for functions that have very nonlinear levelsets, their applicability is limited to a small neighborhood, where the functions may be effectively linearized. This limitation manifests theoretically in the covariance matrix leveraged in the construction of active subspaces which is finite dimensional and lacks the complexity necessary for discovering level-sets that are nonlinear manifolds.

To address this limitation, the present manuscript introduces a new operator valued kernel to stand in place of the covariance matrix of Constantine (2015). This operator valued kernel, based on the Liouville operator given in Section 4, acts on a vector valued RKHS, which is infinite dimensional. This kernel makes available an infinite collection of eigenvalues and eigenvectors that can be leveraged to decompose a function into "active" and "inactive" components, where the active component will effectively represent level sets of the original function. In this learning problem, only function values along trajectories following the gradient direction of the function are required to determine this decomposition. Significantly, the gradient of the original function need not be computed using the present method, which differs from established work (cf. Bridges et al. (2019)).

2. REVIEW OF ACTIVE SUBSPACE METHODS

Let $X \subseteq \mathbb{R}^m$ be a compact subset equipped with a probability measure ρ and suppose that $f : X \to \mathbb{R}$ is a $C^1(X)$ function. Let, $\nabla_x f = [\partial f/\partial x_1, \ldots, \partial f/\partial x_n]^\top$ and define the $n \times n$ matrix C given by

$$C = \mathbb{E}[(\nabla_x f)(\nabla_x f)^\top] = \left(\int_X \frac{\partial f}{\partial x_i} \frac{\partial f}{\partial x_j} \, d\rho \right)_{i,j=1,1}^{n,n}. \quad (1)$$

Since C is a positive semidefinite square matrix it admits an eigenvalue decomposition

$$C = W \Lambda W^\top, \quad \Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_n), \quad \lambda_1 \geq \ldots \geq \lambda_n \geq 0.$$

For a given $m < n$ we can further decompose Λ into a block diagonal matrix $\Lambda = \operatorname{diag}(\Lambda_1, \Lambda_2)$ where $\Lambda_1 = \operatorname{diag}(\lambda_1, \ldots, \lambda_m)$ and $\Lambda_2 = \operatorname{diag}(\lambda_{m+1}, \ldots, \lambda_n)$. Likewise W can be decomposed as $W = [W_1 \, W_2]$, where W_1 is $n \times m$, and

$$C = [W_1 \; W_2] \operatorname{diag}(\Lambda_1, \Lambda_2) [W_1 \; W_2]^\top.$$

Let w_i^1 for $i = 1, \ldots, m$ be the column vectors defined by W_1, For our choice of m we define $\mathcal{A} = \operatorname{span}\{w_i^1 \mid i = 1, \ldots, m\}$ as the active subspace of f. We can interpret C as the uncentered covariance for the gradient and since the eigenvalues in the decomposition are listed in decreasing order the active subspace A corresponds to directions which have greater average variation for the function f. In this paper we develop a generalized version of the active subspace method that enables the learning of nonlinear level sets through the introduction of an operator valued kernel.

3. MATHEMATICAL PRELIMINARIES

The main setting for this generalized approach is vector valued reproducing kernel Hilbert spaces (RKHS). For completeness we will also define reproducing kernel Hilbert spaces.

Definition 3.1. A RKHS, H, over a set X is a Hilbert space of real valued functions over the set X such that for all $x \in X$ the evaluation functional $E_x g := g(x)$ is bounded.

As such, the Riesz representation theorem guarantees, for all $x \in X$, the existence of a function $k_x \in H$ such that $\langle g, k_x\rangle_H = g(x)$, where $\langle\cdot,\cdot\rangle_H$ is the inner product for H.

The function k_x is called the reproducing kernel function at x, and the function $k(x,y) = \langle k_y, k_x\rangle_H$ is called the kernel function corresponding to H.

Vector valued RKHSs began to appear in learning theory over the past decade Carmeli et al. (2010), though their inception dates back at least as far as the 1950s (e.g. Pedrick (1957)).

Definition 3.2. Given a Hilbert space $\mathcal{Y}$ and a set X, a vector valued reproducing kernel Hilbert space, H, is a Hilbert space of functions mapping X to $\mathcal{Y}$, where for each $x \in X$ the evaluation mapping $E_x : H \to \mathcal{Y}$ given by $E_x(f) = f(x)$ is bounded. The operator valued kernel for a vector valued reproducing kernel Hilbert space is given by $K : X \times X \to \mathcal{B}(Y)$, $K(x,y) = E_x E_y^*$, here $\mathcal{B}(\mathcal{Y})$ denotes the bounded operators on $\mathcal{Y}$.

Boundedness of the functional $E_x : H \to \mathcal{Y}$ is equivalent to the boundedness of the functional $H \ni g \mapsto \langle g(x), y\rangle_{\mathcal{Y}}$ for each $x \in X$ and $y \in \mathcal{Y}$. The Riesz representation theorem guarantees for each $x \in X$ and $v \in \mathcal{Y}$ the existence of a function $K_{x,v} \in H$ such that $\langle g, K_{x,v}\rangle_H = \langle g(x), v\rangle_{\mathcal{Y}}$ for all $g \in H$.

Remark 1. In general, for a vector valued reproducing kernel Hilbert space H with kernel K, we can define $K_x v(\cdot) := K(\cdot, x)v \in H$. We note that $K_{x,v} = K_x v = E_x^*(v)$ since

$$(E_x^*(v))(y) = E_y E_x^*(v) = K(y,x)v = (K_x v)(y)$$

for all y and the reproducing property is given by

$$\langle f(x), v\rangle_{\mathcal{Y}} = \langle E_x(y), v\rangle_{\mathcal{Y}} = \langle f, E_x^*(v)\rangle_H = \langle f, K_{x,v}\rangle_H.$$

Definition 3.3. Let $X \subset \mathbb{R}^n$ be compact, H be a $\mathbb{R}^n$ valued RKHS of continuous functions over X, and $\gamma : [0,T] \to X$ be a bounded measurable trajectory. For every $v \in \mathbb{R}^n$, the functional $g \mapsto \left\langle \int_0^T g(\gamma(\tau))d\tau, v\right\rangle_{\mathbb{R}^n}$ is bounded, and may be respresented as $\left\langle \int_0^T g(\gamma(\tau))d\tau, v\right\rangle_{\mathbb{R}^n} = \langle g, \Gamma_{\gamma,v}\rangle_H$, for some $\Gamma_{\gamma,v} \in H$ by the Riesz representation theorem. The function $\Gamma_{\gamma,v}$ is called the occupation kernel corresponding to γ in H and $v \in \mathbb{R}^n$

Definition 3.4. Let $X \subset \mathbb{R}^n$ be compact, H be a $\mathcal{Y}$-valued RKHS of continuous functions over X, and $\gamma : [0,T] \to X$ be a bounded measurable trajectory. Define the operators E_γ and E_γ^* by

$$E_\gamma : H \to \mathcal{Y}, \quad g \mapsto \int_0^T g(\gamma(t))dt \in \mathcal{Y}$$

and

$$E_\gamma^* : \mathcal{Y} \to H, \quad v \mapsto \Gamma_{\gamma,v}.$$

We denote $E_\gamma^*(v) = \Gamma_{\gamma,v}$ by $\Gamma_\gamma v$. Let P be the set of bounded measurable trajectories. We call

$$\Gamma(x,\gamma) : X \times P \to \mathcal{B}(\mathcal{Y}), \quad \Gamma(x,\gamma) := E_x E_\gamma^*$$

the operator valued occupation kernel.

Proposition 3.5. For all $i \in \{1,\dots,n\}$ let $\mathscr{H}_i$ be real-valued reproducing kernel Hilbert spaces on a set X and $H = \bigoplus_{i=1}^n \mathscr{H}_i$ be the associated $\mathbb{R}^n$-valued reproducing kernel Hilbert space. For a given path $\gamma : [0,T] \to X \subset \mathbb{R}^k$, let $\Gamma_\gamma^i \in \mathscr{H}_i$ be the scalar valued occupation kernel associated to γ. The function $\Gamma_{\gamma,v} \in H$ is given by

$$\Gamma_\gamma(x) \odot v$$

where $\Gamma_\gamma(x) = (\Gamma_\gamma^1(x), \dots, \Gamma_\gamma^n(x))^\top$. Here, $\odot$ represents the Hadamard product.

Proof. Let $g = (g_1, \dots, g_n)^\top$ be in H, and $v = (v_1, \dots, v_n)^\top \in \mathbb{R}^n$ then

$$\begin{aligned}\langle g, \Gamma_{\gamma,v}\rangle_H &= \left\langle \int_0^T g(\gamma(t))dt, v\right\rangle_{\mathbb{R}^n} \\ &= \sum_{i=1}^n \int_0^T v_i g_i(\gamma(t))dt \\ &= \sum_{i=1}^n \langle g_i, \Gamma_\gamma^i v_i\rangle_{\mathscr{H}_i} = \langle g, \Gamma_\gamma \odot v\rangle_H.\end{aligned}$$

4. THEORETICAL DESCRIPTION OF THE METHOD

For this section we will assume the functions are over a compact domain $X \subset \mathbb{R}^n$ and are $\mathbb{R}^n$ valued.

Definition 4.1. For an $\mathbb{R}^n$ valued reproducing kernel Hilbert space H and a given symbol $\psi : \mathbb{R}^n \to \mathbb{R}^n$ we define the Liouville operator with symbol ψ as $A_\psi(g) = D(g)\psi$.

Modally, A_ψ is a closed, densely defined, and unbounded operator, owing to the inclusion of the differentiation operator D. Throughout this manuscript, a heuristic assumption that this operator is bounded and even compact will be leveraged in the development of the numerical methods of this paper. This heuristic assumption is justified in several contexts, where the selection of appropriate Hilbert spaces in the range and domain of A_ψ can make it a bounded operator, and the use of scaled versions of this operator (cf. Rosenfeld et al. (2021)) can in fact produce a compact operator that agrees to computational precision with A_ψ on a compact subset of a given workspace.

Given a $f, h \in C^1(\mathbb{R}^n, \mathbb{R})$, define the Liouville operator $A_{\nabla f} : \mathcal{D}(A_{\nabla f}) \to H$. Let $\mathcal{D}_h(A_{\nabla f}) \subset \mathcal{D}(A_{\nabla f})$ be defined as those vectors $g \in \mathcal{D}(A_{\nabla f})$ such that $A_{\nabla f} g \in \mathcal{D}(A_{\nabla h}^*)$. Under the heuristic assumption discussed above, $\mathcal{D}_h(A_{\nabla f}) = H$. Definition 4.2 yields an operator theoretic replacement for the covariance matrix. The advantage gained through this perspective is that the operator valued kernel in Definition 4.2 provides a potentially infinite collection of eigenvalues and eigenfunctions that can be leveraged to decompose $\mathbb{R}^n$ in a nonlinear manner.

Definition 4.2. Let H be a $\mathbb{R}^n$- valued reproducing kernel Hilbert space, we define

$$C(\nabla f, \nabla h) : \mathcal{D}_h(A_f) \to H, \qquad C(\nabla f, \nabla h) := A_{\nabla h}^* A_{\nabla f}.$$

If it is assumed that $A_{\nabla f}$ is compact, which may require an adjustment between the domain and range of the operator (cf. Rosenfeld and Kamalapurkar (2021)), and consequently $C(\nabla f, \nabla f)$ is compact (compact operators form an ideal in the algebra of bounded operators), then as a self adjoint operator, $C(\nabla f, \nabla f)$ is diagonalizable. That is, the eigenfunctions of $C(\nabla f, \nabla f)$ form an orthonormal basis of H. Moreover, $A_{\nabla f}$ has a singular value decomposition, where the right singular vectors are the eigenfunctions of

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$C(\nabla f, \nabla f)$. In the subsequent numerical methods, finite rank representations for $C(\nabla f, \nabla f)$ will be extracted from finite rank representations of $A_{\nabla f}$.

Definition 4.3. Suppose $\varepsilon > 0$ is a given threshold and that $A_{\nabla f}$ is diagonalizable. Define,

$$\mathcal{A}_\varepsilon := \text{span}\{\varphi \mid C(\nabla f, \nabla f)\varphi = \lambda\varphi, \quad \sqrt{|\lambda|} > \varepsilon\}$$
$$\mathcal{I}_\varepsilon := \mathcal{A}_\varepsilon^\perp.$$

Note, our Hilbert space H can be orthogonally decomposed as $H = \mathcal{A}_\varepsilon \oplus \mathcal{I}_\varepsilon$. Furthermore, for notational convenience write $\Sigma := \{\varphi \in H : \exists \lambda \in \mathbb{C}$ such that $C(\nabla f, \nabla f)\varphi = \lambda\varphi\}$ and $\Sigma^* := \{\psi \in H : \exists \lambda \in \mathbb{C}$ such that $A_{\nabla f}A_{\nabla f}^*\psi = \lambda\psi\}$. Each $\varphi \in \Sigma$ is a right singular vector of $A_{\nabla f}$ and maps to the left singular vectors under$A_{\nabla f}$. Moreover, the identity function, $g_{id}(x) = x$, which is assumed to be in H, admits the decomposition

$$x = g_{id}(x) = \sum_{\varphi \in \Sigma} \langle g, \varphi \rangle_H \varphi(x).$$

Set $M = \max_{\varphi \in \Sigma} |\langle \varphi, g_{id} \rangle_H|$ and set $\varepsilon_0 = \varepsilon / M$. Write $\Sigma_\varepsilon := \{\varphi \in \Sigma : \sqrt{|\lambda|} > \varepsilon\}$. Then,

$$\begin{aligned}
&\nabla f(x) \\
&= D(g_{id})\nabla f(g_{\text{id}}(x)) \\
&= D(P_{\mathcal{A}_{\varepsilon_0}} g_{\text{id}}(x))\nabla f(x) + D(P_{\mathcal{I}_{\varepsilon_0}} g_{\text{id}}(x))\nabla f(x) \\
&= \sum_{\varphi \in \Sigma_{\varepsilon_0}} \langle g_{id}, \varphi \rangle_H A_{\nabla f}\varphi(x) + \sum_{\varphi \in \Sigma \setminus \Sigma_{\varepsilon_0}} \langle g_{id}, \varphi \rangle_H A_{\nabla f}\varphi(x) \\
&= \sum_{\varphi \in \Sigma_{\varepsilon_0}} \langle g_{id}, \varphi \rangle_H \sqrt{\lambda}\psi(x) + \sum_{\varphi \in \Sigma \setminus \Sigma_{\varepsilon_0}} \langle g_{id}, \varphi \rangle_H \sqrt{\lambda}\psi(x),
\end{aligned}$$

where ψ are the right singular vectors of $A_{\nabla f}$ corresponding to $\varphi \in \Sigma$.

Definition 4.4. The subspace $\mathcal{A}_{\varepsilon_0}$ described above will be called the *active subspace* within H for f and $P_{\mathcal{A}_{\varepsilon_0}} g_{\text{id}}$ is called the *active* component of g_{id} (of order ε)

Each term of the active component satisfies

$$\langle g_{id}, \varphi \rangle \sqrt{|\lambda|} > \varepsilon.$$

5. FINITE RANK REPRESENTATIONS VIA OCCUPATION KERNELS

To computationally determine an estimation of the eigendecomposition of $C(\nabla f, \nabla f)$, a finite rank representation of A_f will be determined using a collection of trajectories, $\{\gamma_i : [0, T] \to \mathbb{R}^n\}_{i=1}^M$, that satisfy $\dot{\gamma}_i = \nabla f(\gamma_i)$ and their corresponding operator valued occupation kernels, $\{\Gamma_\gamma\}_{i=1}^M$. Significant to the method is the following proposition:

Proposition 5.1. Let H be a $\mathbb{R}^n$ valued RKHS consisting of continuously differentiable funcitons, and let $\gamma : [0, T] \to \mathbb{R}^n$ be a trajectory satisfying $\dot{\gamma} = \nabla f(\gamma)$ for a function $f : \mathbb{R}^n \to \mathbb{R}$ which yields a densely defined Liouville operator, $A_{\nabla f}$, over H. Then the following relation holds

$$\langle A_{\nabla f} g, \Gamma_\gamma v \rangle_H = \langle g, (K_{\gamma(T)} - K_{\gamma(0)})v \rangle_H. \tag{2}$$

Hence, $A_{\nabla f}^* \Gamma_{\gamma, v} = (K_{\gamma(T)} - K_{\gamma(0)})v$.

Proof. Note that

$$\begin{aligned}
\langle A_{\nabla f} g, \Gamma_{\gamma, v} \rangle_H &= \langle D(g)\nabla f, \Gamma_{\gamma, v} \rangle_H \\
&= \left\langle \int_0^T Dg(\gamma(t))\nabla f(\gamma(t))dt, v \right\rangle_{\mathbb{R}^n} \\
&= \left\langle \int_0^T \frac{d}{dt} g(\gamma(t))dt, v \right\rangle_{\mathbb{R}^n} \\
&= \langle g(\gamma(T)) - g(\gamma(0)), v \rangle_{\mathbb{R}^n} \\
&= \langle g, \left(K_{\gamma(T)} - K_{\gamma(0)}\right) v \rangle_H.
\end{aligned}$$

Leveraging this relation, a finite rank representation of $A_{\nabla f}^*$ may be determined, and consequently the transpose of this representation will represent $A_{\nabla f}$ under the boundedness assumption. In particular, replacing v with vectors from the standard basis in $\mathbb{R}^n$, and for a fixed $1 \leq i \leq n$ writing $\beta_i = \text{span}\{\Gamma_{\gamma_j} e_i\}_{j=1}^M$ will give us the following proposition.

Proposition 5.2. Let $\{e_k\}$ denote the standard basis for $\mathbb{R}^n$ and fix an $i \in \{1, \ldots, n\}$. For a finite dimensional subspace given by $\beta_i = \text{span}\{\Gamma_{\gamma_j, e_i}\}_{j=1}^M = \text{span}\{\Gamma_{\gamma_j} e_i\}_{j=1}^M$,

$$[P_{\beta_i} A_{\nabla f}^*]_{\beta_i}^{\beta_i} = \begin{pmatrix} \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_1} e_i \rangle_H \\ \vdots & \ddots & \vdots \\ \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_M} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_M} e_i \rangle_H \end{pmatrix}^{-1}$$
$$\times \begin{pmatrix} \langle (K_{\gamma_1(T)} - K_{\gamma_1(0)}) e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & \langle (K_{\gamma_M(T)} - K_{\gamma_M(0)}) e_i, \Gamma_{\gamma_1} e_i \rangle_H \\ \vdots & \ddots & \vdots \\ \langle (K_{\gamma_1(T)} - K_{\gamma_1(0)}) e_i, \Gamma_{\gamma_M} e_i \rangle_H & \cdots & \langle (K_{\gamma_M(T)} - K_{\gamma_M(0)}) e_i, \Gamma_{\gamma_M} e_i \rangle_H \end{pmatrix}.$$

Proof. For $h \in \mathcal{D}(A_{\nabla f}^*)$, the coefficients $\{a_j\}_{j=1}^M$ in the projection of $A_{\nabla f}^* h$ onto β_i, given by $P_{\beta_i} A_{\nabla f}^* h = \sum_{j=1}^M a_j \Gamma_{\gamma_j} e_i$, can be expressed as

$$\begin{pmatrix} a_1 \\ \vdots \\ a_M \end{pmatrix} = \begin{pmatrix} \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_1} e_i \rangle_H \\ \vdots & \ddots & \vdots \\ \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_M} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_M} e_i \rangle_H \end{pmatrix}^{-1}$$
$$\times \begin{pmatrix} \left\langle A_{\nabla f}^* h, \Gamma_{\gamma_1} e_i \right\rangle_H \\ \vdots \\ \left\langle A_{\nabla f}^* h, \Gamma_{\gamma_M} e_i \right\rangle_H \end{pmatrix}.$$

Assuming that the occupation kernels are in the domain of the Liouville operator, i.e., $\beta_i \subset \mathcal{D}(A_{\nabla f}^*)$, for $h \in \beta_i$, given by $h = \sum_{j=1}^M c_j \Gamma_{\gamma_j} e_i$, for a fixed $k \in \{1, \ldots, M\}$, we have

$$\begin{aligned}
\left\langle A_{\nabla f}^* h, \Gamma_{\gamma_k} e_i \right\rangle_H &= \sum_{j=1}^M c_j \left\langle A_{\nabla f}^* \Gamma_{\gamma_j} e_i, \Gamma_{\gamma_k} e_i \right\rangle_H \\
&= \left(\left\langle A_{\nabla f}^* \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_k} e_i \right\rangle_H \ldots, \left\langle A_{\nabla f}^* \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_k} e_i \right\rangle_H \right) \\
&\quad \cdot (c_1 \ \ldots \ c_M)^\top.
\end{aligned}$$

As a result, a finite rank representation of $A_{\nabla f}^*$ restricted to β_i, i.e., the matrix $[P_{\beta_i} A_{\nabla f}^*]_\alpha^\alpha$ that maps the coefficients $\{c_j\}_{j=1}^M$ to the coefficients $\{a_j\}_{j=1}^M$, is given as

$$[P_{\beta_i} A_{\nabla f}^*]_{\beta_i}^{\beta_i} = \begin{pmatrix} \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_1} e_i \rangle_H \\ \vdots & \ddots & \vdots \\ \langle \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_M} e_i \rangle_H & \cdots & \langle \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_M} e_i \rangle_H \end{pmatrix}^{-1}$$
$$\times \begin{pmatrix} \langle A_{\nabla f}^* \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & \langle A_{\nabla f}^* \Gamma_{\gamma_1} e_i, \Gamma_{\gamma_M} e_i \rangle_H \\ \vdots & \ddots & \vdots \\ \langle A_{\nabla f}^* \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_1} e_i \rangle_H & \cdots & A_{\nabla f}^* \Gamma_{\gamma_M} e_i, \Gamma_{\gamma_M} e_i \rangle_H \end{pmatrix}$$

The proof is completed by an application of Proposition 5.1

Proposition 5.3. Let $\{e_k\}$ denote the standard basis for $\mathbb{R}^n$ and for each $i \in \{1, \ldots, n\}$ let $\beta_i = \text{span}\{\Gamma_{\gamma_j, e_i}\}_{j=1}^M = \text{span}\{\Gamma_{\gamma_j} e_i\}_{j=1}^M$. Let $B = \oplus_{i=1}^n \beta_i$ then

$$[P_B A^*_{\nabla f}]_B^B = \text{diag}([P_{\beta_i} A^*_{\nabla f}]_{\beta_i}^{\beta_i})$$

Proof. Let ℓ and m be arbitrary indices in $\{1, \ldots, M\}$. We must show for $i, j \in \{1, \ldots, n\}$ with $i \neq j$ that

$$\langle A^*_{\nabla f} \Gamma_{\gamma_\ell} e_i, \Gamma_{\gamma_m} e_j \rangle = 0.$$

By an applications of Propositions 3.5 and 5.1 we get

$$\begin{aligned}\langle A^*_{\nabla f} \Gamma_{\gamma_\ell} e_i, \Gamma_{\gamma_m} e_j \rangle &= \langle \Gamma_{\gamma_\ell} e_j, (K_{\gamma_m(T)} - K_{\gamma_m(0)}) e_i \rangle_H \\ &= \langle \Gamma_{\gamma_\ell, e_j}(\gamma_m(T)) - \Gamma_{\gamma_\ell, e_j}(\gamma_m(0)), e_i \rangle_{\mathbb{R}^n}\end{aligned}$$

where we get the difference of the *scalar* valued occupation kernel for γ_ℓ evaluated at $\gamma_m(T)$ and $\gamma_m(0)$ in the j-th spot and a 1 in the i-th spot. Hence, this is non-zero only when $i = j$.

Hence for each dimension of the workspace, a collection of approximate eigenfunctions for $A_{\nabla f}$ may be determined through the SVD of the matrix $([P_{\beta_i} A^*_{\nabla f}]_{\beta_i}^{\beta_i})^T$. For each singular vector of $([P_{\beta_i} A^*_{\nabla f}]_{\beta_i}^{\beta_i})^T$, $\eta = (\eta_1, \ldots, \eta_M)$, with singular value λ, the corresponding normalized singular function in H is given as $\varphi = \frac{1}{\sqrt{\eta^T G \eta}} \sum_{j=1}^M \eta_j \Gamma_{\gamma_j} e_i$, where G is the Gram matrix corresponding to the basis for β_i. Hence, to evaluate $\sum_{\varphi \in \Sigma_{\varepsilon_0}} \langle g_{id}, \varphi \rangle_H \sqrt{\lambda} \psi(x)$ we must be able to compute $\langle g_{id}, \Gamma_{\gamma_j} e_i \rangle$. By definition, this is given as

$$\langle g_{id}, \Gamma_{\gamma_j} e_i \rangle = \left\langle \int_0^T g_{id}(\gamma_j(t)) dt, e_i \right\rangle_{\mathbb{R}^n} = \int_0^T \gamma_j^i(t) dt,$$

i.e. it is the integral of the i-th component of $\gamma_j : [0, T] \to X \subset \mathbb{R}^n$

6. DISCUSSION AND CONCLUSION

This manuscript presents a new dimension reduction technique as a nonlinear version of the active subspace method. To address the limitation of the active subspace routine this manuscript introduces a new operator valued kernel to stand in place of the covariance matrix of Constantine (2015). This operator valued kernel, based on the Liouville operator given in Section 4, acts on a vector valued RKHS, which is infinite dimensional. This kernel makes available an infinite collection of eigenvalues and eigenvectors that can be leveraged to decompose a function into "active" and "inactive" components, where the active component will effectively represent level sets of the original function. The authors expect the same challenges that appear in occupation kernel DMD to be present in this new technique as well. While, in principle any reproducing kernel Hilbert space can be used, choice of RKHS affects the operator theoretic properties of boundedness and compactness of $C(\nabla f, \nabla f)$ and $A_{\nabla f}$. (Russo and Rosenfeld (2022)) explores the properties of Liouville operators over the Hardy space and (Rosenfeld and Kamalapurkar (To Appear)) gives a modification of Liouville operators that allow for compactness. Moreover, it is found in dynamic mode decomposition that careful parameter selection is necessary and a poor choice of parameter can lead to bad reconstruction of the function. This in general is one of the major limitations of the technique.

Abstract: Conventionally, data driven identification and control problems for higher order dynamical systems are solved by augmenting the system state by the derivatives of the output to formulate first order dynamical systems in higher dimensions. However, solution of the augmented problem typically requires knowledge of the full augmented state, which requires numerical differentiation of the original output, frequently resulting in noisy signals. This manuscript develops the theory necessary for a direct analysis of higher order dynamical systems using higher order Liouville operators. Fundamental to this theoretical development is the introduction of signal valued RKHSs and new operators posed over these spaces. Ultimately, it is observed that despite the added abstractions, the necessary computations are remarkably similar to that of first order DMD methods using occupation kernels.

Keywords: system identification, operator theoretic methods in systems theory, model approximation, control system analysis

1. INTRODUCTION

Data driven methods for dynamical systems have developed significantly over the past 20 years (cf. Budišić et al. (2012); Kutz et al. (2016); Proctor et al. (2016); Mauroy and Goncalves (2020); Mauroy and Mezić (2016)). Principle among them are those that leverage Koopman operators (also known as composition operators) over Hilbert function spaces to give a representation of finite dimensional discrete time dynamics as an operator over an infinite dimensional Hilbert space Budišić et al. (2012); Williams et al. (2015). When a continuous time dynamical system is forward complete, it may be discretized by fixing a time-step, $\Delta t > 0$, to yield a discrete time system. In this setting, the Koopman operator has been demonstrated as an effective tool for extracting the underlying governing principles of a dynamical system, and for providing a model for the state which performs well over short time horizons via Dynamic Mode Decompositions (DMD).

In Rosenfeld et al. (2019b), the concept of occupation kernels was introduced as functions inside of a RKHS that, given a signal $\theta : [0, T] \to \mathbb{R}^n$, represent the functional $g \mapsto \int_0^T g(\theta(t))dt$. Occupation kernels generalize the concept of an occupation measure (cf. Lasserre et al. (2008)) by changing the setting from a collection of measures to that of a Hilbert space. Thus, occupation kernels can be leveraged as a basis in a Hilbert space for function approximation and projections (cf. Rosenfeld et al. (2019b,a); Rosenfeld and Kamalapurkar (2021, to appear, see arXiv:2101.02620); Li and Rosenfeld (to appear); Russo et al. (2022)).

One limitation still present in the theory of data driven methods for dynamical systems is that of high order dynamics. Conventionally in systems theory, higher order dynamics are converted to first order systems of augmented state variables. For example, $\ddot{x} = f(x)$ can be adjusted to $z := (x\ \dot{x})^T$ with $\dot{z} = (z_2\ f(z_1))^T$. Theoretically, the augmentation is well justified, but it is computationally problematic in data driven methods. To estimate the new

Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the sponsoring agencies.

state variable of z, data driven methods must compute an approximation of the first derivative of x. Numerical derivatives can be noisy, and if the order of the system exceeds 2, they are unreliable. For example, in Brunton et al. (2016), where numerical differentiation is used for parameter fitting, a considerable amount of filtering was required to get good results. The sensitivity of numerical differentiation techniques to noise motivates the development of methods that avoid numerical differentiation altogether.

This manuscript introduces the necessary theoretical components for the development of a DMD routine for second order dynamical systems that avoids the use of numerical derivatives and augmented state variables. The exposition will be focused on second order dynamical systems. However, the developed methods may be readily adapted to higher order dynamical systems. Underlying the subsequent development are vector valued Reproducing Kernel Hilbert spaces (vvRKHSs), for which the relevant theory is presented in Section 2. Using vvRKHSs as a tool, Section 4 develops a signal valued RKHS, which is a Hilbert space of functions that map d times continuously differentiable signals to a scalar valued RKHS over $[0, T]$. The signal valued RKHS framework allows for the formulation of well defined second order Liouville operators over the Hilbert space beyond the formal expression given in Section 5. Once the essential elements are established, Section 6 presents a DMD method for the modeling of a second order dynamical system, which avoids the use of numerical derivatives.

2. VECTOR VALUED REPRODUCING KERNEL HILBERT SPACES

This section presents the concept of vector valued RKHSs, which recently came to prominence with Carmeli et al. (2010), though their roots extend further back (e.g. Pedrick (1957)). In the context of this manuscript the Hilbert space $\mathcal{Y}$ will be a scalar valued RKHS, which will facilitate the description of a function space on signals.

Definition 1. Given a Hilbert space $\mathcal{Y}$ and a set X, a vector valued reproducing kernel Hilbert space, H, is a Hilbert space of functions mapping X to $\mathcal{Y}$, where for each $x \in X$ and $v \in \mathcal{Y}$ the functional $g \mapsto \langle g(x), v\rangle_{\mathcal{Y}}$ is bounded.

The Riesz representation theorem guarantees for each $x \in X$ and $v \in \mathcal{Y}$ the existence of a function $K_{x,v} \in H$ such that $\langle g, K_{x,v}\rangle_H = \langle g(x), v\rangle_{\mathcal{Y}}$ for all $g \in H$. It is readily apparent that the map $K_x : \mathcal{Y} \to H$, that maps v to $K_{x,v}$, is linear, and as such, is expressed as $K_x v := K_{x,v}$.

3. PROBLEM STATEMENT

Given a collection of trajectories, $\{\gamma_i : [0, T] \to \mathbb{R}^n\}_{i=1}^M$, corresponding to a second order dynamical system $\ddot{\gamma} = f(\gamma)$, where f is unknown, we want to determine a model for a trajectory starting at $x(0) = x_0^0$ and $\dot{x}(0) = x_0^1$. In the following, the model is constructed from a finite rank representation of a second order Liouville operator, B_f, obtained via adjoint relations between the B_f, and a collection of occupation kernels.

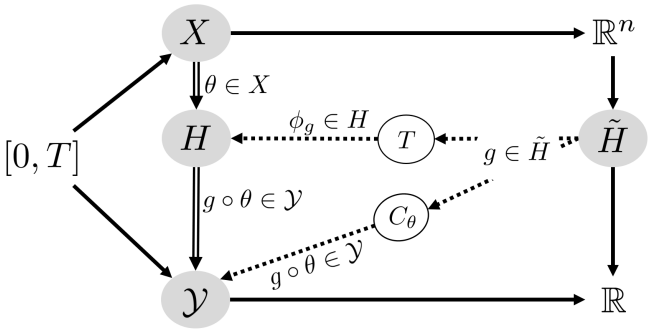

Fig. 1. A visualization of relationships between vector spaces and operators defined in Theorem 1.

4. SIGNAL VALUED RKHSS

In the following, three different RKHSs are under consideration (see Figure 1). The range space, $\mathcal{Y}$, is selected to be a scalar valued RKHS over $[0, T]$, with kernel function $\mathscr{K}$. To construct a vvRKHS of functions that map signals from $C^d([0, T], \mathbb{R}^n)$ (or a suitable substitute) to $\mathcal{Y}$, we define an auxiliary scalar valued RKHS, $\tilde{H}$, consisting of twice continuously differentiable functions from $\mathbb{R}^n$ to $\mathbb{R}$. For each $g \in \tilde{H}$, a map from $C^d([0, T], \mathbb{R}^n)$ to $\mathcal{Y}$ is obtained as $\phi_g[\theta](t) := g(\theta(t))$ for all $\theta \in C^d([0, T], \mathbb{R}^n)$ and $t \in [0, T]$. Theorem 1 shows that the space of all such maps is a vvRKHS.

Theorem 1. Let $X = C^d([0, T], \mathbb{R}^n)$ for some $d \in \mathbb{N}$, and let $\tilde{H}$ be a scalar valued RKHS over $\mathbb{R}^n$. Moreover, suppose there exists a RKHS $\mathcal{Y}$ over $[0, T]$ where the composition operator $C_\theta : \tilde{H} \to \mathcal{Y}$ is a bounded operator for all symbols $\theta \in X$. Define the vector space $H(X) := \{\phi_g : g \in \tilde{H}\}$ of mappings $\phi_g : X \to \mathcal{Y}$ given by $\phi_g[\theta] := g(\theta(\cdot))$, together with the inner product induced by $\tilde{H}$, $\langle \phi_{g_1}, \phi_{g_2}\rangle_H = \langle g_1, g_2\rangle_{\tilde{H}}$. Then $H(X)$ is a vvRKHS.

Definition 2. The vvRKHS, H, given in Theorem 1 will be called the signal valued RKHS from $C^d([0, T], \mathbb{R}^n)$ to $\mathcal{Y}$ derived from $\tilde{H}$, more succinctly a signal valued RKHS, when the other quantities are understood from context.

While a general characterization of pairs of RKHSs $(\tilde{H}, \mathcal{Y})$ that admit bounded composition operators C_θ is difficult, the following example analyzes one such pair.

Example 1. A possible choice for $\tilde{H}$ would be the native space of the Gaussian RBF kernel function, $\tilde{K}(x, y) = \exp\left(-\frac{\|x-y\|_2^2}{\mu}\right)$. Letting $\mathcal{Y}$ be the Sobolev space H^1, it can be seen that $\phi_g[\theta] \in \mathcal{Y}$ for all $\theta \in C^2([0, T], \mathbb{R}^n)$. This follows since g is infinitely differentiable and $\phi_g[\theta](t) = g(\theta(t))$ must then be twice continuously differentiable.

Corollary 1. Example 1 provides a vvRKHS of functions from $C^2([0, T], \mathbb{R}^n)$ to H^1, and it is a signal valued RKHS.

DMD relies on the action of Liouville operators on occupation kernels. As such, it is necessary to define second order occupation kernels in the context of vvRKHSs of the form in Theorem 1. To motivate the definition of higher order occupation kernels, recall Cauchy's formula for iterated integrals given as $h^{(-m)}(T) = \frac{1}{(m-1)!}\int_0^T (T-t)^{m-1} h(t)dt$, where $h^{(-m)}(t) := \int_0^t \int_0^{\tau_1} \cdots \int_0^{\tau_{m-1}} h(\tau_m) d\tau_m \cdots d\tau_2 d\tau_1$.

For a RKHS of continuous functions, $\mathcal{Y}$, as given in Theorem 1, the mapping $h \mapsto h^{(-m)}(T)$ is a bounded functional. As a result, by the Reisz representation theorem, there exists $1^{(-m)} \in \mathcal{Y}$ such that $\langle h, 1^{(-m)}\rangle_{\mathcal{Y}} = \frac{1}{(m-1)!}\int_0^T (T-t)^{m-1}h(t)dt$. Note that for $g \in \tilde{H}$, $\theta \in C^d([0,T],\mathbb{R}^n)$, and $\psi \in H$ such that $\psi = \mathcal{T}g$, the functional

$$\psi \mapsto \langle g\circ\theta, 1^{(-m)}\rangle_{\mathcal{Y}} = \frac{1}{(m-1)!}\int_0^T (T-t)^{m-1}g(\theta(t))dt$$

is bounded. As such, by the Reisz representation theorem, there exists $\Gamma_\theta^{(m)} \in H$ such that $\langle \psi, \Gamma_\theta^{(m)}\rangle_H = \langle g\circ\theta, 1^{(-m)}\rangle_{\mathcal{Y}}$. We define $\Gamma_\theta^{(m)}$ as the *m-th order occupation kernel corresponding to* $\theta \in C^d([0,T],\mathbb{R}^n)$ *in* H.

Due to the fact that $\langle g\circ\theta, 1^{(-m)}\rangle_{\mathcal{Y}} = \langle \psi[\theta], 1^{(-m)}\rangle_{\mathcal{Y}} = \langle \psi, K_{\theta,1^{(-m)}}\rangle_H$, the m-th order occupation kernel corresponding to θ can be identified with the kernel function $K_{\theta,1^{(-m)}} \in H$ of the vvRKHS.

Thus, in contrast with Rosenfeld et al. (2019b), where occupation kernels are integrals of the kernel function of an RKHS along trajectories, the m-th order occupation kernels defined here are a subset of the set of vector valued kernels in a vvRKHS.

5. HIGHER ORDER LIOUVILLE OPERATORS AND OCCUPATION KERNELS

The structure of Liouville operators, given formally as $A_f g(x) = \nabla g(x) f(x)$, derive their form from the orbital derivative. In particular, suppose that $\gamma : [0,T] \to \mathbb{R}^n$ satisfies $\dot\gamma = f(\gamma)$, then $A_f g(\gamma(t)) = \nabla g(\gamma(t))\dot\gamma(t) = \frac{d}{dt}g(\gamma(t))$. Consequently, higher order Liouville operators may be derived via the same process, where g is composed with γ and higher order derivatives with respect to time are taken. To wit, letting $\mathcal{H}[g]$ denote the Hessian of $g : \mathbb{R}^n \to \mathbb{R}$,

$$\frac{d^2}{dt^2} g\circ\gamma(t) = \dot\gamma(t)^T \mathcal{H}[g](\gamma(t))\dot\gamma(t) + \nabla g(\gamma(t))\ddot\gamma(t).$$

Fixing H as a signal valued RKHS as in Theorem 1, let $f : \mathbb{R}^n \to \mathbb{R}^n$ be the symbol for a second order Liouville operator, $B_f : \mathcal{D}(B_f) \to H$, defined as

$$B_f\psi[\theta](t) := \nabla\psi[\theta](t) f(\theta(t)) + \left(\dot\theta(0) + \int_0^t f(\theta(\tau))d\tau\right)^T \mathcal{H}\psi[\theta](t)\left(\dot\theta(0) + \int_0^t f(\theta(\tau))d\tau\right), \quad (1)$$

where $\mathcal{D}(B_f)$ is precisely the collection of ψ for which $B_f\psi \in H$. Note that since $\psi = \phi_g$ for some $g \in \tilde{H}$, $\frac{\partial}{\partial x_i}\psi[\theta](t)$ is defined as $\frac{\partial}{\partial x_i}g(\theta(t))$ for $i = 1,\dots,n$, which facilitates the definitions of the gradient and Hessian of ψ. Hence, when $\ddot\gamma = f(\gamma)$, $B_f\phi_g[\gamma] = \frac{d^2}{dt^2}g\circ\gamma(t)$. Owing to the integral appearing in (1), the operator B_f needs to be posed over a Hilbert space consisting of functions of trajectories. Additionally, in contrast to the first order Liouville operator, B_f is linear in ψ but not in the symbol, f.

The operator B_f is connected to second order occupation kernels in the following manner. If $\ddot\gamma = f(\gamma)$, then $\langle B_f\psi, \Gamma_\gamma^{(2)}\rangle_H = \int_0^T (T-t)B_f\psi[\gamma](t)dt = \int_0^T (T-t)\ddot\psi[\gamma](t)dt = \psi[\gamma](T) - \psi[\gamma](0) - T\nabla\psi[\gamma](0)\dot\gamma(0) = \langle \psi, K_{\gamma,\mathscr{K}_T} - K_{\gamma,\mathscr{K}_0} - TK_{\gamma,\mathscr{K}_0'}\rangle_H$, where $\mathscr{K}_0' := s \mapsto {}^{d(\mathscr{K}(s,t))}/_{dt}|_{t=0} \in \mathcal{Y}$.

Hence, the functional $\psi \mapsto \langle B_f\psi, \Gamma_\gamma^{(2)}\rangle_H$ is bounded, and the following proposition is established.

Proposition 1. Let f be the symbol for a densely defined [1] second order Liouville operator, B_f, over a signal valued RKHS and $\gamma \in C^2([0,T],\mathbb{R}^n)$ be such that $\ddot\gamma = f(\gamma)$. Then, $\Gamma_\gamma^{(2)} \in \mathcal{D}(B_f^*)$, and $B_f^*\Gamma_\gamma^{(2)} = K_{\gamma,\mathscr{K}_T} - K_{\gamma,\mathscr{K}_0} - TK_{\gamma,\mathscr{K}_0'}$.

6. DYNAMIC MODE DECOMPOSITIONS FOR SECOND ORDER DYNAMICAL SYSTEMS

The objective of this section is to give a data driven model for a state governed by an unknown second order dynamical system. The development follows that of occupation kernel DMD detailed in Rosenfeld et al. (2020).

The approach is to determine a finite rank representation of B_f over H and to perform an eigendecomposition on this representation to obtain eigenfunctions and eigenvectors for the representation. Following this, the full state observable is decomposed with respect to the eigenfunctions, which ultimately allows for a model to be extracted for the dynamical system.

Suppose that $\varphi \in \mathcal{D}(B_f)$ is an eigenfunction for B_f with eigenvalue λ. Then for $\ddot\gamma = f(\gamma)$, $\ddot\varphi[\gamma](t) = B_f\varphi[\gamma](t) = \lambda\varphi[\gamma](t)$. Hence,

$$\varphi[\gamma](t) = \frac{1}{2}\left(\varphi[\gamma](0) + \frac{\nabla\varphi[\gamma](0)\dot\gamma(0)}{\sqrt{\lambda}}\right)e^{\sqrt{\lambda}t} + \frac{1}{2}\left(\varphi[\gamma](0) - \frac{\nabla\varphi[\gamma](0)\dot\gamma(0)}{\sqrt{\lambda}}\right)e^{-\sqrt{\lambda}t}.$$

The full state observable for the signal valued case is then given as $\psi_{id}[\theta] = \theta$. The objective is to decompose each dimension of the full state observable with respect to an eigenbasis, $\{\varphi_i\}_{i=1}^\infty$ with eigenvalues $\{\lambda_i\}_{i=1}^\infty$, of B_f, provided that one exists, so as to express $\psi_{id}[\gamma](t)$ as

$$\psi_{id}[\gamma](t) = \gamma(t) = \quad (2)$$

$$\lim_{M\to\infty}\sum_{m=1}^M \xi_{m,M}\left(\frac{1}{2}\left(\varphi_m[\gamma](0) + \frac{\nabla\varphi_m[\gamma](0)\dot\gamma(0)}{\sqrt{\lambda_m}}\right)e^{\sqrt{\lambda_m}t} + \frac{1}{2}\left(\varphi_m[\gamma](0) - \frac{\nabla\varphi_m[\gamma](0)\dot\gamma(0)}{\sqrt{\lambda_m}}\right)e^{-\sqrt{\lambda_m}t}\right). \quad (3)$$

Since the eigenfunctions may not be pairwise orthogonal, addition of each new eigenfunction to the linear combination in (3) may affect the coefficients corresponding to all other eigenfunctions. This dependence of the coefficients on the collection of basis functions is expressed through the second subscript of M. In the following, finite-rank representations of the coefficients $\xi_{m,M}$ are referred to as the second order Liouville modes for the dynamical system.

Since B_f is not known when f is unknown. A finite rank proxy of B_f needs to be constructed from the observed trajectories. In the place of the eigenfunctions of B_f,

[1] An operator $B_f : \mathcal{D}(B_f) \to H$ is called densely defined if $\mathcal{D}(B_f)$ is a dense subset of H.

the eigenfunctions of a finite rank representation will be leveraged to determine an estimate for (3). Let $\{\gamma_i\}_{i=1}^M \subset C^2([0,T],\mathbb{R}^n)$ be a collection of observed trajectories for the second order dynamical system, and let $\alpha = \{\Gamma^{(2)}_{\gamma_i}\}_{i=1}^M$ be the corresponding collection of second order occupation kernels in H. Let P_α be the projection onto $\operatorname{span}\alpha$.

A finite rank representation of B_f restricted to $\operatorname{span}\alpha$, i.e., the matrix $[P_\alpha B_f]_\alpha^\alpha$ that maps the coefficients $\{a_i\}_{i=1}^M$ to the coefficients $\{b_i\}_{i=1}^M$, is given as

$$[P_\alpha B_f]_\alpha^\alpha = \begin{pmatrix} \langle \Gamma^{(2)}_{\gamma_1}, \Gamma^{(2)}_{\gamma_1}\rangle_H & \cdots & \langle \Gamma^{(2)}_{\gamma_1}, \Gamma^{(2)}_{\gamma_M}\rangle_H \\ \vdots & \ddots & \vdots \\ \langle \Gamma^{(2)}_{\gamma_M}, \Gamma^{(2)}_{\gamma_1}\rangle_H & \cdots & \langle \Gamma^{(2)}_{\gamma_M}, \Gamma^{(2)}_{\gamma_M}\rangle_H \end{pmatrix}^{-1} \times \begin{pmatrix} \langle \Gamma^{(2)}_{\gamma_1}, B_f^*\Gamma^{(2)}_{\gamma_1}\rangle_H & \cdots & \langle \Gamma^{(2)}_{\gamma_M}, B_f^*\Gamma^{(2)}_{\gamma_1}\rangle_H \\ \vdots & \ddots & \vdots \\ \langle \Gamma^{(2)}_{\gamma_1}, B_f^*\Gamma^{(2)}_{\gamma_M}\rangle_H & \cdots & \langle \Gamma^{(2)}_{\gamma_M}, B_f^*\Gamma^{(2)}_{\gamma_M}\rangle_H \end{pmatrix}, \tag{4}$$

where B_f was moved to the right of the inner products through the adjoint relation, and the result of the mapping $B_f^*\Gamma^{(2)}_\gamma$ was given in Proposition 1. Letting G denote the Gram matrix $(\langle \Gamma^{(2)}_{\gamma_i}, \Gamma^{(2)}_{\gamma_j}\rangle_H)_{i,j=1}^M$, a normalized "eigenfunction" can be extracted from an eigenvector, ν_j, of $[P_\alpha B_f]_\alpha^\alpha$ with eigenvalue λ_j as

$$\hat{\varphi}_j = \frac{1}{\sqrt{\nu_j^T G \nu_j}} \sum_{i=1}^M (\nu_j)_i \Gamma^{(2)}_{\gamma_i}, \tag{5}$$

which can be leveraged as a proxy for a proper eigenfunction of B_f, in keeping with the implementation of DMD for Koopman and Liouville operators. In (5) and in the following development, $(x)_i$ denotes the projection onto the i-th coordinate of $x \in \mathbb{R}^n$.

The second order Liouville modes can then be constructed by examining the inner products $\left\langle (\psi_{id})_i, \Gamma^{(2)}_{\gamma_j}\right\rangle_H$, where $(\psi_{id})_i$ is the i-th component of the full state observable, i.e., $(\psi_{id})_i[\theta](t) := (\theta(t))_i$. The second order Liouville modes $\{(\xi_m)_i\}_{m=1}^M$ are defined as the coefficients in the projection of $(\psi_{id})_i$ onto the span of the normalized eigenfunctions in (5) that is,

$$\begin{pmatrix} \left\langle (\psi_{id})_1, \Gamma^{(2)}_{\gamma_j}\right\rangle_H \\ \vdots \\ \left\langle (\psi_{id})_n, \Gamma^{(2)}_{\gamma_j}\right\rangle_H \end{pmatrix} \approx \begin{pmatrix} \left\langle \sum_{m=1}^M (\xi_m)_1 \hat{\varphi}_m, \Gamma^{(2)}_{\gamma_j}\right\rangle_H \\ \vdots \\ \left\langle \sum_{m=1}^M (\xi_m)_n \hat{\varphi}_m, \Gamma^{(2)}_{\gamma_j}\right\rangle_H \end{pmatrix}$$
$$= \sum_{m=1}^M \xi_m \sum_{k=1}^M \frac{(\nu_m)_k}{\sqrt{\nu_m^T G \nu_m}} \left\langle \Gamma^{(2)}_{\gamma_k}, \Gamma^{(2)}_{\gamma_j}\right\rangle_H = \sum_{m=1}^M \frac{\xi_m \nu_m^T G^j}{\sqrt{\nu_m^T G \nu_m}},$$

where G^j denotes the j-th column of the Gram matrix. The matrix $\xi := (\xi_1 \cdots \xi_M)$ of second order Liouville modes is then given by

$$\xi = \begin{pmatrix} \left\langle (\psi_{id})_1, \Gamma^{(2)}_{\gamma_1}\right\rangle_H & \cdots & \left\langle (\psi_{id})_1, \Gamma^{(2)}_{\gamma_M}\right\rangle_H \\ \vdots & \ddots & \vdots \\ \left\langle (\psi_{id})_n, \Gamma^{(2)}_{\gamma_1}\right\rangle_H & \cdots & \left\langle (\psi_{id})_n, \Gamma^{(2)}_{\gamma_M}\right\rangle_H \end{pmatrix} \tag{6}$$
$$\times \left(\begin{pmatrix} \frac{\nu_1^T}{\sqrt{\nu_1^T G \nu_1}} \\ \vdots \\ \frac{\nu_M^T}{\sqrt{\nu_M^T G \nu_M}} \end{pmatrix} G \right)^{-1}. \tag{7}$$

Accelerating wound healing with feedback control: a data-driven approach ⋆

Marcella M. Gomez *

* *Applied Mathematcs, University of California at Santa Cruz, Santa Cruz, CA 95064 USA (e-mail: mgomez26@ucsc.edu).*

Abstract: Controlling biological systems presents challenges not typically dealt with in traditional control theoretic approaches but also gives way to leniences not traditionally tolerated. Here, we present a holistic view to this new research area and current developments integrating various data-driven approaches for modeling and control.

Keywords: Systems biology, control systems, machine learning, modeling, wound healing

1. INTRODUCTION

Feedback control can help to advance methods in precision medicine (Selberg et al. (2020a)). Feedback control is essential to the regulation of natural biological processes and has been considered as an approach to artificially guide or enhance existing biological systems (e.g. artificial pancreas (El-Khatib et al. (2010); Quiroz (2019)) and neuro-stimulation (Santaniello et al. (2010))).

Realizing feedback control in wound healing requires a way to direct cellular response without genetic engineering. We propose to achieve this through precise control over external signaling cues using bioelectronic devices. To control biological systems, differential voltages are applied to the bioelectronic device in order to drive the delivery or removal of biochemical or biophysical signals to the extracellular environment (Proctor et al. (2019); Malliaras and Abidian (2015); Noy (2015)). These signaling molecules, in turn, drive cellular response.

Bioelectronic devices provide an interface between signal processing and biological tissue that allow one to program custom feedback control strategies with sufficient resolution for enhanced performance. Thus, bioelectronic devices are a promising technology for precision medicine (Löffler et al. (2017); Wu et al. (2017); Birmingham et al. (2014); Selberg et al. (2020a); Jia and Rolandi (2020)). In particular, bioelectronic devices have been at the center of smart bandages (Mostafalu et al. (2018); Farooqui and Shamim (2016)). Many of these bandages have advanced features on board such as sensors to assess the state of wounds in real-time (McLister et al. (2016); Sharp et al. (2010)) and controlled release of therapeutics in a variety of pathological conditions (Williamson et al. (2015); Proctor et al. (2019); Jonsson et al. (2015)). Here, we propose to advance the capabilities of smart bandages with feedback control.

Methods in control theory typically assume that a predictive model is available. Thus, the models can be used to determine the most suitable type of controller and tune parameters for the controller. The challenges that we face in feedback control ensue from our efforts to control a complex systems for which we do not have a predictive model and there are limited observable states. Additionally, we are trying to achieve a goal at the tissue level response by controlling biological processes at the single cell level. Thus, we need a way of mapping single cell response on short timescales to tissue level response over the course of wound healing.

In summary, we propose that an effective approach to controlling complex biological processes interfaced with a bioelectronic device is through a heirarchical control architecture. The heirarchical feedback control architecture allows one to design the components of the controller independently and their integration provides control objectives at the single-cell level to achieve a desired tissue level response. That is, our controller design at the single-cell level does not have any dependence on the wound healing model. The wound healing model is instead used to inform the desired wound environment to be achieved by the bioelectronic device at the single-cell level. We note that the time scale of the dynamical response of the bioelectronic device to changes in voltages is orders of magnitude faster than that of biological processes in wound healing. We propose the following three layers in this heirarchical structure: the Decision Maker, Planner, and Low-level Controller. We also argue that a data-driven approach allows us to be successful without a complete and predictive mechanistic model of wound healing. Below, we describe our approach in more detail.

2. MACHINE LEARNING FOR COMPLEX SYSTEMS

Machine learning (ML)-based techniques are suitable when accurate control is required in the absence of a precise mathematical model (Marquez et al. (2019)). The best-

known ML techniques rely on the availability of large datasets a priori and have not been applied to control bioelectronic devices (Angermueller et al. (2016); Camacho et al. (2018); Maltarollo et al. (2013); Park and Kellis (2015)). We propose that ML-based techniques that are explored as control solutions outside of biology for cases involving complex non-linear systems are also suitable for closing the loop for bioelectronic systems containing biosensors, biology, and bioelectronic actuators. To this end, tools from control systems theory leveraging ML can be used to learn from new observations for effective real-time operation without data a priori (Jafari and Gomez (2019); Jafari et al. (2020); Kumpati et al. (1990); Lavretsky and Wise (2013)). ML-based techniques can be implemented directly or indirectly to solve complex control problems (Hagan and Demuth (1999); Spooner et al. (2004)). Additionally, we leverage ML to build data-driven models for long term trajectory planning.

3. SYSTEM OF SYSTEMS APPROACH

3.1 Low-level Controller

The low-level controller directly drives cellular response. The architecture of this inner loop resembles a standard feedback control loop composed of the system, sensors, actuators, and controller. A reference trajectory must be provided to the low-level controller. The controller is then tasked with achieving the desired response based on the sensor readout. In this work, we have explored various types of controllers including a NN-based controller with no information a priori and a sliding mode controller that can deal with saturating controller outputs imposed by the limitations of the bioelectronic device.

We have already demonstrated closed-loop control of membrane voltage (Vmem) in human pluripotent stem cells using bioelectronic stimulation (Selberg et al. (2020b)). This type of closed loop control relies on fluorescent readout of cell state. This state is then fed into a NN-based controller that suggests to the bioelectronic device the necessary intervention to achieve the desired state, in this specific example in the form of H+ ions or pH (Jia et al. (2020b)). Unique to this approach is the ability to obtain spatial resolution close to the single cell level (100um) and temporal resolution than spans many timescales from short cell-events (ms) to cell development (hrs and days). This approach goes well beyond Vmem and H+ ions and can be used to control various types of cell behavior (Selberg et al. (2020a, 2018)), including fate, with many types of bioelectronic signals that include ions (Jia et al. (2020a)), small molecules (Poxson et al. (2019)), and electric field.

3.2 Planner

The Planner takes in high level instructions from the Decision Maker and generates reference signals and/or control objectives for the Low-level Controller. In recent work, we have established a qualitative reduced order model of wound healing to understand how timing of macrophage polarization affects overall wound healing time (Zlobina et al. (2021)). Macrophages play an essential role in wound healing. Additionally, there are two primary subtypes termed M1 and M2 macrophages. M1 macrophages are pro-inflammatory and M2 are anti-inflammatory and promote the onset of the proliferative stage of wound healing. The transition and timing of M1 to M2 macrophages is critical to ensuring healthy wound healing. We aim to manipulate the timing and speed of this process in order to reduce inflammation time and accelerate transition into proliferation, thereby, reducing wound healing time.

3.3 Decision Maker

The Decision maker consists of a high-level model of the wound healing process. In particular, this component of the controller is tasked with identifying and monitoring progression through the wound healing stages in order to accurately time interventions designed by the Planner. We present preliminary ML-based models that predict wound healing stage based on gene expression profiles and time series RGB images of the wound.

4. CONCLUSION

In conclusion, we propose a framework for controlling biological systems motivated by our goal to accelerate wound healing. This framework has the potential to be generalized and extendended to other applications in biology such as precision medicine, agriculture, and environmental health, where systems are high dimensional and dynamics are complex. Still some open questions remain such as controllability of the system and safety guarantees.

ACKNOWLEDGEMENTS

The ongoing effort is part of a large collaborative project involving PIs, research scientists, postdocs, and students across various univerisities, departments, and disciplines. The work described in this extended abstract is led by the author but carried out over the course of the project by various lab members. The author would like to give thanks to research scientist Ksenia Zlobina, to former postdocs Mohammad Jafari and Bashir Hosseini Jafari, graduate students Giovanny Marquez, Sam Teymoori, Hector Carrion, and Manasa Kesapragada. Additionally, the author would like to thank former masters students who have contributed to the effort including Eliana Phillips, Brett Sargent, Jiahao Xue, Krishnakant Dasika, and undergraduate reearcher Han Chen.

Abstract: We propose new neural networks algorithms for the approximation of deterministic optimal control problems with maximum running cost. This problem is motivated by the approximation of general optimal control problems in the presence of state constraints. This problem is also related to Hamilton-Jacobi-Bellman equations with an obstacle term. Difficulties arise in particular because of the non-smoothness of the value to be approximated, and appropriate solutions are studied to deal with this specific issue. Numerical examples are given on front propagation problems in the presence of an obstacle, for average dimensions $2 \leq d \leq 8$.

Keywords: deterministic optimal control, maximum running cost, high dimension, deep learning, Hamilton-Jacobi-Bellman equations, state-constraints, obstacle problem, level-set

GENERAL PRESENTATION

In this work (see Bokanowski et al. (Preprint) for details) we present new results and algorithms concerning the use of deep neural network (DNN) approximations for a deterministic finite-horizon optimal control problem in presence of state constraints.

We focus on the value corresponding to a maximum running cost problem with obstacle function $g(.)$, for a given $T > 0$, $t \in [0, T]$ and $x \in \mathbb{R}^d$:

$$v(t,x) = \inf_{a \in mes((0,T),A)} \max_{\theta \in (t,T)} g(y^a_{t,x}(\theta)) \bigvee \varphi(y^a_{t,x}(T)) \quad (1)$$

where $y(.) = y^a_{t,x}(.)$ obeys $\dot{y}(s) = f(y(s), a(s))$ a.e. $s \in (t,T)$ with $y(t) = x$, associated to a measurable control function $a : (0,T) \to A$, $A \subset \mathbb{R}^\kappa$ is a compact set, and $g(.), \varphi(.), f(.,.)$ are assumed Lipschitz continuous.

This problem is motivated by the computation of backward reachable set with state constraints (see Bokanowski et al. (2010)). Moreover, this framework can be used in order to compute the value of general deterministic optimal control problems with a running cost, terminal cost, and state constraints, following Altarovici et al. (2013): an auxiliary value problem with one more variable enables to deal with the state constraints and avoids discontinuous value functions.

This setting was generalized in Germain et al. (2021) for the control of state-constrained McKean-Vlasov equations (using DNN approximations). It is also applied for *optimistic control* in Bokanowski et al. (2022).

⋆ This research benefited from the support of the FMJH program PGMO and from the FiME laboratory

The value is also the solution of an Hamilton-Jacobi-Bellman (HJB) equation in presence of an obstacle term

$$\begin{aligned} &\min(v_t + H(x, \nabla_x v),\ v - g(x)) = 0, \quad t \in [0,T],\ x \in \mathbb{R}^d \\ &v(T,x) = \max(\varphi(x), g(x)), \quad x \in \mathbb{R}^d \end{aligned} \quad (2)$$

hence an approximation for (1) is also valid for (2).

Recently, deep neural network (DNN) approximations for control in a probabilistic context have been introduced in Han et al. (2018) (deep BSDE algorithm), and also in Huré et al. (2021) and Bachouch et al. (2022), for the approximation of stochastic control problems on finite horizon.

We are motivated in dealing with state-constrained deterministic control problems of average state dimension (such as e.g. 5 to 10) where a brute force discretization of the HJB equation (or of the dynamic programming principle) is in general intractable or too costly to consider. In this framework, in the absence of diffusion terms, the value function is less regular than the usual setting for DNN approximations schemes. In general the presence of state constraints also prevents the value to be regular (because of the possible non-existence of feasible trajectories). Then the DNN may fail to well approximate the desired value function. From a theoretical point of view, the known convergence results for deep neural network (DNN) approximations use at some the level the presence of diffusion. The approach in Huré et al. (2021) utilizes that the law of the process has a density, which is not the case for deterministic evolution equations. Also, the general convergence result for deep BSDE in Han and Long (2020) needs a diffusion assumption on the SDE model as well as restrictive assumptions on the dynamics.

Here, we investigate, in the deterministic setting and by using a level-set approach, the use of DNN schemes based on the approximation of the dynamic programming principle. We develop new schemes extending some ideas coming from stochastic control of Huré et al. (2021), Bachouch et al. (2022) and Germain et al. (2022). These schemes are based on a time discretization of the PDE and some time local optimizations using classical feedforward networks (in our experiments, global methods such as the deep Galerkin method of Sirignano and Spiliopoulos (2018) may fail to see the obstacle).

We are able to prove the convergence of the algorithm in some L^1 norm. We also illustrate numerically the potential of the algorithm (and variants) on some academic front propagation problems in presence of obstacles in average dimensions (e.g. 2 to 8).

IDEA OF THE RESULT

We will use an equivalent formulation of Bellman's dynamic programming principle using feedback controls $a \in \mathcal{A} := mes(\mathbb{R}^d, A)$, the set of measurable functions from $\mathbb{R}^d$ into A. For a given $N \geq 1$, let $\Delta t = \frac{T}{N}$, $t_k = k\Delta t$, and consider approximate characteristics with time step Δt, denoted $F^a(x)$, for the approximation of $\dot{y}(t) = f(y(t), a(y(t)))$, $y(t_n) = x$, $t \in [t_n, t_{n+1}]$. For instance, the Euler scheme is

$$F^a(x) = x + \Delta t f(x, a(x));$$

the Heun scheme in our setting reads

$$F^a(x) = x + \frac{\Delta t}{2}(f(x, a(x) + f(x_1, a(x))$$

where $x_1 = x + \Delta t f(x, a(x))$ (here the control is frozen at the value $a(x)$ where x is the foot of the characteristic), etc. More complex explicit or implicit RK schemes have also to be considered (see Bokanowski et al. (Preprint)). The problem is then to compute an approximation of

$$V_n(x) := \min_{(a_n,\dots,a_{N-1})\in\mathcal{A}^{N-n}} \Big(\max_{k=n,\dots,N} g(X^a_{k,x}) \Big) \bigvee \varphi(X^a_{N,x})$$

where, for $a = (a_n, \dots, a_{N-1})$, the discrete dynamics $(X^a_{k,x})_{k=n,\dots,N}$ is such that

$$\begin{aligned} &X^a_{n,x} := x \\ &X^a_{k+1} := F^{a_k}(X^a_{k,x}), \quad \forall k = n, \dots, N-1. \end{aligned}$$

One of the considered scheme (the "Lagragian scheme") in a simplified form, is as follows. Let $(\hat{A}^\Theta_n)_{n\in[\![0,N-1]\!]}$ be a given sequence of finite-dimensional spaces (such as feedforward neural networks), for the approximation of feedback controls. We also consider a sequence of random variables $(X_k)_{k=0,\dots,N}$ with associated densities $\rho_k \in L^1(\mathbb{R}^d)$ (assuming for instance $\rho_k > 0$).

Algorithm ("Lagrangian scheme") *Set $\hat{V}_N := g \vee \varphi$. Then, for $n \in N-1, \dots, 0$, compute $\hat{a}_n \in \hat{A}^\Theta_n$ and set $\hat{V}_n$ as follows:*

$$\hat{a}_n \in \operatorname*{argmin}_{a\in\hat{A}^\Theta_n} \mathbb{E}\Big[g(X_n) \bigvee \hat{V}_{n+1}(F^a(X_k)) \Big] \tag{3a}$$

$$\hat{V}_n(x) := g(x) \bigvee \hat{V}_{n+1}\left(F^{\hat{a}_k}(x)\right) \tag{3b}$$

In this algorithm, only the feedback controls $(\hat{a}_k)$ are stored ($\hat{V}_n$ is not stored). In practice, the minimization problem (3a) is dealt with a stochastic gradient method. Each evaluation of the value $\hat{V}_{n+1}(x)$ uses the previous controls $(\hat{a}_{n+1}, \dots, \hat{a}_{N-1})$ to compute the approximated characteristic, in a full Lagrangian philosophy. Then we can show a convergence result in average, of the form

$$\max_{0\leq k\leq N} \mathbb{E}[|\hat{V}_k(X_k) - V_k(X_k)|] \overset{\Theta\to\infty}{\to} 0$$

as the parameters Θ for the neural network approximation space grows to infinity that is, assuming that

$$\max_{0\leq k\leq N-1} \inf_{a_k\in\hat{A}^\Theta_k} \mathbb{E}[|a_k(X_k) - \bar{a}_k(X_k)|] \overset{\Theta\to\infty}{\to} 0,$$

$(\bar{a}_k)_{0\leq k\leq n}$ beeing given optimal feedback controls for V_0. A difficulty in showing the convergence is the lack of regularity of the controls in feedback form, which are in general discontinuous. In order to deal with this issue, we first construct near optimal Lipschitz continuous feedback controls in order to approximate the value in some average norm; then we show that our algorithm can produce approximations of these controls (and associated values) up to arbitrary precision, therefore leading to a global convergence result for the approximated values.

A mathematical model for depression

Björn S. Rüffer *

* *Bauhaus-Universität Weimar, 99421 Weimar, Germany*
(e-mail: bjoern.rueffer@uni-weimar.de)

Abstract: A basic dynamical model for (clinical) depression is proposed that describes the time evolution of two coupled states: a depression symptom and the memory of past symptoms. The model consists of a system of two coupled first order differential equations with unit coefficients that qualitatively captures different courses of illness.

Keywords: Clinical depression, dynamical system, ordinary differential equations, stability analysis.

1. INTRODUCTION

According to the World Health Organization (WHO), depression is a common mental disorder affecting 5% of the adult population and a leading cause of disability worldwide, and can lead to suicide. The WHO further estimates that over 700 000 people die due to suicide every year, with suicide being the fourth leading cause of death in 15–29 year-olds (World Health Organization, 2021).

While the WHO also states that "there is effective treatment for mild, moderate, and severe depression", anecdotal evidence observed by the author has it that in some individuals depression can be very difficult to treat, has temporally fluctuating features, and psychiatric treatment often involves a long trial-and-error process for finding an effective medication regime that strikes an acceptable balance between effectiveness and its often severe side effects.

Clinical depression, also known as major or severe depression, is the stronger form of depression, and its treatment is more involved than simply administering the right drug (after identifying the right one in the first place). Research on the development of medical drugs would naturally involve neuroscience and neurobiology as well as medical studies.

At the same time, there exist a wealth of psychological research and established therapies for treating depression without administering drugs, including behavioral therapy (attributed independently to Wolpe; to Skinner; as well as to Rachman and Eysenck) and Aaron T. Beck's cognitive therapy and cognitive behavioral therapy.

There exist mathematical models in both of these reasonably distinct branches of depression research, e.g., Byrum et al. (1999); Disner et al. (2011). A common feature that can often be seen on both sides consists of causality networks that show how signaling pathways and areas in the brain influence each other, or how schemas, memories, triggers and behaviors are coupled in different psychological theories. An aspect most often overlooked, or at least not studied at the same level of detail, is the time axis, and the dynamical behavior of these graph-based models.

It is important to note that unlike in mathematics or the exact sciences, it is practically impossible to either derive a model from first principles or to identify a model from data, and that a model that is "as simple as possible but not any simpler" is the most desirable model. Another difficulty is that it is often unclear whether the root source of a patient's depression is genetic or a result of external factors, or a combination.

In the present contribution we propose a dynamical model that only implements the most basic coupling topology. Our model is simple in terms of its mathematical description, but not too simple to not exhibit complex enough behaviors consistent with anecdotal observations about the course of a depression.

There are two states in our model. One state represents the severity of depression or another suitable symptom that is a good indicator of depression. This is something that would commonly be measured by a practitioner using a questionnaire, such as the Beck Depression Inventory-Second Edition (BDI-2), a widely used 21-item self-report inventory measuring the severity of depression in adolescents and adults (Beck et al., 1996), or the Beck Hopelessness Scale (BHS), an instrument for assessing cognitive thoughts among suicidal persons (Beck et al., 1988). The second state measures the memory of past depression experiences, following the schema idea in Beck's cognitive theory (Disner et al., 2011). In a nutshell, this memory represents internal belief representations of past negative stimuli or experiences, which has influence on the effect of new stimuli. Unlike the depression state, the memory state evades direct measurement and for a given individual may only be inferred by the course of the illness in relation to external stimuli, which are just as difficult to measure and quantify.

The two states are coupled, and higher values of the memory state effect that external stimuli (which commonly would consist of negative life events for the individual) more severely worsen the depression, thus increase the depression state. Persistently large values of the depression state on the other hand effect a stronger increase of the memory state, while in the absence of depression symptoms, the memory state attenuates over time.

In Section 2 we propose a mathematical model from the informal description given above, along with some design choices for the numerical range of the states and the nature of the coupling. As our modeling aims to be qualitative and not to quantitatively match a given individual, there is no loss in generality to assume that all coupling coefficients have unit value. In Section 3 we examine properties of the model and study several scenarios in some detail. Section 4 concludes this study and provides some ideas for future research.

2. THE MATHEMATICAL MODEL OF DEPRESSION

Without loss of generality, we can normalize both the depression state (according to a scale such as BDI-2 or BHS, which naturally have a bounded range of possible values), which we call s, and the memory state, which we denote by m, to the unit interval $[0, 1]$, with zero denoting the absence of depression or a memory of it, and one the most severe form of depression and maximal memory of it.

We denote the external stimulus or influence to the model by $e \geq 0$, with the convention that zero means absence of the stimulus and larger values mean more severe and pronounced forms of negative life events affecting the individual. This stimulus may change with time.

With this notation the evolution of the symptom is given by

$$\dot{s} = \big(e(1 + s + m) - s(1 - m)\big)(1 - s)s \tag{1}$$

where the second and third factors, $(1-s)$ and s, are simply there to confine the solutions to the interval $[0, 1]$. The growth term $e(1+s+m)$ is always non-negative. It models that the symptom increases if there is an external influence (non-zero e), and that this rate of change is increased by the combined effect of current symptom severity (s) as well as symptom history (m). The decay term $-s(1 - m)$ is always non-positive and models the attenuation of the symptom. The net change rate is the combination of the growth and decay terms.

The evolution of the memory is given by

$$\dot{m} = \big(s - (1 - s)m\big)(1 - m)m. \tag{2}$$

Again the second and third factor ensure that the memory remains confined to the interval $[0, 1]$. The growth term in the change rate is simply s, the symptom severity, while the decay term is $-(1 - s)m$, modeling an an attenuation of the the memory that is stronger if symptoms are low, and less pronounced if symptoms are more developed.

Denoting the tuple $x := (x_1, x_2)^T := (s, m)^T \in [0, 1]^2$, we can write the model in the more compact form

$$\dot{x} = f(x, e) \tag{3}$$

with

$$f(x, e) = \begin{pmatrix} \big(e(1 + x_1 + x_2) - x_1(1 - x_2)\big)(1 - x_1)x_1 \\ \big(x_1 - (1 - x_1)x_2\big)(1 - x_2)x_2 \end{pmatrix}.$$

Expanding f, it is apparent that the model is nonlinear (polynomial in fact), which allows it to accommodate a rich set of dynamics as we shall see next.

3. PROPERTIES OF THE MODEL OF DEPRESSION

3.1 Equilibria

Using $x = (x_1, x_2)^T$ and $(s, m)^T$ interchangeably and treating $e \geq 0$ as a fixed parameter, we find the following list of equilibrium points for system (3):

$$\begin{aligned}
\bar{x}_1 &= (0, 0)^T \\
\bar{x}_2 &= (-\tfrac{e}{e-1}, 0)^T \\
\bar{x}_3 &= (1, 0)^T \\
\bar{x}_4 &= (\tfrac{e+\sqrt{5\,e^2-10\,e+1}-1}{2\,(e-2)}, -\tfrac{3\,e+\sqrt{5\,e^2-10\,e+1}-1}{2\,(e+1)})^T \\
\bar{x}_5 &= (\tfrac{e-\sqrt{5\,e^2-10\,e+1}-1}{2\,(e-2)}, -\tfrac{3\,e-\sqrt{5\,e^2-10\,e+1}-1}{2\,(e+1)})^T \\
\bar{x}_6 &= (0, 1)^T \\
\bar{x}_7 &= (-2, 1)^T \\
\bar{x}_8 &= (1, 1)^T
\end{aligned}$$

Of these, equilibrium point $\bar{x}_7$ is clearly outside our state space $[0, 1]^2$ and can be ignored in subsequent investigations.

Equilibria $\bar{x}_2$, $\bar{x}_4$, and $\bar{x}_5$ are dependent on the input e, which may vary with time.

Equilibria $\bar{x}_1$, $\bar{x}_3$, $\bar{x}_6$, and $\bar{x}_8$ are by construction of the model, while the point $\bar{x}_2$ is well-defined and in the domain $[0, 1]^2$ only if $e < 1$.

Provided that $e \leq 1 - \frac{2}{5}\sqrt{5} \approx 0.1$, the equilibria at $\bar{x}_4$ and $\bar{x}_5$ are well-defined and located in $[0, 1]^2$.

Already at this point it is clear that the model will exhibit changes in dynamics when the value of e varies across the value of $1 - \frac{2}{5}\sqrt{5} \approx 0.1$ or about 1.

It is an artifact of the design choices in this model that the points $\bar{x}_1$, $\bar{x}_3$, $\bar{x}_6$, $\bar{x}_8$ are equilibria irrespective of the value of e, meaning that an individual who has, say, zero symptoms and memory, will always remain this way, unfazed by any external stimuli. For practical purposes, however, it is a more realistic scenario to consider whether the states asymptotically converge to zero, or remain close to zero, which is a question of (asymptotic) stability.

Put differently, no real world and alive individual can ever be found in states $\bar{x}_1$ or $\bar{x}_8$, as everyone will have had some negative experiences in their lives.

3.2 Linearization and local stability analysis

Linearizing f at x we obtain the Jacobian $J(x, e) := \frac{\partial f}{\partial x}(x, e)$. At every point $x \in [0, 1]^2$ the matrix $J(x, e)$ is Metzler, i.e., it has non-negative off-diagonal entries. This means that the system $\dot{x} = f(x, e)$ is monotone (in x), which further implies that it is positive (i.e., positive initial conditions result in states that remain positive) and solutions for initial condition in $[0, 1]^2$ and arbitrary non-negative and locally integrable input $e = e(t)$ exist for all times and are confined to $[0, 1]^2$, see, e.g., Smith (1995) for an introduction to monotone systems. We'll discuss monotonicity in more detail in Section 3.4.

Evaluating the Jacobian of f at the equilibrium points in the four corners of the state space, we find

- $J(\bar{x}_1) = \begin{pmatrix} e & 0 \\ 0 & 0 \end{pmatrix}$,
- $J(\bar{x}_3) = \begin{pmatrix} -2\,e+1 & 0 \\ 0 & 1 \end{pmatrix}$,
- $J(\bar{x}_6) = \begin{pmatrix} 2\,e & 0 \\ 0 & 1 \end{pmatrix}$, and
- $J(\bar{x}_8) = \begin{pmatrix} -3\,e & 0 \\ 0 & -1 \end{pmatrix}$.

We can immediately read off the eigenvalues from the diagonals and conclude that

- equilibrium $\bar{x}_1$ is unstable for $e > 0$; no conclusion can be made for $e = 0$,
- equilibria $\bar{x}_3$ and $\bar{x}_6$ are unstable,
- equilibrium $\bar{x}_8$ is asymptotically stable for $e > 0$ and no conclusion can be made for $e = 0$.

An important case to study remains: the stability properties of $\bar{x}_1$ in the case that $e = 0$. While we cannot deduce (asymptotic) stability from $J(\bar{x}_1)$, the consideration of $J(\bar{x}_4)$ for $e \searrow 0$ suggests that the origin should indeed be asymptotically stable even for $e = 0$. We will come back to this question in Section 3.4 after considering some sample trajectories for time varying inputs in the next section, so as to gain more insight into the system.

3.3 Sample trajectories

To demonstrate the nonlinear effects of the model, let us consider the system response to two marginally different, piece-wise constant inputs

$$e_1(t) = \begin{cases} 0 & \text{if } t < 20 \\ 0.8 & \text{if } 20 \le t < 24 \\ 0.01 & \text{if } 24 \le t < 60 \\ 0.4 & \text{if } 60 \le t < 70 \\ 0.1 & \text{if } t \ge 70 \end{cases}$$

and

$$e_2(t) = \begin{cases} 0 & \text{if } t < 30 \\ 0.8 & \text{if } 30 \le t < 34 \\ 0.01 & \text{if } 34 \le t < 60 \\ 0.4 & \text{if } 60 \le t < 70 \\ 0.1 & \text{if } t \ge 70 \end{cases}.$$

The difference is the occurrence of the first step of the external stimulus, which happens at $t = 20$ and $t = 30$, respectively, but lasts the same duration, and the remainder of what might be thought of as environmental exposure is the same. Let us assume that for both inputs the system starts at $x^0 = (0.01, 0.01)^T$.

We find that the individual subject to $e_1(t)$ ultimately seems to recover from the external stimuli, or at least we can conclude that the level of the states remains bounded away from the point $(1, 1)$ (because we see a monotonic decrease in both states and the system is monotone).

If the first stimulus happens 10 time units later, though, we see that our individual, if instead subjected to $e_2(t)$ does not recover, and propels into a severe depression, as both states asymptotically reach 1.

Investigating the time evolution, we see two qualitatively rather similar evolutions up to the end of the second stimulus. Keeping in mind that the depression state is the only thing that can be somewhat measured (even though not with great accuracy and resolution through questionnaires), the obvious conclusion must be that timing is important for the overall outcome for the patient, as is the elusive memory state.

Another insight compatible with anecdotal evidence is that removal of external stimuli alone may not lead to recovery of an individual. For this consider the input

$$e_3(t) = \begin{cases} 0 & \text{if } t < 20 \\ 0.5 & \text{if } 20 \le t < 33 \\ 0 & \text{if } 33 \le t < 200 \\ 0.1 & \text{if } 200 \le t < 210 \\ 0 & \text{if } t \ge 210 \end{cases}$$

corresponding to a moderately severe life event at $t = 20$ and another mild one at $t = 200$. Neither event is particularly long, but the individual has a prior memory of depression with $m_0 = 0.5$ (and $s_0 = 0.01$ as before). If left without external stimulus, the memory would fade away to zero over time. But due to the first stimulus commencing at $t = 20$, the memory value is increased, and increased too far, so that it does not recover after the stimulus has ceased. Now a later and in comparison small, secondary stimulus at $t = 200$ is sufficient to push the individual into the a severe depression from which there is no recovery, even after all stimuli are over.

3.4 Consequences of monotonicity

Much of the following analysis hinges on the following fact, which can be gathered from Chapter 1 of Smith (1995) utilizing the fact that our system (3) is cooperative. By ordering we mean the component-wise ordering, i.e., for vectors x, y we have $x \ge y$ if for each component i we have $x_i \ge y_i$.

Theorem 1. (e.g., Smith (1995)). Let $x^0 \ge y^0$ be ordered initial conditions, and let locally integrable input signals e_1, e_2 be ordered point-wise, i.e., $e_1(t) \ge e_2(t)$ for all t. Denote by $x(t)$ the solution to the initial value problem $\dot{x} = f(x, e_1(t))$ with $x(0) = x^0$, and similarly $y(t)$ for the initial condition y^0 and input $e_2(t)$. Then the solutions remain ordered for all times, that is $x(t) \ge y(t)$ for all $t \ge 0$.

The first consequence is a stability result for the origin.

Corollary 2. If there is an $e^* < 1 - 2\sqrt{5}/5$ such that $e(t) < e^*$ for all $t \ge 0$ and $x^0 \le \bar{x}_4(e^*) := (\frac{e^*+\sqrt{5\,(e^*)^2-10\,e^*+1}-1}{2\,(e^*-2)}, -\frac{3\,e^*+\sqrt{5\,(e^*)^2-10\,e^*+1}-1}{2\,(e^*+1)})^T$, then the solution to the initial value problem $\dot{x} = f(x, e(t))$, $x(0) = x^0$, satisfies $x(t) \le \bar{x}_4(e^*)$ for all $t \ge 0$.

Since the order interval $[0, \bar{x}_4(e^*)] := \{x \in \mathbb{R}^2 \colon (0,0)^T \le x \le \bar{x}_4(e^*)\}$ defines an arbitrarily small neighborhood of the origin with e^* arbitrarily close to zero, we have the more specific result:

Corollary 3. If $e \equiv 0$ then the origin is stable with respect to (3).

The corollary states that if an individual with mild depression symptoms and very minor memory of such symptoms

experiences no further external stimuli, then neither the depression nor memory of it does increase.

A different question is whether both of the states actually dissipate to zero in this scenario. For that we need a different tool.

Asymptotic stability analysis of the origin in the case $e = 0$. In this case we can easily generate a specific trajectory for $e \equiv 0$ that converges to the origin. This trajectory comes from the initial condition $x^0 = \bar{x}_4(0.1)$. And because this trajectory converges to the origin as $t \to \infty$, we conclude with the help of Theorem 1 that *all* trajectories commencing in a neighborhood of the origin must converge to the origin, as they are dominated by one that does converge. We summarize this observation as follows.

Corollary 4. For $e \equiv 0$ the origin is asymptotically stable.

This result supports the intuition that "time heals all wounds" at least as long as the wound is a) small enough and b) any external stimuli causing further damage are completely removed.

4. CONCLUSION AND OUTLOOK

Our analysis is preliminary at this stage, but it is able to recover with a basic mathematical model a range of features that seem compatible with anecdotal evidence observed in individuals suffering from depression.

The model follows the paradigm to be as simple as possible but not simpler. It supports observations that a patient should continue to take their medication despite already feeling better—as the internal memory state may not have recovered yet and as this may take a substantially longer amount of time. It also supports scenarios where a patient is catapulted back into a severe depression by seemingly small trigger events that leave healthy individuals unaffected.

At the same time, the modeling process used here has made no attempt to seek grounding in more elaborate models of schema therapy or causal networks of signaling pathways in the brain as they are studied in neuroscience. The objective here was merely to propose a model that captures essential qualitative behavior, while being tractable by standard methods and concepts of the systems theory community, and we argue that this objective has been achieved.

A number of extensions are of course possible. On the mathematical side, more analysis can be done, for example by computing regions of attraction, by considering stability notions such as input-to-state stability, by designing observers for the memory state using only measurements of inputs and possibly quantized measurements of the symptom state. At the expense of simplicity, the model could further be augmented to account for treatment options such as medication, or to accommodate multiple symptoms and memory features or a resilience concept.

ACKNOWLEDGEMENTS

The author thanks practicing psychiatrist Irosh Fernando for discussions that inspired this paper.

Signed Tropicalizations of Convex Semialgebraic Sets ⋆

Mateusz Skomra *

* *LAAS-CNRS, Université de Toulouse, CNRS, Toulouse, France (e-mail: mateusz.skomra@laas.fr).*

Abstract: We study the signed valuations of convex semialgebraic sets defined over non-Archimedean fields. This is motivated by the efforts to understand the structure of semialgebraic sets that arise in convex optimization, such as the spectrahedra and the hyperbolicity cones. We give a full characterization of regular sets that are obtained as signed tropicalizations of convex semialgebraic sets, and we prove that the signed tropicalizations of hyperbolicity cones have a more restrictive structure. To obtain our results, we combine two recent advances in the area of tropical geometry: the study of signed valuations of general semialgebraic sets and the separation theorems for signed tropical convexities.

Keywords: Convex algebraic geometry, Tropical geometry, Hyperbolicity cones, Semialgebraic sets, Non-Archimedean fields

AMS Subject Classification: 90C25, 14T05, 14P10

1. INTRODUCTION

Convex semialgebraic sets arise naturally in convex optimization problems such as the semidefinite programming or the hyperbolic programming. As a result, questions motivated by optimization problems, such as the study of the expressivity of semidefinite programming, lead to questions in real algebraic geometry (e.g., study of classes of sets that are representable by linear matrix inequalities). We refer to Blekherman et al. (2013) for more information about the interactions between these disciplines. In this work, we apply techniques from tropical geometry to study convex semialgebraic sets.

One of the research directions in tropical geometry is to analyze the (semi)algebraic sets defined over non-Archimedean fields with the help of the valuation map. This idea was first applied to sets arising in convex optimization by Develin and Yu (2007), who studied the tropicalizations of polyhedra. This inspired numerous other works on the tropicalizations of polyhedra, see, e.g., Allamigeon et al. (2015, 2018); Allamigeon and Katz (2017); Joswig and Smith (2018). The study of tropical polyhedra was also extended to more general semialgebraic sets, such as spectrahedra (Yu, 2015; Allamigeon et al., 2020), hyperbolicity cones in dimension 3 (Le Texier, 2021), convex semialgebraic sets (Allamigeon et al., 2019), and arbitrary semialgebraic sets (Alessandrini, 2013; Allamigeon et al., 2020; Jell et al., 2022). A recent idea proposed by Jell et al. (2022) is to study the tropicalizations of semialgebraic sets using a *signed* valuation map. In other recent development, Loho and Végh (2020) and Loho and Skomra (2022b) started a systematic study of tropical convexities in the signed setting and proved new tropical analogues of the hyperplane separation theorem. In this work, we combine both ideas by studying the *signed* valuations of *convex* semialgebraic sets. Our main goal is to generalize the known results about tropical polyhedra and spectrahedra to the tropicalizations of hyperbolicity cones in arbitrary dimension. We present the first results in this direction, by characterizing the regular sets arising as tropicalizations of convex semialgebraic sets, and by showing that the tropicalizations of hyperbolicity cones have a more restricted, "tropically quadratic" structure.

2. PRELIMINARIES

2.1 Generalized Puiseux series

In this work, we denote by $\mathbb{K}$ the field of *absolutely convergent generalized real Puiseux series*, i.e., series of the form

$$\boldsymbol{x} = \boldsymbol{x}(t) = c_1 t^{\alpha_1} + c_2 t^{\alpha_2} + \dots , \tag{1}$$

where both the coefficients c_i and the exponents α_i are real numbers. We further suppose that the sequence $(\alpha_i)_{i\geqslant 1}$ is strictly decreasing and either finite or unbounded and that the series $\boldsymbol{x}(t)$ is absolutely convergent for all sufficiently large $t > 0$. It is known that $\mathbb{K}$ is a real closed field (van den Dries and Speissegger, 1998). In particular, $\mathbb{K}$ is ordered by putting $\boldsymbol{x} \geqslant 0 \iff c_1 \geqslant 0$. We state our results for $\mathbb{K}$, but we note that a quantifier elimination argument discussed in Allamigeon et al. (2020) allows to transfer our main theorems from $\mathbb{K}$ to any real closed field equipped with a nontrivial and convex valuation whose value group is $\mathbb{R}$.

As a non-Archimedean field, $\mathbb{K}$ has a valuation function $\mathsf{val}\colon \mathbb{K} \to \mathbb{R} \cup \{-\infty\}$ that maps a series of the form (1) to its leading exponent, $\mathsf{val}(\boldsymbol{x}) = \alpha_1$, with $\mathsf{val}(0) = -\infty$. We note that the usual convention in the theory of valued fields would be to define the valuation as $-\alpha_1$ rather than α_1. We use the opposite convention for the sake of coherence

with the max-plus tropical semiring introduced below. One can easily adapt our results to the other setting. We also use an extended valuation map that keeps track not only of the leading exponent of the series but also of its sign.

Definition 1. We define the *signed valuation* $\mathsf{sval}\colon \mathbb{K} \to (\{-1,1\}\times\mathbb{R})\cup\{-\infty\}$ by setting $\mathsf{sval}(\boldsymbol{x}) = \big(\operatorname{sign}(\boldsymbol{x}), \mathsf{val}(\boldsymbol{x})\big)$, with the convention that $\mathsf{sval}(0) = -\infty$.

We extend the definitions of val and sval to vectors by applying them coordinatewise. A *signed tropicalization* of a semialgebraic set $\boldsymbol{X} \subset \mathbb{K}^n$ is then given by $\mathsf{sval}(\boldsymbol{X})$. An alternative viewpoint follows from the work of Alessandrini (2013), who showed that if $\boldsymbol{X} \subset \mathbb{K}^n_{>0}$, then $\mathsf{val}(\boldsymbol{X})$ coincides with the "log-limit" of sets $\boldsymbol{X}(t) \subset \mathbb{R}^n_{>0}$ obtained by fixing the parameter t, $\mathsf{val}(\boldsymbol{X}) = \lim_{t\to\infty} \log_t\big(\boldsymbol{X}(t)\big)$. In this way, if $\boldsymbol{X} \subset \mathbb{K}^n$, then $\mathsf{sval}(\boldsymbol{X})$ is obtained by "gluing" the log-limits given by all sign patterns.

2.2 Signed tropical numbers

Tropicalizations of semialgebraic sets are studied with the help of an algebraic structure known as the tropical semiring, see Maclagan and Sturmfels (2015); Joswig (2021) for more information. The *tropical (max-plus) semiring* is defined as $\mathbb{T} = (\mathbb{R}\cup\{-\infty\}, \oplus, \odot)$, where $a\oplus b = \max\{a,b\}$ and $a\odot b = a+b$. In order to replace valuation by the signed valuation, we extend $\mathbb{T}$ to signed tropical numbers. The set of signed tropical numbers is $\mathbb{T}_\pm = (\{-1,1\}\times\mathbb{R})\cup\{-\infty\}$. By convention, we denote the numbers of the form $(1,a)$ by a and call them *positive*. We also denote the numbers of the form $(-1,a)$ by $\ominus a$ and call them *negative*. Then, the set $\mathbb{T}_\pm$ is ordered by mimicking the order of the real line, with $-\infty$ having the role of zero, so that

$$\ominus 2 < \ominus 1 < \ominus(-1) < -\infty < (-1) < 1 < 2\,.$$

We denote by $[a,b]$ the interval from a to b in $\mathbb{T}_\pm$ and we embed the set $\mathbb{T}$ in $\mathbb{T}_\pm$ by identifying it with the set of signed tropical numbers that are not smaller than $-\infty$. We equip $\mathbb{T}_\pm$ with the topology induced by the order and use the product topology on $\mathbb{T}^n_\pm$. We also use a sign function $\operatorname{tsign}\colon \mathbb{T}_\pm \to \{-1,0,1\}$ that gives the sign of a signed tropical number, $\operatorname{tsign}(-\infty) = 0$, and an absolute value function $|\cdot|\colon \mathbb{T}_\pm \to \mathbb{T}$ that acts by forgetting the sign of a tropical number. In this way, the function $\phi\colon \mathbb{T}_\pm \to \mathbb{R}$ defined as $\phi(x) = \operatorname{tsign}(x)\exp(|x|)$ is an order-preserving homeomorphism. Thus, $\mathbb{T}^n_\pm$ and $\mathbb{R}^n$ are homeomorphic.

In order to equip $\mathbb{T}_\pm$ with an algebraic structure, we first define the multiplication on $\mathbb{T}_\pm$ (still denoted by $\odot$) as $a\odot b = -\infty$ if $-\infty \in \{a,b\}$ and

$$a\odot b = \big(\operatorname{tsign}(a)\operatorname{tsign}(b), |a|+|b|\big)$$

otherwise. As an example, $(\ominus 2)\odot 3 = \ominus 5$, $(\ominus 3)\odot(\ominus 4) = 7$. Defining the addition is more problematic as there is no way to define an addition that extends $\oplus$ and turns $\mathbb{T}_\pm$ into a semiring. As a way to overcome this difficulty, we equip $\mathbb{T}_\pm$ with a multivalued addition $\boxplus\colon \mathbb{T}_\pm \to 2^{\mathbb{T}_\pm}$ defined as

$$a \boxplus b = \begin{cases} a & \text{if } |a| > |b| \text{ or } a = b,\\ b & \text{if } |b| > |a|,\\ [\ominus|a|, |a|] & \text{otherwise.}\end{cases}$$

In this way $(\ominus 2)\boxplus 3 = 3$, but $(\ominus 2)\boxplus 2 = [\ominus 2, 2]$. We extend the addition to vectors by applying it coordinatewise and to sets $A, B \subset \mathbb{T}_\pm$ by putting $A\boxplus B = \cup\{a\boxplus b\colon a\in A, b\in B\}$. These operations turn $(\mathbb{T}_\pm, \boxplus, \odot)$ into a *hyperfield*, see Baker and Bowler (2019) for more information. The following lemma gives a link between the signed valuation and the hyperfield operations.

Lemma 2. For any $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{K}$ we have $\mathsf{sval}(\boldsymbol{xy}) = \mathsf{sval}(\boldsymbol{x}) \odot \mathsf{sval}(\boldsymbol{y})$ and $\mathsf{sval}(\boldsymbol{x}+\boldsymbol{y}) \in \mathsf{sval}(\boldsymbol{x}) \boxplus \mathsf{sval}(\boldsymbol{y})$.

2.3 Tropical polynomials

A *(signed) tropical polynomial* $P(x) \in \mathbb{T}_\pm[x]$ is an expression of the form

$$\bigboxplus_{\alpha\in\Lambda} c_\alpha \odot x_1^{\odot\alpha_1} \odot \ldots \odot x_n^{\odot\alpha_n}\,,$$

where $c_\alpha \in \mathbb{T}_\pm$. A tropical polynomial defines a multivalued function $P\colon \mathbb{T}^n_\pm \to 2^{\mathbb{T}_\pm}$. One can check that if we evaluate P on a point $x \in \mathbb{T}^n_\pm$, then the result is either a singleton in $\mathbb{T}_\pm$ or an interval of the form $[\ominus a, a]$ for some $a > -\infty$. We define the *(signed) tropical hypersurface* of P as the set $\{x \in \mathbb{T}^n_\pm\colon -\infty \in P(x)\}$. Furthermore, given a polynomial $\boldsymbol{P} \in \mathbb{K}[x]$ of the form $\boldsymbol{P}(\boldsymbol{x}) = \sum_{\alpha\in\Lambda} \boldsymbol{c}_\alpha \boldsymbol{x}_1^{\alpha_1}\ldots\boldsymbol{x}_n^{\alpha_n}$, we define its *formal tropicalization* as $\operatorname{trop}(\boldsymbol{P}) = \bigboxplus_{\alpha\in\Lambda} \mathsf{sval}(\boldsymbol{c}_\alpha) \odot x_1^{\odot\alpha_1} \odot \ldots \odot x_n^{\odot\alpha_n}$. The next lemma follows from Lemma 2 and links the classical and tropical hypersurfaces.

Lemma 3. Let $\boldsymbol{P} \in \mathbb{K}[x]$ be a polynomial. Then, the set

$$\mathsf{sval}\big(\{\boldsymbol{x} \in \mathbb{K}^n\colon \boldsymbol{P}(\boldsymbol{x}) = 0\}\big)$$

is included in the tropical hypersurface of $\operatorname{trop}(\boldsymbol{P})$. In general, this inclusion may be strict.

Example 4. Consider the bivariate polynomial $\boldsymbol{P} \in \mathbb{K}[x]$ defined as $\boldsymbol{P}(\boldsymbol{x}) = (\boldsymbol{x}_1 - 1 - t^{-1})^4 + \boldsymbol{x}_2^4 - 1$. By opening the parentheses, one can see that the formal tropicalization of $\boldsymbol{P}$ is given by $x_2^{\odot 4} \boxplus x_1^{\odot 4} \boxplus (\ominus x_1^{\odot 3}) \boxplus x_1^{\odot 2} \boxplus (\ominus x_1) \boxplus (-1)$. The tropical hypersurface of $\operatorname{trop}(\boldsymbol{P})$ is the boundary of the set depicted in Figure 1. In this case, the inclusion from Lemma 3 is satisfied as an equality.

2.4 Tropical convexity

In the unsigned case, we say that a subset $X \subset \mathbb{T}^n$ is *tropically convex* if for every $x, y \in X$ and for all $\lambda, \mu \in \mathbb{T}$ such that $\lambda\oplus\mu = 0$ we have $(\lambda\odot x)\oplus(\mu\odot y) \in X$. We note that this mimics the definition of convexity over $\mathbb{R}^n$, since 0 is the neutral element of $\odot$ and the weights λ, μ are always "nonnegative", as they satisfy $\lambda, \mu \geqslant -\infty$. The following lemma relates the classical and tropical convexity, see, e.g., Develin and Sturmfels (2004), Develin and Yu (2007), Allamigeon et al. (2019) for more information.

Lemma 5. If $\boldsymbol{X} \subset \mathbb{K}^n$ is convex, then $\mathsf{val}(\boldsymbol{X}) \subset \mathbb{T}^n$ is tropically convex.

The following extension of tropical convexity to $\mathbb{T}_\pm$ was introduced by Loho and Végh (2020).

Definition 6. We say that a set $X \subset \mathbb{T}^n_\pm$ is *TO-convex* if for every $x, y \in X$ and for all $\lambda, \mu \in \mathbb{T}_\pm$ such that $\lambda, \mu \geqslant -\infty$ and $\lambda \boxplus \mu = 0$ we have $(\lambda\odot x)\boxplus(\mu\odot y) \subset X$.

The drawback of multivalued addition is that the TO-convexity is a rather strong property. In particular, Lemma 5 does not generalize to the signed setting (this requires to use a weaker notion of TC-convexity). Nevertheless, we still have a weaker property.

Lemma 7. (Loho and Skomra (2022a)). If $\boldsymbol{X} \subset \mathbb{K}^n$ is convex, then the interior of $\mathsf{sval}(\boldsymbol{X}) \subset \mathbb{T}^n_\pm$ is TO-convex.

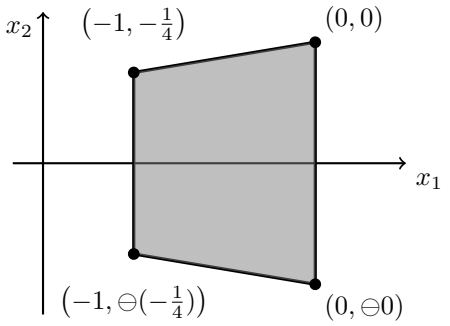

Fig. 1. Signed valuation of a convex semialgebraic set.

Example 8. The *TV screen set* is a convex set in $\mathbb{R}^2$ defined as $\{x \in \mathbb{R}^2 \colon x_1^4 + x_2^4 \leqslant 1\}$. The convexity of the TV screen set implies that the set $\boldsymbol{S}_1 = \{\boldsymbol{x} \in \mathbb{K}^2 \colon (\boldsymbol{x}_1 - 1 - t^{-1})^4 + \boldsymbol{x}_2^4 \leqslant 1\}$ is also convex. Figure 1 depicts the set $\mathsf{sval}(\boldsymbol{S}_1)$. We note that this set is TO-convex.

Example 9. The *bean curve* is the curve defined by the polynomial $p(x) = x_1(x_1^2 + x_2^2) - x_1^4 - x_1^2x_2^2 - x_2^4$. The region $\{x \in \mathbb{R}^2 \colon p(x) \geqslant 0\}$ is convex. This implies that the set $\boldsymbol{S}_2 = \{\boldsymbol{x} \in \mathbb{K}^2 \colon \boldsymbol{x}_1 \geqslant t^{-1}, p(1 - \boldsymbol{x}_1, \boldsymbol{x}_2) \geqslant 0\}$ is also convex. Its signed valuation is the same as in the previous example, $\mathsf{sval}(\boldsymbol{S}_1) = \mathsf{sval}(\boldsymbol{S}_2)$.

3. MAIN RESULTS

We now state our main results concerning the signed valuations of convex semialgebraic sets. Some of these results were obtained in collaboration with Georg Loho.

For the purpose of this work, we say that a set $X \subset \mathbb{T}_\pm^n$ is *regular* if it is equal to the closure of its interior. Regular sets arise naturally in the study of valuations of convex sets—it is known that generic tropical polyhedra are regular (Allamigeon et al., 2015) and the same is true for tropical Metlzer spectrahedra (Allamigeon et al., 2020).

3.1 Polyhedra

The signed valuations of polyhedra are studied in Loho and Végh (2020); Loho and Skomra (2022a,b). In particular, we have the following result.

Theorem 10. (Loho and Skomra (2022a)). Let $X \subset \mathbb{T}_\pm^n$ be a regular set. Then, the following are equivalent:

(1) X is an intersection of finitely many signed tropical halfspaces.
(2) X is a signed valuation of a polyhedron.

Here, a *signed tropical halfspace* is a set of the form

$$\{x \in \mathbb{T}_\pm^n \colon P(x) \cap [-\infty, +\infty) \neq \emptyset\},$$

where $P(x)$ is an affine tropical polynomial,

$$P(x) = c_0 \boxplus (c_1 \odot x_1) \boxplus \ldots \boxplus (c_n \odot x_n).$$

For the unsigned valuation, it is known that Theorem 10 holds even without the regularity assumption, see Develin and Yu (2007); Gaubert and Katz (2011). On the other hand, some assumption is necessary in the signed case. Indeed, an intersection of finitely many signed tropical halfspaces does not need to be connected, whereas a signed valuation of a convex set is always connected. It is an open question if Theorem 10 is true if we replace the assumption "X is regular" by "X is connected".

3.2 General convex semialgebraic sets

In order to characterize the regular sets that arise as images of convex semialgebraic sets, we need the following definition.

Definition 11. Let $X \subset \mathbb{T}_\pm^n$ be any set and let $\sigma \in \{-1, 1\}^n$ be a vector of signs. Then, the *maximal stratum of X given by σ* is the subset of $\mathbb{R}^n$ defined as

$$\mathrm{str}(\sigma, X) = \{(|x_1|, \ldots, |x_n|) \colon x \in X \wedge \forall i, \mathrm{tsign}(x_i) = \sigma_i\}.$$

We also say that a closed subset of $\mathbb{R}^n$ is *semilinear* if it is a union of polyhedra of the form $\{x \colon Ax \geqslant b\}$, where $b \in \mathbb{R}^m$ and $A \in \mathbb{Q}^{m \times n}$ is a rational matrix. The following theorem is our main result about tropicalizations of convex semialgebraic sets.

Theorem 12. Suppose that the set $X \subset \mathbb{T}_\pm^n$ is regular. Then, the following are equivalent:

(1) X has a TO-convex interior and semilinear maximal strata.
(2) X is a signed valuation of a convex semialgebraic set.

For the unsigned valuation, a full characterization that does not require regularity was given by Allamigeon et al. (2019). As in the case of polyhedra, it is an open question to obtain a generalization of Theorem 12 that does not require regularity.

The next corollary gives more insight into the structure of signed valuations of convex cones.

Corollary 13. Suppose that $\boldsymbol{X} \subset \mathbb{K}^n$ is a convex semialgebraic cone such that $\mathsf{sval}(\boldsymbol{X})$ is regular. Let $\mathcal{W}$ be any nonempty maximal stratum of $\mathsf{sval}(\boldsymbol{X})$. Then, $\mathcal{W}$ is a support of a pure polyhedral complex of dimension n. Furthermore, if F is an $(n-1)$-dimensional face of this complex, then the affine space spanned by F is of the form

$$\{x \in \mathbb{R}^n \colon \lambda + x_k = p^T x\}$$

for some $k \in [n]$, $\lambda \in \mathbb{R}$, and $p \in \mathbb{Q}^n_{\geqslant 0}$ that satisfies $p_k = 0$ and $\sum_{i=1}^n p_i = 1$.

Example 14. Consider the cone $\boldsymbol{S}_3 = \{\boldsymbol{x} \in \mathbb{K}^3 \colon \left(\boldsymbol{x}_1 - (1 + t^{-1})\boldsymbol{x}_3\right)^4 + \boldsymbol{x}_2^4 - \boldsymbol{x}_3^4 \leqslant 0, \boldsymbol{x}_3 \geqslant 0\}$, which is a homogenized version of the set $\boldsymbol{S}_1$ from Example 8. Its signed valuation $S = \mathsf{sval}(\boldsymbol{S}_3)$ is therefore a (tropically) homogenized version of the set depicted in Figure 1. If we fix $\sigma = (1, 1, 1)$, then $\mathrm{str}(\sigma, S)$ is a polyhedral complex with three faces of dimension 2. These faces are included in affine spaces given by $x_3 = x_1$, $x_3 - 1 = x_1$, and

$$x_2 = \frac{1}{4}x_1 + \frac{3}{4}x_3. \tag{2}$$

3.3 Hyperbolicity cones

Let us recall that a homogeneous polynomial $\boldsymbol{P} \in \mathbb{K}[x]$ is *hyperbolic with respect to* $\boldsymbol{e} \in \mathbb{K}^n$ if $\boldsymbol{P}(\boldsymbol{e}) > 0$ and, for all $\boldsymbol{x} \in \mathbb{K}^n$, all the roots of the univariate polynomial $\boldsymbol{\lambda} \mapsto \boldsymbol{P}(\boldsymbol{e} - \boldsymbol{\lambda}\boldsymbol{x})$ belong to $\mathbb{K}$. If $\boldsymbol{P}$ is hyperbolic with respect to $\boldsymbol{e}$, then the set

$$\{\boldsymbol{x} \in \mathbb{K}^n \colon \boldsymbol{\lambda} \mapsto \boldsymbol{P}(\boldsymbol{e} - \boldsymbol{\lambda}\boldsymbol{x}) \text{ has only nonnegative roots}\}$$

is called its *hyperbolicity cone*. The following lemmas summarize basic properties of hyperbolicity cones. They are stated over $\mathbb{R}$ in Renegar (2006), but they hold in all real closed fields.

Lemma 15. Hyperbolicity cones are convex.

Lemma 16. The hyperbolicity cone of $\boldsymbol{P}$ with respect to $\boldsymbol{e}$ is equal to the closure of the connected component of the set $\{\boldsymbol{x} \in \mathbb{K}^n \colon \boldsymbol{P}(\boldsymbol{x}) > 0\}$ that contains $\boldsymbol{e}$.

Our first result gives a tropical analogue of Lemma 16.

Proposition 17. Suppose that $\boldsymbol{X} \subset \mathbb{K}^n$ is a hyperbolicity cone of $\boldsymbol{P}$ with respect to some point. Furthermore, suppose that $\mathsf{sval}(\boldsymbol{X})$ is regular and let e be any point in the interior of $\mathsf{sval}(\boldsymbol{X})$. Then, $\mathsf{sval}(\boldsymbol{X})$ is equal to the closure of the connected component of the set

$$\{x \in \mathbb{T}_{\pm}^n \colon \operatorname{trop}(\boldsymbol{P})(x) \text{ is a positive singleton}\}$$

that contains e.

We note that the boundary of the connected component mentioned in Proposition 17 belongs to the tropical hypersurface of $\operatorname{trop}(\boldsymbol{P})$. Proposition 17 implies that this boundary is a subset of $\mathsf{sval}\big(\{\boldsymbol{x} \in \mathbb{K}^n \colon \boldsymbol{P}(\boldsymbol{x}) = 0\}\big)$.

Our final result implies that signed valuations of hyperbolicity cones have more restricted structure than signed valuations of general convex semialgebraic sets.

Theorem 18. Suppose that $\boldsymbol{X} \subset \mathbb{K}^n$ is a hyperbolicity cone such that $\mathsf{sval}(\boldsymbol{X})$ is regular. Let $\mathcal{W}$ be a nonempty maximal stratum of $\mathsf{sval}(\boldsymbol{X})$ and let F be an $(n-1)$-dimensional face of a polyhedral complex with support $\mathcal{W}$. Then, the affine space spanned by F is of the form

$$\{x \in \mathbb{R}^n \colon \lambda + x_k = p^T x\}, \tag{3}$$

for some $k \in [n]$, $\lambda \in \mathbb{R}$, and $p \in \{0, \frac{1}{2}, 1\}^n$ that satisfies $p_k = 0$ and $\sum_{i=1}^n p_i = 1$. In particular, p has either one or two nonzero coefficients.

Example 19. Equation (2) implies that the set $\boldsymbol{S}_3$ from Example 14 does not satisfy the condition of Theorem 18. In particular, $\boldsymbol{S}_3$ is not a hyperbolicity cone. By the discussion in Examples 8 and 9, we recover the known fact that neither the TV screen set nor the set bounded by the bean curve are spectrahedral, see Helton and Vinnikov (2007); Henrion (2010) for more discussion.

Informally, Theorem 18 can be interpreted by saying that signed valuations of hyperbolicity cones are "tropically quadratic" since the hyperplanes of the form (3) are given by tropical polynomials of degree 2. In this sense, Theorem 18 generalizes the result of Allamigeon et al. (2020) who showed that generic tropical Metzler spectrahedral cones are described by systems of tropical quadratic inequalities. We note however that Theorem 18 is only a local result: it states that every face separately can be described by a tropically quadratic polynomial, but does not give a global characterization of $\mathsf{sval}(\boldsymbol{X})$. I particular, the following is the main open question about the tropicalizations of hyperbolicity cones. This question is the tropical analogue of the generalized Lax conjecture, see Amini and Brändén (2018) for more information.

Problem 20. Suppose that $X \subset \mathbb{T}_{\pm}^n$ is a signed valuation of a hyperbolicity cone. Does this imply that X is a signed valuation of a spectrahedron?

We note that if the answer to Problem 20 is negative and a counterexample is obtained from a linear transformation of a real polynomial (like in Example 14), then we would obtain a negative answer to the generalized Lax conjecture over the real numbers.

Robust Adaptive Model Predictive Control with Persistent Excitation Conditions

Xiaonan Lu *, **Mark Cannon** *

Abstract: For constrained linear systems with bounded disturbances and parametric uncertainty, we propose a robust adaptive model predictive control (MPC) scheme with online parameter estimation. Constraints enforcing persistent excitation in closed loop operation are introduced to ensure asymptotic parameter convergence. The algorithm requires the online solution of a convex optimisation problem, satisfies constraints robustly, and ensures recursive feasibility and input-to-state stability. Almost sure convergence to the actual system parameters is obtained under mild conditions on stabilisability and the tightness of disturbance bounds.

Keywords: Model Predictive Control, Robust Adaptive Control, Constrained Systems, System Identfication

1. INTRODUCTION

To be effective, model predictive controllers require accurate models of the controlled system. Adaptive MPC algorithms allow model parameters to be estimated online, reducing model uncertainty without expensive or disruptive offline testing. In system identification and adaptive control, persistent excitation (PE) conditions play a key role in establishing convergence of parameter estimates (Green and Moore, 1986; Shimkin and Feuer, 1987). By incorporating constraints to ensure appropriate PE conditions, a constrained MPC strategy can impose a lower bound on the expected rate of parameter convergence. As a result, adaptive MPC has the potential to estimate system parameters while controlling the system subject to constraints. Various approaches have been proposed (Mayne, 2014), but robust, computationally tractable adaptive MPC remains an open topic under research.

Adaptive MPC strategies usually have the dual purpose of regulating the system via feedback and providing sufficient excitation for identification of the system. Different adaptive MPC approaches place varying emphasis on these two competing objectives. Some focus on robust constraint satisfaction and stability (e.g. through constraint tightening (Di Cairano, 2016), min-max cost formulations (Adetola et al., 2009; Wang et al., 2017) or tube MPC (Lorenzen et al., 2019; Lu and Cannon, 2019)) but omit persistent excitation conditions in the problem formulation. On the other hand, some approaches consider a nominal MPC problem and force the control law to be persistently exciting, but fail to ensure constraint satisfaction and closed loop system stability (Goodwin and Sin, 1984; Marafioti et al., 2014).

Other approaches aim to achieve the dual objectives of system regulation and sufficient excitation simultaneously. For example, Weiss and Di Cairano (2014) use an augmented cost function to make the resulting control law more likely to be persistently exciting, but this is not guaranteed. Tanaskovic et al. (2014) avoids imposing PE conditions by considering the discrepancy between the nominal and actual models. However, this requires a nonconvex, infinite-dimensional optimisation that can only be simplified for specific examples. Gonzalez et al. (2014) uses a dual mode control strategy that injects persistent excitation into the system whenever the state enters a target region for parameter identification. The proposed algorithm is only applicable to open-loop stable linear systems however, and the existence of the target region is example-dependent. Hernandez Vicente and Trodden (2019) propose an algorithm that satisfies a PE condition and state and input constraints recursively, but the system model cannot be adapted online. Parsi et al. (2022) explicitly predicts the effect of future model updates in order to ensure sufficiently accurate parameter estimates, but this requires the online solution of a nonconvex problem.

In addition, although the importance of Persistent Excitation conditions have been widely acknowledged in the adaptive control literature (Narendra and Annaswamy, 1987), few strategies incorporate these conditions in a convex optimisation formulation. For example, Marafioti et al. (2014) simplifies the PE condition by expressing it as a nonconvex quadratic inequality in terms of the control input. Similarly, Hernandez Vicente and Trodden (2019) demonstrate that a PE condition can be satisfied using a periodic solution computed offline, but this solution might not be optimal. Other approaches (Lu and Cannon, 2019; Lu et al., 2021) use linearisation of the PE condition around a reference trajectory to determine sufficient conditions for persistency of excitation, but are unable to ensure closed loop satisfaction of PE conditions through recursively feasible constraints.

In this work we consider linear models with parametric uncertainty and unknown bounded additive disturbances. Building on Lu et al. (2021), we propose an adaptive MPC algorithm that combines set-based parameter identification, robust regulation, and recursively feasible con-

straints. The algorithm is input-to-state stable (ISS) and ensures convergence of parameter estimates with probability 1. Using a random excitation sequence injected into a terminal control law, we derive closed loop bounds on the expectation of PE coefficients. The algorithm employs a convex online optimisation and uses a randomised check to enforce a non-convex PE condition. The algorithm is convex and computationally tractable due to its fixed-complexity polytopic tube representation.

Notation: $\mathbb{N}_{\geq 0}, \mathbb{R}_{\geq 0}$ are the non-negative integers and reals respectively, and $\mathbb{N}_{[p,q]}$ denotes $\{n \in \mathbb{N} : p \leq n \leq q\}$. The identity matrix is $\mathcal{I}$. The ith element of a vector a is $[a]_i$ and $\|a\|$ denotes the Euclidean norm. The ith row of a matrix A is $[A]_i$, and $\text{vec}(A)$ is the vector formed by stacking the columns of A. For $\mathcal{X}, \mathcal{Y} \subset \mathbb{R}^n$, $A\mathcal{X} = \{Ax : x \in \mathcal{X}\}$, $\mathcal{X} \oplus \mathcal{Y} = \{x + y : x \in \mathcal{X}, y \in \mathcal{Y}\}$. Expectation is $\mathbb{E}$ and $y_{k|t}$ is the k steps ahead prediction of y at time t.

2. PERSISTENT EXCITATION

The system state $x_t \in \mathbb{R}^{n_x}$, control input $u_t \in \mathbb{R}^{n_u}$ and unknown disturbance input $w_t \in \mathbb{R}^{n_w}$, satisfy

$$x_{t+1} = A(\theta^*)x_t + B(\theta^*)u_t + Fw_t. \tag{1}$$

at all times $t \in \mathbb{N}_{\geq 0}$. Matrices $A(\theta^*)$ and $B(\theta^*)$ depend on an unknown constant parameter $\theta^* \in \mathbb{R}^p$.

Assumption 1. (Additive disturbance). The disturbance sequence $\{w_t \in \mathcal{W}, t \in \mathbb{N}_{\geq 0}\}$ is independent and identically distributed (i.i.d.), $\mathbb{E}(w_t) = 0$, $\mathbb{E}(w_t w_t^\top) \succeq \epsilon_w \mathcal{I}$, $\epsilon_w > 0$, and $\mathcal{W}$ is a known convex polyhedral set.

Assumption 2. (Model parameters). (a). $A(\theta), B(\theta)$ are defined in terms of known matrices A_j, B_j, $j \in \mathbb{N}_{[0,p]}$:

$$(A(\theta), B(\theta)) = (A_0, B_0) + \sum_{i=1}^{p} (A_i, B_i)[\theta]_i, \quad \forall \theta \in \Theta_0.$$

(b). Θ_0 is a known polytopic set containing θ^*:

$$\theta^* \in \Theta_0 = \{\theta : M_\Theta \theta \leq \mu_0\} = \text{Co}\{\theta_0^{(1)}, \ldots, \theta_0^{(m)}\}.$$

(c). The pair $\big(A(\theta^*), B(\theta^*)\big)$ is reachable.
(d). $(A(\theta), B(\theta)) = (A(\theta^*), B(\theta^*))$ if and only if $\theta = \theta^*$.

2.1 Set-based parameter estimation

Parameter identification methods include recursive least squares (Heirung et al., 2017), comparison sets (Aswani et al., 2013), set membership identification (Tanaskovic et al., 2014; Lorenzen et al., 2019) and neural network training (Akpan and Hassapis, 2011). Here we use a set membership approach to enable robust satisfaction of constraints. Set-based parameter identification was proposed in (Chisci et al., 1998; Veres et al., 1999) and it was shown in Lu et al. (2021) that the estimated parameter set converges to the true parameter value with probability 1 if the associated regressor is persistently exciting (PE).

At times $t \in \mathbb{N}_{>0}$ we use observations of the state x_t to determine a set Δ_t of unfalsified model parameters. This is combined with Θ_{t-1} to construct a new parameter set estimate Θ_t. The model (1) can be rewritten as

$$x_{t+1} = \Phi(x_t, u_t)\theta^* + \phi(x_t, u_t) + Fw_t$$

where Φ_t and ϕ_t are known at time t and are defined by

$$\Phi_t = \Phi(x_t, u_t) = [A_1 x_t + B_1 u_t \ \cdots \ A_p x_t + B_p u_t] \tag{2}$$

$$\phi_t = \phi(x_t, u_t) = A_0 x_t + B_0 u_t. \tag{3}$$

Given x_t, x_{t-1}, u_{t-1} and the disturbance set $\mathcal{W}$, the unfalsified parameter set at time t is given by

$$\Delta_t = \{\theta : x_t - A(\theta)x_{t-1} - B(\theta)u_{t-1} \in F\mathcal{W}\}$$

The parameter set Θ_t may be updated using Δ_t by various methods, including minimal (Chisci et al., 1998), fixed-complexity (Lorenzen et al., 2019), and limited-complexity (Tanaskovic et al., 2014) update laws. In each case, Θ_t is non-increasing and $\Theta_t \subseteq \Theta_{t-1}$ for all $t \in \mathbb{N}_{>0}$.

For a fixed-complexity parameter set update law, the parameter set estimate Θ_t is defined as $\Theta_t = \Theta(\mu_t) = \{\theta : M_\Theta \theta \leq \mu_t\}$ where $M_\Theta \in \mathbb{R}^{r \times p}$ is an *a priori* chosen matrix and $\mu_t \in \mathbb{R}^r$ is determined so that Θ_t is the smallest set containing the intersection of Θ_{t-1} and the unfalsified sets $\Delta_{t-N_\mu+1}, \ldots, \Delta_t$,

$$\mu_t := \min_{\mu \in \mathbb{R}^r} \text{vol}\big(\Theta(\mu)\big) \ \text{ s.t. } \bigcap_{j=t-N_\mu+1}^{t} \Delta_j \cap \Theta_{t-1} \subseteq \Theta(\mu) \tag{4}$$

where $\Delta_j := \mathbb{R}^p$ for $j \leq 0$ and N_μ is the parameter update window length. Note that μ_t can be computed by solving a set of linear programs.

We briefly recap the definition of persistent excitation (PE). The regressor Φ_t in (2) is persistently exciting if there exists a horizon N_u and a scalar $\epsilon_\Phi > 0$ such that

$$\sum_{k=t}^{t+N_u-1} \Phi_k^\top \Phi_k \succeq \epsilon_\Phi \mathcal{I} \tag{5}$$

for all $t \in \mathbb{N}_{\geq 0}$. In the current work however, we define persistent excitation using the expectation condition

$$\sum_{k=t}^{t+N_u-1} \mathbb{E}\big\{\Phi_k^\top \Phi_k\big\} \succeq \epsilon_\Phi \mathcal{I}, \tag{6}$$

which is required to hold for some $\epsilon_\Phi > 0$ with non-zero probability, for all $t \in \mathbb{N}_{\geq 0}$. We refer to the interval $\mathbb{N}_{[t,t+N_u-1]}$ as a PE window.

Assumption 3. (Tight disturbance bound). For all $w^0 \in \partial\mathcal{W}$ and any $\epsilon > 0$ the disturbance sequence $\{w_0, w_1, \ldots\}$ satisfies $\Pr\big\{\|w_t - w^0\| < \epsilon\big\} \geq p_w(\epsilon)$, for all $t \in \mathbb{N}_{\geq 0}$, where $p_w(\epsilon) > 0$ whenever $\epsilon > 0$.

The following result extends Lu et al. (2021), Corollaries 2 and 3, to the case of the modified PE condition (6).

Lemma 1. Under Assumptions 1 and 3, if Φ_t satisfies the PE condition (6) with probability $p > 0$ for all t, then the minimal and fixed complexity parameter set estimates Θ_t with $N_\mu \geq N_u$ converge to $\{\theta^*\}$ with probability 1.

Assumption 1 on the disturbance sequence $\{w_t, t \in \mathbb{N}_{\geq 0}\}$ is common in practice. Assumption 3 may be more difficult to verify, but we note that this assumption can be relaxed at the expense of some residual uncertainty in the parameter set estimate (see Lu et al. (2021) for details).

2.2 Linear feedback with injected noise

Consider a feedback law with injected noise:

$$u_t = Kx_t + s_t \tag{7}$$

where s_t is a stochastic variable. To simplify notation we define $A_K(\theta) = A(\theta) + B(\theta)K$, $A_{K,i} = A_i + B_i K$, $i \in \mathbb{N}_{[0,p]}$.

Assumption 4. (Stability). For $z_t \in \mathbb{R}^{n_x}$ and $t \in \mathbb{N}_{\geq 0}$, $z_{t+1} \in \text{Co}\{A_K(\theta)z_t, \theta \in \Theta_0\}$ is quadratically stable.

Assumption 5. The sequence $\{s_t \in \mathcal{S}, t \in \mathbb{N}_{\geq 0}\}$ is i.i.d. with $\mathbb{E}(s_t) = 0$, $\mathbb{E}(s_t s_t^\top) \succeq \epsilon_s \mathcal{I}$, $\epsilon_s > 0$, s_t is independent of x_t and w_t, and $\mathcal{S}$ is a known polytopic set.

Theorem 2. If $N_u > n_x$, then under Assumptions 1, 2, 4 and 5, the regressor Φ_t in (2) of the system (1) with $u_t = Kx_t + s_t$ satisfies, for some $\epsilon_\Phi > 0$ and all $k \in \mathbb{N}_{\geq 0}$,

$$\sum_{k=t}^{t+N_u-1} \mathbb{E}\big(\Phi_k^\top \Phi_k\big) \succeq \epsilon_\Phi \mathcal{I}. \tag{8}$$

3. ADAPTIVE ROBUST MPC

The noise s_t injected into the feedback law (7) can cause poor tracking performance and may violate state and control constraints. However, a receding horizon control law incorporating injected noise can avoid these undesirable effects while exploiting the PE properties it provides. Consider a predicted control law parameterised at time t in terms of decision variables $\mathbf{v}_t = \{v_{0|t}, \dots, v_{N-1|t}\}$:

$$u_{k|t} = \begin{cases} Kx_{k|t} + v_{k|t}, & k \in \mathbb{N}_{[0,N-1]} \\ Kx_{k|t} + s_{k|t}, & k \in \mathbb{N}_{[N,N+N_u-1]} \end{cases} \tag{9}$$

where N is the prediction horizon. We assume linear state and control input constraints

$$x_{k|t} \in \mathcal{X}, \quad u_{k|t} \in \mathcal{U}, \quad \forall k \in \mathbb{N}_{[0,N+N_u-1]}, \tag{10}$$

where $\mathcal{X}$, $\mathcal{U}$ are given polytopes. To enforce these constraints we define a terminal set $\mathcal{X}_T$ satisfying

$$\mathcal{X}_T \subseteq \mathcal{X}, \quad K\mathcal{X}_T \oplus \mathcal{S} \subseteq \mathcal{U}, \tag{11}$$

$$A_K(\theta)\mathcal{X} \oplus B(\theta)\mathcal{S} \oplus F\mathcal{W} \subseteq \mathcal{X}_T \quad \forall \theta \in \Theta_t. \tag{12}$$

3.1 Tube MPC formulation

To ensure satisfaction of constraints (10) we construct a sequence of sets denoted $\mathbf{X}_t = \{\mathcal{X}_{k|t}, k \in \mathbb{N}_{[0,N+N_u-1]}\}$, satisfying, for all $\theta \in \Theta_t$ and $k \in \mathbb{N}_{[0,N-1]}$,

$$\mathcal{X}_{k|t} \subseteq \mathcal{X}, \quad K\mathcal{X}_{k|t} \oplus \{v_{k|t}\} \subseteq \mathcal{U}, \tag{13}$$

$$A_K(\theta)\mathcal{X}_{k|t} \oplus \{B(\theta)v_{k|t}\} \oplus F\mathcal{W} \subseteq \mathcal{X}_{k+1|t}. \tag{14}$$

The initial and terminal conditions are given by

$$\mathcal{X}_{0|t} = \{x_t\}, \tag{15}$$

$$\mathcal{X}_{k|t} = \mathcal{X}_T, \ k \in \mathbb{N}_{[N,N+N_u-1]} \tag{16}$$

where $\mathcal{X}_T$ satisfies (11)-(12). We consider a nominal cost defined for a given nominal parameter vector $\bar{\theta}_t \in \Theta_t$ by

$$J(x_t, \mathbf{v}_t, \bar{\theta}_t) = \sum_{k=0}^{N-1} l(\bar{x}_{k|t}, K\bar{x}_{k|t} + v_{k|t}) + V_{N|t}(\bar{x}_{N|t})$$

with $\bar{x}_{0|t} = x_t$, $\bar{x}_{k+1|t} = A_K(\bar{\theta}_t)\bar{x}_{k|t} + B(\bar{\theta}_t)v_{k|t}$, $k \in \mathbb{N}_{[0,N-1]}$. The stage cost $l(\cdot,\cdot)$ and terminal cost $V_{N|t}(\cdot)$ are assumed to be positive definite quadratic functions satisfying, for given $\bar{\theta}_t \in \Theta_0$ and all $x \in \mathbb{R}^{n_x}$,

$$V_{N|t}(x) = V_{N|t}\big(A_K(\bar{\theta}_t)x\big) + l(x, Kx). \tag{17}$$

The MPC law is determined by the solution, denoted $(\mathbf{v}_t^o, \mathbf{X}_t^o)$, of the problem of minimising $J(x_t, \mathbf{v}_t, \bar{\theta}_t)$ over $\mathbf{v}_t$ and $\mathbf{X}_t$ subject to (13)-(16) and additional constraints described in Section 3.2 to ensure the PE condition (6).

3.2 PE condition

To define a recursively feasible set of constraints, we construct a series of N_{pe} overlapping PE windows extending from the past and across the prediction horizon, where

$$N_{pe} = \begin{cases} N + t, & t < N_u - 1 \\ N + N_u - 1, & t \geq N_u - 1. \end{cases}$$

Consider the PE conditions defined at time $t \in \mathbb{N}_{>0}$ for given $\mathbf{v}_t$, $\mathbf{s}_t$, $\mathbf{X}_t$ and all $\kappa \in \mathbb{N}_{[N-N_{pe},N-1]}$ by

$$\sum_{k=\kappa}^{\kappa+N_u-1} \Phi(x_{k|t}, Kx_{k|t} + q_{k|t})^\top \Phi(x_{k|t}, Kx_{k|t} + q_{k|t}) \succeq \beta_{\kappa|t}\mathcal{I} \tag{18}$$

for all $x_{k|t} \in \mathcal{X}_{k|t}$, $k \in \mathbb{N}_{[\kappa,\kappa+N_u-1]}$, where $q_{k|t} := v_{k|t}$ if $k < N$ and $q_{k|t} := s_{k|t}$ if $k \geq N$. These conditions are nonconvex in $\mathbf{v}_t$, $\mathbf{X}_t$, and hence unsuitable as constraints in an online MPC optimisation. However, following Lu et al. (2021) we can linearise these conditions around a reference trajectory $(\hat{\mathbf{x}}_t, \hat{\mathbf{u}}_t) = \{(\hat{x}_{k|t}, \hat{u}_{k|t}), k \in \mathbb{N}_{[0,N+N_u-1]}\}$. For a given nominal parameter vector $\bar{\theta}_t$ and sequences $\hat{\mathbf{v}}_t$, $\mathbf{s}_t$, this reference trajectory is defined by

$$\hat{x}_{0|t} = x_t \tag{19a}$$

$$\hat{x}_{k+1|t} = A(\bar{\theta}_t)\hat{x}_{k|t} + B(\bar{\theta}_t)\hat{u}_{k|t}, \ k \in \mathbb{N}_{[0,N+N_u-2]} \tag{19b}$$

$$\hat{u}_{k|t} = \begin{cases} K\hat{x}_{k|t} + \hat{v}_{k|t}, & k \in \mathbb{N}_{[0,N-1]} \\ K\hat{x}_{k|t} + s_{k|t}, & k \in \mathbb{N}_{[N,N+N_u-1]}. \end{cases} \tag{19c}$$

We define the sequence $\hat{\mathbf{v}}_t$ for $t \in \mathbb{N}_{>0}$ using the solution of the MPC optimisation at time $t-1$, denoted $\mathbf{v}_{t-1}^o = \{v_{0|t-1}^o, \dots, v_{N-1|t-1}^o\}$, and $s_{N|t}$:

$$\hat{v}_{k|t} = \begin{cases} v_{k+1|t-1}^o, & k \in \mathbb{N}_{[0,N-2]} \\ s_{N-1|t}, & k = N-1. \end{cases} \tag{20}$$

Linearising (18) by neglecting quadratic terms in the decision variables $(\mathbf{v}_t, \mathbf{X}_t)$ yields a set of LMIs in $\mathbf{v}_t$, the vertices, $x_{k|t}^{(j)}$, of $\mathbf{X}_t$, and additional optimisation variables $\boldsymbol{\beta}_t' = \{\beta_{\kappa|t}', \kappa \in \mathbb{N}_{[N-N_{pe},N-1]}\}$, given for $\kappa \in \mathbb{N}_{[N-N_{pe},N-1]}$ by

$$\sum_{k=\kappa}^{-1} \Phi_{k+t}^\top \Phi_{k+t} + \sum_{k=\max\{0,\kappa\}}^{\kappa+N_u-1} M_{k|t} \succeq \beta_{\kappa|t}'\mathcal{I} \tag{21}$$

where $M_{k|t} = M_{k|t}^\top \in \mathbb{R}^{p\times p}$, $k \in \mathbb{N}_{[0,N+N_u-2]}$ satisfies

$$\begin{aligned} M_{k|t} \preceq\ & \hat{\Phi}_{k|t}^\top \hat{\Phi}_{k|t} + \hat{\Phi}_{k|t}^\top \Phi(x_{k|t}^{(j)} - \hat{x}_{k|t}, Kx_{k|t}^{(j)} + q_{k|t} - \hat{u}_{k|t}) \\ & + \Phi(x_{k|t}^{(j)} - \hat{x}_{k|t}, Kx_{k|t}^{(j)} + q_{k|t} - \hat{u}_{k|t})^\top \hat{\Phi}_{k|t}, \end{aligned}$$

for all $j \in \mathbb{N}_{[1,\nu]}$, with $\hat{\Phi}_{k|t} = \Phi(\hat{x}_{k|t}, \hat{u}_{k|t})$.

To increase the probability of the solution satisfying (6), we include (21) in the MPC optimisation at times $t > 0$ with the following constraints on $\boldsymbol{\beta}_t'$

$$\beta_{\kappa|t}' \geq \hat{\beta}_{\kappa|t}', \quad \forall \kappa \in \mathbb{N}_{[N-N_{pe},N-1]}, \tag{22}$$

where $\hat{\beta}_{\kappa|t}'$ is a lower bound on the maximum value of $\beta_{\kappa|t}'$ satisfying (21) for $(\mathbf{v}_t, \mathbf{X}_t)$ satisfying (13)-(16). Thus we determine $\hat{\boldsymbol{\beta}}_t' = \{\hat{\beta}_{\kappa|t}', \kappa \in \mathbb{N}_{[N-N_{pe},N-1]}\}$ by finding $\hat{\beta}_{\kappa|t}'$ in (22) as the solution of

$$\hat{\beta}_{\kappa|t}' := \max_{\beta_{\kappa|t}' \in \mathbb{R}} \beta_{\kappa|t}' \ \text{ s.t. } (21) \tag{23}$$

with $q_{k|t} := \hat{v}_{k|t}$ if $k < N$ and $q_{k|t} := s_{k|t}$ if $k \geq N$, and with $x_{k|t}^{(j)} := x_{k+1|t-1}^{(j)\,o}$, $\forall j \in \mathbb{N}_{[1,\nu]}$, $k > 0$, where $x_{k|t-1}^{(j)\,o}$ denotes a vertex of $\mathbf{X}_{t-1}^o$.

To impose (6) with non-zero probability, we propose a computationally undemanding check whether the solution of the online MPC optimisation using sampling:

$$\beta^s_{\kappa|t} \geq \hat{\beta}^s_{\kappa|t}, \qquad \forall \kappa \in \mathbb{N}_{[N-N_{pe},N-1]}. \tag{24}$$

Here $\beta^s_{\kappa|t}$ denotes the maximum $\beta_{\kappa|t}$ satisfying (18) with $q_{k|t} = v^o_{k|t}$, $k < N$ and $x_{k|t} \in \{x^{(1)}_{k|t}, \ldots, x^{(N_s)}_{k|t}\}$ where $x^{(i)}_{k|t} \in \mathcal{X}^o_{k|t}$ for $i \in \mathbb{N}_{[1,N_s]}$, $k \in \mathbb{N}_{[\kappa,\kappa+N_u-1]}$ are random samples, and $\hat{\beta}^s_{\kappa|t}$ is defined analogously with $q_{k|t} = \hat{v}_{k|t}$ for $k < N$ and random samples of $\mathcal{X}^o_{k+1|t-1}$, $k \in \mathbb{N}_{[\kappa,\kappa+N_u-1]}$.

Theorem 3. (Stability). Let Assumptions 1, 2 and 4 hold. Then the system (1) under Algorithm 1 is input-to-state practically stable (ISpS) (Limon et al., 2009, Def. 6) in the set of initial conditions x_0 for which $\mathcal{P}_0$ is feasible.

Theorem 4. (PE). Under Assumptions 1, 2, 4 and 5 and with $N_u > n_x$, the system (1) with the control law of Algorithm 1 satisfies the PE condition (6) with probability $p > 0$ for some $\epsilon_\Phi > 0$, for all t.

Theorem 3 implies (Limon et al., 2009; Lu et al., 2021) the existence of a $\mathcal{KL}$-function η and $\mathcal{K}$-functions ψ, ξ satisfying, for all x_0 such that $\mathcal{P}_0$ is feasible, the bound

$$\begin{aligned}\|x_t\| \leq \eta(\|x_0\|, t) + \psi\big(\max_{\tau \in \mathbb{N}_{[0,t-1]}} \|Fw_\tau + B(\theta^*)s_\tau\|\big) \\ + \xi\big(\max_{\tau \in \mathbb{N}_{[0,t-1]}} \|\bar{\theta}_\tau - \theta^*\|\big).\end{aligned} \tag{25}$$

Thus Lemma 1 and Theorems 3 and 4 imply that: (i) the parameter set estimate Θ_t converges asymptotically to $\{\theta^*\}$; (ii) system (1) is ISS under the action of Algorithm 1.

Algorithm 1 Adaptive MPC with PE constraints

At $t = 0$: Choose Θ_0 and $\mathcal{S}$. Determine K satisfying Assumption 4 and $\mathcal{X}_T$, $V_{N|0}$ satisfying (11)-(12) and (17). Define N, N_u, N_w, N_θ. Obtain $\bar{\theta}_0$ and x_0 and compute the solution, $(\mathbf{v}^o_0, \mathbf{X}^o_0)$, of the quadratic program (QP):

$$\mathcal{P}_0: \underset{\mathbf{v}_0, \mathbf{X}_0}{\text{minimise}} \; J(x_0, \mathbf{v}_0, \bar{\theta}_0) \;\; \text{s.t. (13)-(16).} \tag{26}$$

Apply the control input $u_0 = Kx_0 + v^o_{0|0}$.

At times $t = 1, 2, \ldots$:

(a). Obtain the current state x_t.

(b). Update $\bar{\theta}_t$ and Θ_t using (4) and $V_{N|t}$ via (17).

(c). Generate the noise sequence $\mathbf{s}_t$ and compute $\hat{\mathbf{x}}_t$, $\hat{\mathbf{u}}_t$, $\hat{\mathbf{v}}_t$, $\hat{\boldsymbol{\beta}}'_t$ using (19), (20) and (23).

(d). Find the solution $(\mathbf{v}^o_t, \mathbf{X}^o_t)$ of the semidefinite program

$$\begin{aligned}\mathcal{P}_{>0}: \underset{\mathbf{v_t}, \mathbf{X}_t, \boldsymbol{\beta}_t}{\text{minimise}} \; & J(x_t, \mathbf{v}_t, \bar{\theta}_t) \\ & \text{s.t. (13)-(16), (21) and (22).}\end{aligned} \tag{27}$$

(e). Generate N_s samples of $\mathcal{X}_{k|t}$ and $\mathcal{X}^o_{k+1|t-1}$ for $k \in \mathbb{N}_{[\kappa,\kappa+N_u-1]}$ and compute $\beta^s_{\kappa|t}$, $\hat{\beta}^s_{\kappa|t}$ for $\kappa \in \mathbb{N}_{[N-N_{pe},N-1]}$. If (24) is not satisfied, set $\mathbf{v}^o_t := \hat{\mathbf{v}}_t$ and $\mathbf{X}^o_t := \big\{\{x_t\}, \mathcal{X}^o_{2|t-1}, \ldots, \mathcal{X}^o_{N-1|t-1}, \mathcal{X}_T, \ldots, \mathcal{X}_T\big\}$.

(f). Apply the control input $u_t = Kx_t + v^o_{0|t}$

Error Bounds for Locally Optimal Distributed Filters over Random Graphs

Aneel Tanwani *

Abstract: In this extended abstract, we consider the problem of analyzing the performance of distributed filters for continuous-time linear stochastic systems under certain information constraints. We associate an undirected and connected graph with the measurements of the system, where the nodes have access to partial measurements in continuous time. Each node executes a locally optimally filter based on the available measurements. In addition, a node communicates its estimate to a neighbor at some randomly drawn discrete time instants, and these activation times of the graph edges are governed by independent Poisson counters. When a node gets some information from its neighbor, it resets its state using a convex combination of the available information. Consequently, each node implements a filtering algorithm in the form of a stochastic hybrid system. We derive bounds on expected value of error covariance for each node, and show that they converge to a common value for each node if the mean sampling rates for communication between nodes are large enough. The material covered in this extended abstract is based on the publications (Tanwani, 2021, 2022).

Keywords: Stochastic hybrid system; distributed filtering; graph theory; random communication.

1. INTRODUCTION

Modern engineering systems often involve integration of several components connected to one another to execute a complex task with efficient use of resources. Implementation of such architectures have paved way for distributed decision making and consequently, this has lead to immense research on design and analysis of distributed algorithms, see for example (DeGroot, 1974; Tsitsiklis et al., 1986). In particular, the problem of state estimation, and filtering, in dynamical systems has received particular attention (Olfati-Saber, 2007, 2009). Distributed filtering allows us to disintegrate a centralized output into several components, and then associate a filtering algorithm with each of these smaller components, see Figure 1 for a conventional layout of such architectures. In the usual operation of distributed filters, it is assumed that the sensor units, represented by the nodes in a graph, communicate the information about their own estimate to their neighbors (determined by the graph topology) at all times. In our work, however, we put constraints on the communication between these dynamic agents, which represent the individual filtering units. This makes the underlying graph time-varying and the asymptotic behavior of distributed algorithms in such cases has been studied in (Jadbabaie et al., 2003; Moreau, 2005; Cao et al., 2008). In our setup, we assume that each link in the graph is activated at random time-instants and the random process, which determines the discrete-times at which two neighbors communicate, is described by a Poisson counter. For this problem setup, we propose filtering algorithm in the form of a stochastic hybrid system. Such framework has been advocated in (Hespanha, 2014) for control problems over networks with communication constraints. Some historical developments on the use of Poisson counters for sampling process are provided in (Tanwani et al., 2018). Some recent work from the author deals with analyzing the performance of model predictive control under random sampling (Tanwani et al., 2019). The results proposed in this work build on the centralized filtering case studied in Tanwani and Yufereva (2020).

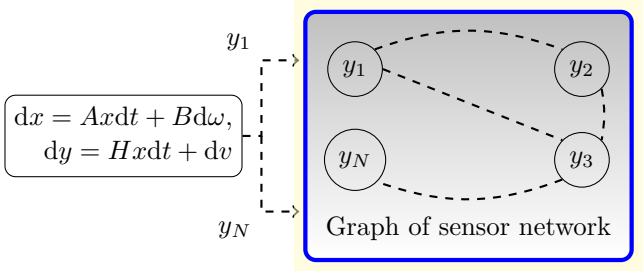

Fig. 1. Layout of distributed filters, where dashed lines represent communication at random times.

2. LOCALLY OPTIMAL DISTRIBUTED FILTERING

Let us begin with the description of the system class and the formulation of the distributed filtering problem studied in this paper. In the process, we describe the graph structure representing the interconnection between sensor nodes, and the sampling process at which the connected nodes (or the neighbors) exchange information.

2.1 System Class

We consider dynamical systems modeled by linear stochastic differential equations of the form

$$\mathrm{d}x = Ax\,\mathrm{d}t + B\,\mathrm{d}\omega \tag{1}$$

where $(x(t))_{t\geq 0}$ is an $\mathbb{R}^n$-valued diffusion process describing the state. Let $(\Omega, \mathcal{F}, \mathsf{P})$ denote the underlying probability space. It is assumed that, for each $t \geq 0$, $(\omega(t))_{t\geq 0}$ is a zero mean $\mathbb{R}^m$-valued standard Wiener process adapted to the filtration $\mathcal{F}_t \subset \mathcal{F}$, with the property that $\mathsf{E}[\mathrm{d}\omega(t)\,\mathrm{d}\omega(t)^\top] = I_m \mathrm{d}t$, for each $t \geq 0$. The matrices $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{n\times m}$ are taken as constant with (A, B) controllable, and the process $(\omega(t))_{t\geq 0}$ does not depend on the state. The solutions of the stochastic differential equation (1) are interpreted in the sense of Itô stochastic integral.

The centralized output measurement associated to the process (1) is of the form

$$\mathrm{d}y = Hx\,\mathrm{d}t + \mathrm{d}v \tag{2}$$

where $H \in \mathbb{R}^{p\times n}$ is a constant matrix, with (A, H) being observable, and $(v(t))_{t\geq 0}$ is a zero mean $\mathbb{R}^p$-valued standard Wiener process. The conventional filtering problem, with initial state having Gaussian distribution, deals with constructing a mean-square estimate of the state x_t, denoted by $\widehat{x}_t$ so that $\mathsf{E}[|x_t - \widehat{x}_t|^2 \,|\, (\mathrm{d}y(s))_{s\leq t}]$ is minimized. The optimal estimate which achieves this minimum value is $\mathsf{E}[x_t \,|\, (\mathrm{d}y(s))_{s\leq t}]$ and is computed recursively using a Kalman-Bucy filter. For the problem studied in this paper, it is assumed that the centralized measurements are not available and we address the filtering problem with similar assumptions on system data, but under different information constraints which are described next.

2.2 Information Structure

The measurements associated with system (1) are obtained from a set of N sensors which are distributed in their localization. Each of these sensors provides a partial measurement about the state described as,

$$\mathrm{d}y_i = H_i x\,\mathrm{d}t + \mathrm{d}v_i, \quad i = 1, \ldots, N, \tag{3}$$

where $H_i \in \mathbb{R}^{p_i\times n}$, and $\sum_{i=1}^N p_i = p$. That is, for each node, $(y_i(t))_{t\geq 0}$ describes an $\mathbb{R}^{p_i}$-valued continuous-time observation process. In the observation equation (3), $v_i(t)$ is a zero mean $\mathcal{F}_t$-adapted standard Wiener process, taking values in $\mathbb{R}^{p_i}$, and $\mathsf{E}[\mathrm{d}v_i(t)\,\mathrm{d}v_i(t)^\top] = V_i \mathrm{d}t$, with $V_i \in \mathbb{R}^{p_i\times p_i}$ assumed to be positive definite. The optimal filter which minimizes the mean square estimation error conditioned upon the information available through the measurements $\{\mathrm{d}y_i(s) | s \leq t\}$ is,

$$\mathrm{d}\widehat{x}_i(t) = A\widehat{x}_i(t)\mathrm{d}t + P_i(t)H_i^\top V_i^{-1}(\mathrm{d}y_i(t) - H_i\widehat{x}_i(t)\mathrm{d}t) \tag{4a}$$

$$\dot{P}_i = AP_i + P_iA^\top - P_iH_i^\top V_i^{-1}H_iP_i + BB^\top, \tag{4b}$$

with $\widehat{x}_i(0) = \mathsf{E}[x(0)]$, and $P_i(t)$ is exactly the error covariance $\mathsf{E}[(x_i(t) - \widehat{x}_i(t))(x_i(t) - \widehat{x}_i(t))^\top \,|\, \mathrm{d}y_i(s), s \leq t]$ if $P_i(0) = \mathsf{E}[(x_i(0) - \widehat{x}_i(0))(x_i(0) - \widehat{x}_i(0))^\top]$.

Communication Graph: The sensor nodes are connected via a graph $\mathcal{G} = (\mathscr{V}, \mathscr{E})$, where $\mathscr{V} = \{1, \ldots, N\}$ is the set of graph nodes, and $\mathscr{E}$ contains all the edges defined by a subset of the pairs (i, j), $i \neq j$, $i, j \in \mathscr{V}$. We assume that the graph is undirected and connected. The neighbors of a node $i \in \mathscr{V}$ are denoted by $\mathcal{N}_i$ and we adopt the convention that $i \notin \mathcal{N}_i$. The adjacency matrix $\mathcal{A} := [\alpha_{ij}] \in \{0, 1\}^{N\times N}$ of the graph, which is symmetric, provides the information about which sensor nodes can communicate with each other, that is, if $\alpha_{ij} = 1$ then sensor i and j can communicate, whereas $\alpha_{ij} = 0$ means there is no communication possible between those sensors. The degree of a node $i \in \mathscr{V}$ is defined as $|\mathcal{N}_i|$, that is, the cardinality of the set $\mathcal{N}_i$. The diagonal matrix $\mathcal{D} = [d_{ii}]$, with $d_{ii} = |\mathcal{N}_i|$ is therefore the degree matrix. We associate a Laplacian $\mathcal{L}$ with this graph, defined as, $\mathcal{L} = \mathcal{D} - \mathcal{A}$. For our purposes, the nonnegative matrix $\Pi = [\pi_{ij}] \in \mathbb{R}^{N\times N}$, defined as

$$\Pi := I_N - \epsilon\mathcal{L} \tag{5}$$

where $0 < \epsilon \leq \min_{i\in\mathscr{V}} \frac{1}{|\mathcal{N}_i|}$ plays an important role. Note that, by construction, Π is a doubly stochastic matrix, that is, for each row and each column, the sum of their entries equals one.

Random Sampling: The next main ingredient of our problem formulation is the description of the time instants at which the communication takes place between two sensor nodes connected by an edge. Corresponding to each edge $(i, j) \in \mathscr{E}$, it is stipulated that there is an increasing and divergent sequence $(\tau_k^{ij})_{k\in\mathbb{N}} \subset [0, +\infty[$ with $\tau_0^{ij} := 0$, and

- for each $(i, j) \in \mathscr{E}$, the sensor nodes $i, j \in \mathscr{V}$ transmit the value of their state estimate to each other at τ_k^{ij}, $k \in \mathbb{N}$.

In this article, we are interested in the case where the sampling times $(\tau_k^{ij})_{k\in\mathbb{N}}$ are generated *randomly*. Formally, we define

$$N_t^{ij} := \sup\big\{k \in \mathbb{N} \,\big|\, \tau_k^{ij} \leq t\big\} \quad \text{for } t \geq 0 \tag{6}$$

and assume in addition that, tor each $(i, j) \in \mathscr{E}$, $(N_t^{ij})_{t\geq 0}$ is a continuous-time stochastic process such that $\tau_{N_t^{ij}}^{ij} \to +\infty$ almost surely as $t \to +\infty$. The map $t \mapsto N_t^{ij}$ increments by 1 at random times, and it provides a description of the number of times the nodes i, j communicate with each other up to and including time t. For the sake of computational tractability, it is stipulated that

- For each $(i, j) \in \mathscr{E}$, $(N_t^{ij})_{t\geq 0}$ is an independent *Poisson process of intensity* $\lambda_{ij} > 0$. That is, $(N_t^{ij})_{t\geq 0}$ is a Markov process taking values in $\mathbb{N}$, has independent increments, and satisfies $N_0^{ij} = 0$, and for $h \searrow 0$ and $t \geq 0$,

$$\mathsf{P}\big(N_{t+h}^{ij} - N_t^{ij} = k \,\big|\, N_t^{ij}\big) = \begin{cases} 1 - \lambda_{ij}h + o(h) & \text{if } k = 0, \\ \lambda_{ij}h + o(h) & \text{if } k = 1, \\ o(h) & \text{if } k \geq 2, \end{cases}$$

  where the terms $o(h)$ do not depend on t.

Because of the arrival of new information at random times, the estimate $\widehat{x}_i$, $i \in \mathscr{V}$, gets updated. To describe this update rule, we associate with each node $i \in \mathscr{V}$, the process N_t^i,

$$N_t^i := \sum_{j\in\mathcal{N}_i} N_t^{ij}$$

so that N_t^i increments by one whenever node $i \in \mathscr{V}$ exchanges information with any of its neighbor. We recall

that N_t^i is also a Poisson process of intensity $\lambda_i := \sum_{j\in\mathcal{N}_i}\lambda_{ij}$. The times at which N_t^i gets incremented are denoted by $\tau_{N_t^i}$. We can now introduce the activation set $\mathcal{A}_t^i$,

$$\mathcal{A}_t^i := \left\{ j \in \mathcal{N}_i \,\middle|\, N_t^{ij} - N_{\underline{t}}^{ij} \neq 0, \underline{t} = \tau_{N_t^i - 1} \right\},$$

so that, at communication times $t_c = \tau_{N_t^i}$, the set $\mathcal{A}_{t_c}^i$ describes the neighbors of node $i \in \mathscr{V}$ that communicate their estimate to node $i \in \mathscr{V}$. Consequently, at $t_c = \tau_{N_t^i}$, we update the state estimate as follows:

$$\widehat{x}_i(t_c^+) = \sum_{j\in\mathcal{A}_{t_c}^i} \pi_{ij}\widehat{x}_j(t_c^-) + \Big(1 - \sum_{j\in\mathcal{A}_{t_c}^i}\pi_{ij}\Big)\widehat{x}_i(t_c^-), \quad (7)$$

where π_{ij} are the elements of the matrix Π introduced in (5). If $e_i := x - \widehat{x}_i$ denotes the estimation error, then because of this update rule, it is observed that,

$$e_i(t_c^+)e_i^\top(t_c^+) \leq \Big(1 - \sum_{j\in\mathcal{A}_{t_c}^i}\pi_{ij}\Big)e_i(t_c^-)e_i^\top(t_c^-) + \sum_{j\in\mathcal{A}_{t_c}^i}\pi_{ij}e_i(t_c^-)e_i^\top(t_c^-)$$

which is a direct consequence of the following lemma, whose proof appears in (Tanwani, 2022, Lemma III.3):

Lemma 1. Let m be a positive integer, and let $x_1, \ldots, x_m \in \mathbb{R}^n$. If $z := \sum_{j=1}^m \gamma_j x_j$ for some $\gamma_j \in [0,1]$, then

$$zz^\top \leq \sum_{j=1}^m \gamma_j x_j x_j^\top. \quad (8)$$

2.3 Summary of Filtering Algorithm

So far, we have specified the information available to each sensor node and a filtering algorithm, (4), (7), which uses this available information. If $\mathcal{Y}_t^i$ denotes the information available to sensor node $i \in \mathscr{V}$ up till time $t \in [0, +\infty[$, then we can write $\mathcal{Y}_t^i = \{(\mathrm{d}y_i(s), \widehat{x}_j(\tau_{N_s^i})) \,|\, s \leq t, j \in \mathcal{N}_i\}$. Our goal is to quantify the performance of these distributed filters by computing a bound on expected value of the error covariance matrices, that is, $\mathsf{E}[\mathsf{E}[(x(t) - \widehat{x}_i(t))(x(t) - \widehat{x}_i(t))^\top \,|\, \mathcal{Y}_t^i]]$, for $t \geq 0$. Here, the outer expectation is with respect to the random update times, and the inner expectation is with respect to the noise process in the state and output equation. The estimate computed by each node $i \in \mathscr{V}$ is obtained by executing the following steps:

- Integrate (4a) and (4b) over the interval $[\tau_{N_t^i}, \tau_{N_t^i+1}[$,
- At $t_c = \tau_{N_t^i}$, reset the state $\widehat{x}_i$ via (7), and set

$$P_i(t_c^+) = \big(1 - \sum_{j\in\mathcal{A}_{t_c}^i}\pi_{ij}\big)P_i(t_c^-) + \sum_{j\in\mathcal{A}_{t_c}^i}\pi_{ij}P_j(t_c^-) \quad (9)$$

with $P_i(0) \geq \mathsf{E}[(x(0) - \widehat{x}_i(0))(x(0) - \widehat{x}_i(0))]$.

As a first step in obtaining the desired bounds, one immediately observes that, for each $i \in \mathscr{V}$, if we fix the times at which node $i \in \mathscr{V}$ communicates with its neighbors, then

$$\mathsf{E}[(x(t) - \widehat{x}_i(t))(x(t) - \widehat{x}_i(t))^\top \,|\, \mathcal{Y}_t^i] \leq P_i(t), \quad t \geq 0 \quad (10)$$

where P_i is described by (4b), (9). The remaining task therefore is to compute expectation with respect to the distributions assigned to the times at which information between sensor nodes takes place.

3. MAIN RESULTS

The basic problem studied in this paper is the performance of the distributed filters proposed in the previous section. In particular, we want to relate the mean sampling rates λ_{ij}, corresponding to the edges $(i,j) \in \mathscr{E}$, with the bounds on the error covariance. As our first main result, we compute an upper bound on the expectation (with respect to sampling process N_t^i) of the error covariance matrices $\mathsf{E}[\mathsf{E}[(x(t) - \widehat{x}_i(t))(x(t) - \widehat{x}_i(t))^\top \,|\, \mathcal{Y}_t^i]]$, for $t \geq 0$.

Theorem 2. Consider system (1) with distributed measurements (3) and the corresponding hybrid filters (4), (7), (9) linked together by an undirected and connected graph $\mathcal{G} = (\mathscr{V}, \mathscr{E})$. For an edge $(i,j) \in \mathscr{E}$, if the communication between nodes $i, j \in \mathscr{V}$ takes place at random times generated by a Poisson process of intensity $\lambda_{ij} > 0$, then for each $i = 1, \cdots, N$, it holds that

$$\mathsf{E}[\mathsf{E}[(x(t) - \widehat{x}_i(t))(x(t) - \widehat{x}_i(t))^\top \,|\, \mathcal{Y}_t^i]] \leq \mathcal{P}_i(t), \quad (11)$$

where the matrix-valued function $\mathcal{P}_i : [0, \infty[\to \mathbb{R}^{n\times n}$ satisfies the differential equation

$$\dot{\mathcal{P}}_i = A\mathcal{P}_i + \mathcal{P}_i A^\top - \mathcal{P}_i H_i^\top V_i^{-1} H_i \mathcal{P}_i + BB^\top + \sum_{j\in\mathcal{N}_i}\lambda_{ij}\pi_{ij}(\mathcal{P}_j - \mathcal{P}_i). \quad (12)$$

The proof of Theorem 2 follows from the proof of (Tanwani, 2022, Theorem III.1, item 1)). The result of Theorem 2 provides a bound on the evolution of error covariance for each node in terms of a differential equation. These equations are quadratic (and hence nonlinear), driven by a constant term which corresponds to the noise level in the system, and are interconnected by some coupling term. Such systems in the literature are studied under the framework of heterogenous multi-agent systems since the dynamics of $\mathcal{P}_i$ are different for each $i \in \mathscr{V}$. In contrast to homogenous agents, consensus in heterogenous agents is not possible in general. However, one can get the states of all the agents close to desired accuracy by increasing the coupling strength. The next result relates to the asymptotic behavior of the coupled differential equations (12).

Theorem 3. For $i = 1, \ldots, N$, consider the matrix-valued equations (12) and assume that $\lambda_{ij} = \lambda$ is the same for each $(i,j) \in \mathscr{E}$. Let $S \in \mathbb{R}^{n\times n}$ be symmetric positive semidefinite matrix satisfying

$$0 = AS + SA^\top - \frac{1}{N}S\left(\sum_{i=1}^N H_i^\top V_i^{-1} H_i\right)S + BB^\top. \quad (13)$$

Then for every $\delta > 0$, there exists $\lambda > 0$ sufficiently large, such that the corresponding solution of (12) satisfies [1]

$$\limsup_{t\to\infty} \|\mathcal{P}_i(t) - S\| \leq \delta. \quad (14)$$

The proof of Theorem 3 is carried out in (Tanwani, 2021). To conclude this section, we provide some remarks about our main results.

Remark 4. The injection gains used in (4) over an interval $[\tau_{N_t^i}, \tau_{N_t^i+1}[$ do not need any information about how the other filters in the network choose their gains. Moreover, they minimize the value of P_i in (4b) over the class of linear time-varying gains. The latter statement follows from the fact that

[1] When taking the norm of a matrix, we refer to Frobenius norm.

$$(A-L_iH_i)P_i+P_i(A_i-L_iH_i)^\top+L_iV_iL_i^\top = (A-\overline{L}_iH_i)P_i + P_i(A_i-\overline{L}_iH_i)^\top + \overline{L}_iV_i\overline{L}_i^\top - (\overline{L}_i-L_i)V_i(\overline{L}_i-L_i)^\top \quad (15)$$

for any constant matrix $\overline{L}_i \in \mathbb{R}^{n\times p_i}$, and $L_i = P_iH_i^\top V_i^{-1}$. This shows that the filters (4) perform better than the constant linear gains proposed by the author in (Tanwani, 2022).

Remark 5. In Theorem 3, we basically study convergence of the differential equations (12) which contain quadratic nonlinearities. In general, such nonlinearities result in semiglobal convergence, that is, the solutions converge starting from initial conditions in a compact set. However, because of the minimum property described in Remark 4, we get global convergence with no restrictions on the initial condition. However, the convergence is not necessarily asymptotic, but only up to a neighborhood of a fixed point, which we often call practical convergence. The practical aspect of the convergence is unavoidable since we allow different noise covariance levels for each filter.

Remark 6. In the formulation of Theorem 2, since we associate a different Poisson process to each link, the nodes communicate with each other at different times. However, we associate the same sampling rate λ with each edge (i,j). The motivation for doing so is that, when we write the collective dynamics for each node, the last term in (12) is written as a scalar multiple of the Laplacian. If we assume that the process N_t^{ij} associated with edge (i,j) has intensity λ_{ij}, then the arguments required for establishing practical convergence are more involved and are not carried out in this paper. One would expect that if each $\lambda_{ij} > 0$ is large enough, then we do get practical convergence.

Abstract: This is an extended abstract of a paper "Positivity is undecidable in tensor products of free algebras" which is currently in preparation. In quantum information, we are interested in tensor products of free algebras and related algebras, since these tensor products model spatially separated subsystems with entanglement. The recent MIP*=RE result shows that it is undecidable to determine whether an element in the tensor product of two free group algebras is positive in all finite-dimensional representations. This shows that this tensor product is not RFD, resolving the Connes embedding problem. In this work, we show that these tensor products are also not archimedean-closed, by showing that it is undecidable to determine if an element of the tensor product is positive. The result also holds for tensor products of related algebras, like algebra of *-polynomials or the group algebra of a free product of abelian groups.

1. INTRODUCTION

An element of a *-algebra is said to be positive if it is positive in all *-representations. It is a natural problem to determine whether or not a given element of a *-algebra is positive, and if it is, find some certificate of positivity, like a sum of squares decomposition. For commutative algebras, this problem has a long history. For the group algebra of the free group, this problem can be solved in two ways:

(1) by Bakonyi and Timotin (2007), the algebra is archimedean-closed, so every positive element has a sum of squares decomposition, and
(2) by Choi (1980) the algebra is RFD, meaning that an element is positive if and only if it is positive in all finite-dimensional *-representations.

Thus for this algebra we can find certificates of both positivity and non-positivity. A similar solution is possible for the the algebra of *-polynomials and the algebra of contractions by Helton (2002) and Helton and McCullough (2004). Similarly, the semi-pre-C^*-algebra $\mathcal{A}(n,m)$ generated by positive elements p_a^x, $1 \leq x \leq n$, $1 \leq a \leq m$ and satisfying relations $\sum_{a=1}^m p_a^x = 1$ for all $1 \leq x \leq n$ is archimedean-closed and RFD by, e.g., Helton et al. (2012). (See also Ozawa (2013) for background on semi-pre-C^*-algebras.)

In quantum information, $\mathcal{A}(n,m)$ models a physical system with n possible measurements, each with m outcomes. The tensor product $\mathcal{A}(n,m) \otimes \mathcal{A}(n,m)$ models two spatially separated (but possibly entangled) subsystems of this form. The recent MIP*=RE result of Ji, Natarajan, Vidick, Wright, and Yuen shows that it is undecidable to determine whether an element in $\mathcal{A}(n,m) \otimes \mathcal{A}(n,m)$ is positive in all finite-dimensional representations (Ji et al. (2020)). This shows that this tensor product is not RFD, resolving the Connes embedding problem (see Ozawa (2013) for more background on this problem). In this work, we show that:

Theorem 1. There is a mapping from Turing machines M to elements $\alpha_M \in \mathcal{A}(n,m) \otimes \mathcal{A}(n,m)$ such that M halts if and only if α_M is not positive.

In other words, determining whether or not an element is positive in $\mathcal{A}(n,m) \otimes \mathcal{A}(n,m)$ is coRE-hard. As a corollary, this shows that $\mathcal{A}(n,m) \otimes \mathcal{A}(n,m)$ is not archimedean-closed. The result also holds for tensor products of related algebras, like algebra of *-polynomials, the algebra of contractions, or the group algebra of a free group.

Robust Output-Feedback Adaptive Control of Finite Sets of Linear Systems ⋆

Olle Kjellqvist *

* *Lund University, Sweden, (e-mail: olle.kjellqvist@ control.lth.se).*

Abstract: This paper concerns the problem of bounded ℓ_2-gain adaptive control with noisy measurements for linear time-invariant systems with uncertain parameters belonging to a finite set. We show that it is necessary and sufficient to consider observer-based control with a multiple-observer structure consisting of one $\mathcal{H}_\infty$-observer paired with model fitness metric per candidate model for minimax optimality.

Keywords: adaptive control, machine learning and control

1. INTRODUCTION

The great control engineer is lazy; her models are simplified and imperfect, the operating environment may be poorly controlled — yet her solutions perform well. Robust control provides excellent tools to guarantee performance if the uncertainty is small Zhou and Doyle (1998). If the uncertainty is large, one can perform laborious system identification offline to reduce model uncertainty and synthesize a robust controller. An appealing alternative is to trade the engineering effort for a more sophisticated controller, particularly a learning-based component that improves controller performance as more data is collected. However, for such a controller to be implemented, it had better be robust to any prevalent unmodeled dynamics. Currently, there is considerable research interest in the boundary between machine learning, system identification, and adaptive control. For a review, see for example Matni et al. (2019). Most of the studies concern stochastic uncertainty and disturbances and assume perfect state measurements. Recently, works connecting to worst-case disturbances have started to appear. For example, non-stochastic control was introduced for known systems with unknown cost functions in Agarwal et al. (2019) and extended to unknown dynamics and output feedback, under the assumption of bounded disturbances and prior knowledge of a stabilizing proportional feedback controller in Simchowitz (2020). In Dean et al. (2019) the authors leverage novel robustness results to ensure constraint satisfaction while actively exploring the system dynamics. In this contribution, the focus is on worst-case models for disturbances and uncertain parameters as discussed in Didinsky and Basar (1994) and Vinnicombe (2004) and more recently in Rantzer (2021), but differ in that we consider output-feedback. See Figure 1 for an illustration of the considered problem. This paper extends Kjellqvist and Rantzer (submitted) to multiple input, multiple output systems and Theorem 1 in Rantzer (2021) to the output-feedback setting.

⋆ This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme under grant agreement No 834142 (ScalableControl).

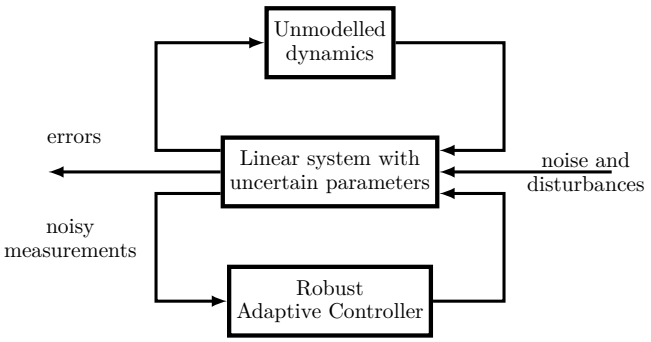

Fig. 1. For a finite set of linear time-invariant models, the Robust Adaptive Controller minimizes the ℓ_2-gain from noise and disturbances to errors for any realization of the unknown model parameters. This gain bound guarantees robustness to unmodelled dynamics.

The outline is as follows. We establish the notation in section 2. Section 3 defines the problem of finite-gain adaptive control and constructs a corresponding two-player dynamic game whose solution also solves the finite-gain adaptive control problem. We introduce the multi-observer as an information state in Section 4. Section 5 exploits the results from the previous setting to construct an equivalent full-information game and shows how it can be solved using dynamic programming. Concluding remarks are given in section 6.

2. NOTATION

The set of $n \times m$ matrices with real coefficients is denoted $\mathbb{R}^{n\times m}$. The transpose of a matrix A is denoted $A^\top$. For a symmetric matrix $A \in \mathbb{R}^{n\times n}$ and a vector $x \in \mathbb{R}^n$ we use the expression $|x|_A^2$ as shorthand for $x^\top Ax$. We write $A \prec (\preceq)\ 0$ to say that A is positive (semi)definite. We refer to the value of a signal w at time t as $w(t)$ and use the shorthand notation $w_{0:t}$ for the sequence $(w(\tau))_{\tau=0}^t$.

3. PROBLEM FORMULATION

We consider uncertain linear systems of the form

$$\begin{aligned} x(t+1) &= Ax(t) + Bu(t) + Gw(t), \quad x(0) = x_0 \\ y(t) &= Cx(t) + Hv(t), \quad t \geq 0, \\ M &= (A, B, C, G, H) \in \mathcal{M}, \end{aligned} \tag{1}$$

where the control signal $u(t) \in \mathbb{R}^{n_u}$ is generated by a causal output-feedback control policy

$$u(t) = \mu_t(y(0), \ldots, y(t), u(0), \ldots, u(t-1). \tag{2}$$

In (1), $x(t) \in \mathbb{R}^{n_x}$ is the state, $y(t) \in \mathbb{R}^{n_y}$ is the measurement, the model M is unknown but belongs to $\mathcal{M}$. For every model M, the matrix $H \in \mathbb{R}^{n_y \times n_v}$ is assumed to be surjective. Similarly to $\mathcal{H}_\infty$-control, we do not make explicit assumptions of the probability distributions of the disturbances $v(t) \in \mathbb{R}^{n_v}$ and $w(t) \in \mathbb{R}^{n_w}$. We are interested in control that makes the closed-loop system finite gain, with gain from (w, v, x_0) to $(Q^{1/2}x, R^{1/2}u)$ bounded above by γ. That is, the quantity

$$\begin{aligned} \alpha(T, \hat{x}_0) &:= |x(T)|_Q^2 + \sum_{t=0}^{T-1} \left(|x(t)|_Q^2 + |u(t)|_R^2 \right) \\ &- \gamma^2 \sum_{t=0}^{T-1} \left(w(t)^2 + v(t)^2 \right) - \gamma^2 |v(T)|^2 - |x(0) - \hat{x}_0^2|_{P_M}^2 \end{aligned} \tag{3}$$

must be bounded for all $T \geq 0$, any admissible disturbances, initial state and the possible realizations M of (1). P_M quantifies prior information on the initial state and is taken as a positive solution to the Riccati equation

$$\begin{aligned} P_M &= \left(AX_M^{-1}A^\top + \gamma^{-2} GG^\top \right)^{-1}, \\ X_M &= P_M + \gamma^2 C^\top (HH^\top)^{-1} C - Q). \end{aligned} \tag{4}$$

We cannot evaluate condition (3) directly since disturbances w, noise v and the active plant M are unknown. We can, however, evaluate the worst case (the supremum), and will consider the dynamic game with dynamics as in (1), (2) and the objective:

$$J_\star(\hat{x}_0) = \inf_\mu \sup_{w_{0:T-1}, v_{0:T}, x_0, M, T} \alpha(T, \hat{x}_0). \tag{5}$$

This problem setup is similar to a standard linear-quadratic game Didinsky and Basar (1994) but differs because the adversary selects the active model $M \in \mathcal{M}$.

4. A MULTI-OBSERVER INFORMATION STATE

Consider the case when the data, $(y_{0:T}, u_{0:T-1})$, is generated by the dynamics (1) and (2) under model M and control policy μ. Let $\alpha_M(T, \hat{x}_0)$ be the largest value of $\alpha(T, \hat{x}_0)$ consistent with the data and the dynamics,

$$\begin{aligned} \alpha_M(T) = \sup_{w_{0:T-1}, v_{0:T}, x_0} \Big\{ &\alpha(T) : \\ &(y_{0:T}, u_{0:T-1}) \text{ generated by (1) and (2) under } M \Big\}. \end{aligned} \tag{6}$$

We can partition the supremum in (5) into

$$J_\star(\hat{x}_0) = \inf_\mu \sup_{y_{0:T}, M, T} \alpha_M(T, \hat{x}_0).$$

Define the state-dependent past cost by

$$\begin{aligned} W_M(t+1, x, \hat{x}_0) = \sup_{w_{0:t}, v_{0:t}, x_0} \Bigg\{ &\sum_{\tau=0}^{t} \left(|x(\tau)|_Q^2 + |u(\tau)_R^2 \right) \\ &- \gamma^2 \sum_{\tau=0}^{t} \left(|w(\tau)|^2 + |v(\tau)^2 \right) - |x(0) - \hat{x}_0|_{P_M}^2 \Bigg\}, \end{aligned} \tag{7}$$

where the supremum is taken with respect to the dynamics (1) and a fixed trajectory $(y_{0:t}, u_{0:t})$. Then α_M becomes

$$\begin{aligned} &\alpha_M(T, \hat{x}_0) \\ &= \sup_x \left\{ |x|_Q^2 - \gamma^2 |Cx - y(T)|_{(HH^\top)^{-1}}^2 + W_M(T, x, \hat{x}_0) \right\}. \end{aligned} \tag{8}$$

In (Basar and Bernhard, 1995, Chapter 6), the authors show how to express W_M recursively. We summarize these results in the following Lemma:

Lemma 1. Given a known model $M \in \mathcal{M}$, a positive quantity γ, positive definite matrices $Q \in \mathbb{R}^{n_x \times n_x}$ and $R \in \mathbb{R}^{n_u \times n_u}$. Assume that the Riccati equation (4) has a positive definite solution P_M such that X_M is positive definite. For a fixed trajectory $(u_{0:T}, y_{0:T})$, W_M in (7) obeys

$$W_M(t, x, \hat{x}_0) = -|x - \hat{x}_M(t)|_{P_M}^2 + l_M(t). \tag{9}$$

The observer state $\hat{x}_M(t)$ is the solution to the dynamical system

$$\begin{aligned} \hat{x}_M(t+1) &= A\hat{x}_M(t) + Bu(t) \\ &\quad + K_M(y(t) - C\hat{x}_M(t)) + \hat{w}_M(t) \\ K_M &= \gamma^2 A X_M^{-1} C^\top (HH^\top)^{-1}, \\ \hat{w}_M(t) &= A X_M^{-1} Q \hat{x}_M(t), \end{aligned} \tag{10}$$

and l_M obeys the recurrence relation

$$\begin{aligned} l_M(t+1) &= l_M(t) - |\hat{x}_M(t)|_{P_M}^2 - \gamma^2 |y(t)|_{(HH^\top)^{-1}}^2 \\ &+ |u(t)|_R^2 + |P_M \hat{x}_M(t) + \gamma^2 C^\top (HH^\top)^{-1} y(t)|_{X_M^{-1}}^2. \end{aligned} \tag{11}$$

The initial conditions are $(\hat{x}_M(0), l_M(0)) = (\hat{x}_0, 0)$.

We can evaluate the supremum in (8),

$$\begin{aligned} \alpha_M(T) &= l_M(T) - |\hat{x}_M(T)|_{P_M}^2 - \gamma^2 |y(T)|_{(HH^\top)^{-1}}^2 \\ &\quad + |P_M \hat{x}_M(T) + \gamma^2 C^\top (HH^\top)^{-1} y(T)|_{X_M^{-1}}^2 \end{aligned} \tag{12}$$

Thus, the collection of model performance quantities $\{l_M(t) : M \in \mathcal{M}\}$ is sufficient information to evaluate the finite-gain condition at time $t-1$ together with the observer states $\{\hat{x}_M(t) : M \in \mathcal{M}\}$, and together with $y(t)$ we have all the information necessary to compute $l_M(t+1)$. In other words, we have compressed the information in the sequences $(y_{0:t-1}, u_{0:t-1})$ of increasing length, to one quantity l_M and one state-vector $\hat{x}_M$ per model M.

5. OUTPUT-FEEDBACK MINIMAX DYNAMIC PROGRAMMING

In this section we will construct a full-information dynamic game, whose value equals (5). We then show that the game can be solved using dynamic programming in Theorem 2. Consider the game defined by the objective function

$$\inf_\eta \sup_{y, T, M} \left\{ |\hat{x}_M(T)|_{(Q^{-1} - P_M^{-1})^{-1}}^2 + l_M(T) \right\} \tag{13}$$

and the observer dynamics described in (10) and (11). The control signal is computed according to

$$u(t) = \eta(\mathcal{O}(t), y(t)),$$

where $\mathcal{O}$ is the multi-observer state,

$$\mathcal{O}(t) := \{(\hat{x}_M(t), l_M(t)) : M \in \mathcal{M}\}. \tag{14}$$

Define the Bellman operator $\mathcal{F}$ and the corresponding value iterations $V_0, V_1, \dots$ by

$$\mathcal{F}V(\mathcal{O}(t)) = \max_y \min_u V(\mathcal{O}(t+1)), \tag{15}$$

and

$$\begin{aligned} V_0(\mathcal{O}) &:= \max_{M\in\mathcal{M}} \left\{ |\hat{x}_M|^2_{(Q^{-1}-P_M^{-1})^{-1}} + l_M \right\} \\ V_{t+1}(\mathcal{O}) &= \mathcal{F}V_t(\mathcal{O}). \end{aligned} \tag{16}$$

where $\hat{x}_M(t+1)$ and $l_M(t+1)$ are computed as in (10) and (11).

The following theorem is an extension of (Rantzer, 2021, Theorem 1) to the output feedback setting. Both results rely on establishing an information state that replaces the uncertainty in the dynamics by a terminal cost. The theorem establishes that the values (5) and (13) are equal, and that the value iteration can be used to construct optimal and suboptimal controllers for (5). The corresponding controller architecture is illustrated in Fig. 2.

Theorem 2. Given a finite set $\mathcal{M}$ of linear dynamical systems, positive definite matrices $Q \in \mathbb{R}^{n_x \times n_x}$, $R \in \mathbb{R}^{n_u \times n_u}$ and a positive quantity γ. Assume that the Riccati equations (4), have positive definite solutions $P_M \succ Q$ for each model $M \in \mathcal{M}$. Then the values of (5) and (13) are finite if and only if the value iteration $V_0, V_1, \dots$ defined in (5) is bounded. If the value iteration is bounded, the limit $V_\star = \lim_{k\to\infty} V_k$ exists and the values of (5) and (13) are both equal to $V_\star(\mathcal{O}_0)$, where $\mathcal{O}_0 = \{(\hat{x}_0, 0) : M \in \mathcal{M}\}$ is the initial observer state as in (14).

Furthermore, denote by $\eta_\star$ the minimizing argument of $\mathcal{F}V_\star$, then $\eta_\star$ is optimal for (13), and the policy

$$\mu_\star(y(0), \dots, y(t), u(0), \dots, u(t-1)) := \eta_\star(\mathcal{O}(t), y(t)),$$

is optimal for (5).

If there exists a function $\bar{V} \geq V_0$, and a control policy $\bar{\eta}$ such that

$$\max_y \bar{V}(\mathcal{O}(t+1)) \leq \bar{V}(\mathcal{O}(t)),$$

where $u_t = \bar{\eta}(\mathcal{O}(t), y(t))$, then the values (5) and (13) are bounded above by $\bar{V}(\mathcal{O}_0)$. The control policy $u_t = \bar{\eta}(\mathcal{O}(t), y(t))$ achieves

$$J_{\bar{\mu}}(\hat{x}_0) := \sup_{w_{0:T-1}, v_{0:T}, x_0, M, T} \alpha(T, \hat{x}_0) \leq \bar{V}(\mathcal{O}_0).$$

The proof follows closely that of (Rantzer, 2021, Theorem 1), but differs in the dynamics of the information state.

Proof. Consider,

$$\begin{aligned} \mathcal{F}V_0(\mathcal{O}) &\geq \max_{M,y} \Big\{ l_M - |\hat{x}_M|^2_{P_M} \\ &\quad - \gamma^2 |y|^2_{(HH^\top)^{-1}} + |P_M \hat{x}_M + \gamma^2 C^\top (HH^\top)^{-1} y|^2_{X_M^{-1}} \Big\} \\ &= \max_M \{ |\hat{x}_M|^2_{(Q^{-1}-P_M^{-1})^{-1}} + l_M \} = V_0(\mathcal{O}). \end{aligned}$$

As $\mathcal{F}$ is monotone increasing in V, the sequence $V_0, V_1, V_2, \dots$ is monotonically non-decreasing. For any fix $T \geq 0$, $J_\star(\hat{x}_0)$ is bounded below by the finite-time objective

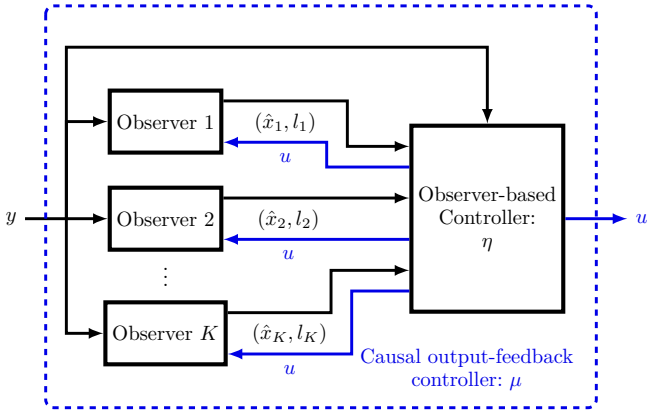

Fig. 2. Illustration of the proposed multi-observer control architecture. One $\mathcal{H}_\infty$-observer for each model $M \in \mathcal{M}$ outputs its state-estimate $\hat{x}_M(t)$ and model performance quantity $l_M(t)$ at each time t. The observer-based control policy η maps the observer states, performance quantities and the current output to the actuator signal $u(t)$.This control architecture forms the causal control policy $\mu(y_{0:t}, u_{0:(t-1)})$ that solves (5).

$$\inf_\mu \sup_{w_{0:T-1}, v_{0:T}, x_0, M} \alpha(T, \hat{x}_0). \tag{17}$$

Equation (17) is increasing in T, and $J_\star$ is obtained in the limit. By Lemma 1, (17) is equal to

$$\inf_\mu \sup_{y,M} \left\{ |\hat{x}_M(T)|^2_{(Q^{-1}-P_M^{-1})^{-1}} + l_M(T) \right\}. \tag{18}$$

Standard dynamic programming arguments show that the value of (18) is equal to $V_{T+1}(\mathcal{O}_0)$. This proves that (5) has a finite value if and only if $\{V_k(\mathcal{O}_0)\}_{k=0}^\infty$ is upper bounded, and that the value is equal to the limit $V_\star(\mathcal{O}_0) = \lim_{k\to\infty} V_k(\mathcal{O}_0)$.

To show that $V_\star(\mathcal{O})$ exists for any observer state $\mathcal{O}$ we first note that for any other $\hat{x}_0' \in \mathbb{R}^{n_x}$,

$$-\max_M |\hat{x}_0 - \hat{x}_0'|_{P_M} \leq J_\star(\hat{x}_0) - J_\star(\hat{x}_0') \leq \max_M |\hat{x}_0 - \hat{x}_0'|_{P_M}.$$

This shows that the value iteration remains bounded if we replace the initial states $\hat{x}_0$. To see that the iteration is bounded for arbitrary values of the performance quantities, let $\mathcal{O}' = \{(\hat{x}_0, l_M') : M \in \mathcal{M}\}$, then

$$\min_{M\in\mathcal{M}} l_M' \leq V_k(\mathcal{O}') - V_k(\mathcal{O}_0) \leq \max_{M\in\mathcal{M}} l_M'.$$

We conclude that if $V_k(\mathcal{O}_0)$ is bounded for $k = 1, 2, \dots$, so is $V_k(\mathcal{O}')$ and that $V_\star(\mathcal{O})$ exists for all multi-observer states $\mathcal{O}$.

If (13) is finite, then V_t is bounded above by (13), so the limit $V_\star$ is finite. Conversely, if $V_0 \leq \bar{V} \leq \infty$ and $\mathcal{F}_{\bar{\eta}}\bar{V} \leq \bar{V}$, we may define the sequence $\hat{V}_0, \hat{V}_1, \dots$ by the recursion $\hat{V}_0 := V_0$ and

$$\hat{V}_{t+1} := \mathcal{F}_{\bar{\eta}} \hat{V}_t.$$

By construction, (13) is bounded above by $\lim_{t\to\infty} \hat{V}_t(\mathcal{O}_0)$. By induction, $\bar{V} \geq \hat{V}_k$ for all k, so $V_\star \leq \lim_{k\to\infty} \leq \bar{V}$. This proves that $V_\star(\mathcal{O}_0) \leq J_{\bar{\mu}}(\hat{x}_0) \leq \bar{V}(\mathcal{O}_0)$. In particular, the control law is optimal if $\bar{V} = V_\star$.

6. CONCLUSIONS

We have shown that it is both necessary and sufficient to consider multi-observer-based feedback for minimax optimal control of a linear system with uncertain parameters belonging to a finite set. Such a controller guarantees that the ℓ_2-gain from disturbances to output is bounded. In future research, we aim to leverage these results together with approximate dynamic programming to synthesize control policies with a guaranteed upper bound on the gain from disturbances to error.

On the stabilizing properties of nonlinear MPC with arbitrary positive definite cost functions

Mircea Lazar *

* *Eindhoven University of Technology, Eindhoven, Netherlands*
(e-mail: m.lazar@tue.nl)

Abstract: Recently, a unifying approach to the stability analysis of nonlinear model predictive controllers (MPC) with arbitrary positive definite cost functions has been presented based on dissipativity theory. We have established that regardless of the choice of the positive definite cost function, the resulting value function always satisfies a dissipation inequality. This led to less conservative stability conditions for nonlinear MPC that do not require monotonic decrease of the optimal cost function along closed–loop trajectories. In this extended abstract we recall these results and we analyze recursive feasibility, which has not yet been addressed. To this end we use a control contractive terminal set and an adaptive prediction horizon, without adding a terminal cost.

Keywords: Predictive control, Recursive feasibility, Control contractive sets, Stability of nonlinear systems.

1. INTRODUCTION

Model predictive control (MPC) computes a control action online by minimizing a finite–horizon cost function subject to constraints. Standard stabilizing conditions for MPC (Mayne, 2014; Rawlings et al., 2017) utilize the corresponding optimal cost function as a monotonic Lyapunov function (LF). These conditions can be classified as follows (Mayne, 2014): *(i)* terminal state and input equal to steady–state values, e.g., see (Bemporad et al., 1994); *(ii)* local control Lyapunov function (CLF) as terminal cost and terminal state constrained to a controlled invariant set, e.g., see (Mayne, 2013); *(iii)* local CLF as terminal cost, no terminal state constraint and sufficiently long prediction horizon, e.g., see (Mayne, 2001; Limon et al., 2006); and *(iv)* no terminal cost, no terminal constraint, stage cost satisfies an asymptotic controllability assumption and sufficiently long prediction horizon, e.g., see (Grüne, 2012; Boccia et al., 2014). These approaches to stability analysis of nominal MPC consider a known, time–invariant steady–state equilibrium, typically chosen as the origin, and they require monotonically decreasing MPC cost functions.

However, predictive control with arbitrary positive definite cost functions and prediction horizon values often yields converging trajectories without imposing the above mentioned conditions, allowing even for non–monotonic cost functions. Also, industrial practice for MPC tuning typically employs a sufficiently long prediction horizon, yielding converging trajectories, instead of enforcing a monotonically decreasing cost. It is thus of interest to identify conditions under which predictive control with arbitrary positive definite cost functions results in stable closed–loop systems and recursively feasible optimization problems.

Recently, (Lazar, 2021) presented a unifying approach to the stability analysis of nonlinear model predictive control (MPC) with arbitrary positive definite cost functions based on dissipativity theory. Therein, it was established that regardless of the choice of the positive definite cost function, the resulting value function always satisfies a dissipation inequality. Then, it became clear that nonlinear MPC with arbitrary positive definite stage costs is stabilizing whenever the supply function induced by the stage cost is negative definite along closed–loop trajectories.

In this extended abstract we provide a summary of the main result of (Lazar, 2021) and we address the problem of guaranteeing recursive feasibility for nonlinear MPC with arbitrary positive definite cost functions. We show that recursive feasibility and asymptotic stability of nonlinear MPC with an arbitrary positive definite cost function can be achieved by using control contractive terminal sets, as proposed in (Limon et al., 2005). Therein the focus was on enlarging the region of attraction of stabilizing nonlinear MPC with a special terminal cost by using a sequence of controllable or contractive terminal sets. In this work we show that a control contractive terminal set suffices to guarantee recursive feasibility and asymptotic stability for nonlinear MPC with arbitrary positive definite cost functions, i.e., without using a special terminal cost function. This may require however dynamic, online adaptation of the prediction horizon.

2. PRELIMINARIES

Let $\mathbb{R}$, $\mathbb{R}_+$ and $\mathbb{N}$ denote the field of real numbers, the set of non–negative reals and the set of natural numbers, respectively. For a vector $x \in \mathbb{R}^n$, $\|x\|$ denotes an arbitrary p-norm, $p \in \mathbb{N}_{\geq 1} \cup \infty$. A function $\varphi : \mathbb{R}_+ \to \mathbb{R}_+$ *belongs to class* $\mathcal{K}$ if it is continuous, strictly increasing and $\varphi(0) = 0$.

A function $\varphi : \mathbb{R}_+ \to \mathbb{R}_+$ *belongs to class* $\mathcal{K}_\infty$ if $\varphi \in \mathcal{K}$ and $\lim_{s\to\infty} \varphi(s) = \infty$.

Consider a discrete–time dynamical system

$$x(k+1) = f(x(k), u(k)), \quad k \in \mathbb{N}, \tag{1}$$

where $f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ is a suitable function that is zero at zero. We assume that the origin is a stabilizable equilibrium for (1). The system variables are constrained to compact sets with the origin in their interior, i.e. $(x, u) \in \mathbb{X} \times \mathbb{U}$. We assume that $\mathbb{X}$ is a constrained control invariant set, i.e., for all $x \in \mathbb{X}$, there exists a $u := \kappa(x) \in \mathbb{U}$ with $\kappa(0) = 0$ such that $f(x, u) \in \mathbb{X}$. For brevity, we refer to (Lazar, 2006) for the definition of asymptotic Lyapunov stability in $\mathbb{X}$.

Consider the following discrete–time dissipation inequality

$$V(x(k+1)) - V(x(k)) \leq s(x(k), u(k)), \quad \forall k \in \mathbb{N}, \tag{2}$$

where $V : \mathbb{R}^n \to \mathbb{R}$ is a positive definite storage function and $s : \mathbb{R}^n \to \mathbb{R}$ is a supply function that is bounded on bounded sets and $s(0, 0) = 0$.

In what follows we relax the latter requirement and provide a less conservative condition on the supply function s for inferring asymptotic stability from dissipativity. To this end, the following assumptions are instrumental.

Assumption 1. Controlled $\mathcal{K}$–boundedness: For the systems dynamics $f(\cdot, \cdot)$ and the state–feedback control law $u(k) = \kappa(x(k))$ that renders $\mathbb{X}$ controlled invariant it holds that $\|f(x, \kappa(x))\| \leq \sigma(\|x\|)$ for all $x \in \mathbb{X}$ and some $\sigma \in \mathcal{K}$.

Assumption 2. The storage function V satisfies

$$\alpha_1(\|x\|) \leq V(x) \leq \alpha_2(\|x\|), \quad \forall x \in \mathbb{X}, \tag{3}$$

for some $\alpha_1, \alpha_2 \in \mathcal{K}_\infty$.

Theorem 3. (Lazar, 2021) Let Assumption 1 and Assumption 2 hold and let $\alpha_s \in \mathcal{K}_\infty$. Suppose that $\{u(k)\}_{k\in\mathbb{N}} = \{\kappa(x(k))\}_{k\in\mathbb{N}}$ is such that the dissipation inequality (2) holds for all $x(0) \in \mathbb{X}$ and all $k \in \mathbb{N}$ and $(x(k), u(k)) \in \mathbb{X} \times \mathbb{U}$ for all $k \in \mathbb{N}$. Furthermore, suppose that there exists a $M \in \mathbb{N}_{\geq 1}$ such that for all $x(0) \in \mathbb{X}$ it holds that

$$\sum_{i=0}^{M-1} s(x(k+i), u(k+i)) \leq -\alpha_s(\|x(k)\|), \quad \forall k \in \mathbb{N}. \tag{4}$$

Then the origin of system (1) in closed–loop with $u(k) = \kappa(x(k))$ is asymptotically Lyapunov stable in $\mathbb{X}$.

3. STABILITY OF NONLINEAR MPC

In this section we analyze stability of state–space nonlinear MPC via Theorem 3. We will use the notation $x(i|k)$ to denote the predicted state at time $i \in \mathbb{N}_{[1,N]}$, given measured state $x(0|k) := x(k)$, and similarly $u(i|k)$ to denote the predicted input at time $i \in \mathbb{N}_{[0,N-1]}$, while setting $u(k) := u(0|k)$. The prediction model is a copy of (1), i.e.,

$$x(i+1|k) = f(x(i|k), u(i|k)), \quad i \in \mathbb{N}_{[0,N-1]},\ k \in \mathbb{N}.$$

Defining $\mathbf{u}(k) := \{u(0|k), \ldots, u(N-1|k)\}$ yields the MPC optimization problem:

$$\min_{\mathbf{u}(k)} J(x(k), \mathbf{u}(k)) := l_N(x(N|k)) + \sum_{i=0}^{N-1} l(x(i|k), u(i|k)) \tag{5a}$$

subject to constraints:

$$x(i+1|k) = f(x(i|k), u(i|k)), \quad \forall i \in \mathbb{N}_{[0,N-1]}, \tag{5b}$$

$$(x(i+1|k), u(i|k)) \in \mathbb{X} \times \mathbb{U}, \quad \forall i \in \mathbb{N}_{[0,N-1]}. \tag{5c}$$

In equation (5a) $l_N : \mathbb{R}^n \to \mathbb{R}_+$ denotes the terminal cost and $l : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}_+$ denotes the stage cost. The following assumptions are required to ensure Assumption 2 for the nonlinear MPC optimal cost.

Assumption 4. There exists $\alpha_{1,l} \in \mathcal{K}_\infty$ such that

$$\alpha_{1,l}(\|x\|) \leq l(x, u), \quad \forall (x, u) \in \mathbb{X} \times \mathbb{U}.$$

Let $\mathbf{u}^*(k)$ and $\mathbf{x}^*(k) := \{x^*(i|k)\}_{i\in\mathbb{N}_{[1,N]}}$ denote optimal input and state trajectories obtained by solving the MPC problem (5) at time k. Let $\mathbf{u}^s(k) := \{u^*(1|k), \ldots, u^*(N-1|k), u^s(N|k)\}$ with $u^s(N|k) \in \mathbb{U}$ and $x^s(N+1|k) := f(x^*(N|k), u^s(N|k)) \in \mathbb{X}$ denote a shifted input trajectory constructed at time k from the optimal trajectory computed at time k. Let $J(x(k), \mathbf{u}^*(k))$ denote the optimal cost function or value function at time k.

Assumption 5. There exists $\alpha_{2,J} \in \mathcal{K}_\infty$ such that

$$J(x, \mathbf{u}^*) \leq \alpha_{2,J}(\|x\|), \quad \forall x \in \mathbb{X}.$$

Next, we state the nominal MPC dissipativity result.

Theorem 6. (Lazar, 2021) Suppose that $\mathbb{X} \times \mathbb{U}$ is constrained control invariant for system (1). Let the stage cost be any positive definite function that satisfies Assumption 4. For the terminal cost either of the following choices can be made: any positive definite function that is zero at zero or a zero terminal cost. Define the storage function $V(x(k)) := J(x(k), \mathbf{u}^*(k))$ and the supply function

$$\begin{aligned} s(x(k), u(k)) :=& l_N(x^s(N+1|k)) + l(x^*(N|k), u^s(N|k)) \\ &- l_N(x^*(N|k)) - l(x(k), u(k)), \quad k \in \mathbb{N}. \end{aligned} \tag{6}$$

Then for all $x(0) \in \mathbb{X}$, the dissipation inequality

$$V(x(k+1)) - V(x(k)) \leq s(x(k), u(k)), \quad \forall k \in \mathbb{N} \tag{7}$$

holds along the trajectories of system (1) in closed–loop with $u(k) := u^*(0|k)$ obtained by solving problem (5).

Let the MPC closed–loop system denote system (1) in closed–loop with $u^*(0|k)$ obtained by solving (5). Next we state the nominal MPC asymptotic stability result.

Corollary 7. (Lazar, 2021) Let the stage cost in the MPC problem (5) satisfy Assumption 4, suppose Assumption 5 holds and assume $\mathbb{X} \times \mathbb{U}$ is constrained control invariant. Suppose that there exists a $\rho \in \mathcal{K}_\infty$ and an $M \in \mathbb{N}_{\geq 1}$ such that Assumption 1 holds for the trajectories of the MPC closed–loop system, and the MPC supply function defined in (6) satisfies for all $x(0) \in \mathbb{X}$

$$\sum_{i=0}^{M-1} s(x(k+i), u(k+i)) \leq -\rho \circ l(x(k), u(k)), \quad \forall k \in \mathbb{N}. \tag{8}$$

Then the origin of the MPC closed–loop system is asymptotically Lyapunov stable in $\mathbb{X}$.

Relation with existing stabilizing conditions: The stabilizing conditions corresponding to approach *(i)* (terminal

equality constraint) force $x(N|k) = 0$, which allows setting $u^s(N|k) = 0$ and $x^s(N+1|k) = 0$. Hence, $s(x(k), u(k)) = -l(x(k), u(k))$ and condition (8) holds with $M = 1$ and $\rho = \mathrm{id}$. Approach *(ii)* (terminal set constraint) constructs $u^s(N|k) = h(x^*(N|k))$ such that $l_N(x)$ is a Lyapunov function for $x(k+1) = f(x(k), h(x(k)))$ which yields

$$l_N(x^s(N+1|k)) - l_N(x^*(N|k)) + l(x^*(N|k), u^s(N|k)) \leq 0.$$

Hence, $s(x(k), u(k)) \leq -l(x(k), u(k))$ and condition (8) holds with $M = 1$ and $\rho = \mathrm{id}$. Approach *(iii)* (MPC without terminal constraint and with CLF terminal cost) requires that $l_N(x)$ is a control Lyapunov function, i.e.,

$$\min_{u^s(N|k)} l_N(x^s(N+1|k)) - l_N(x^*(N|k)) + l(x^*(N|k), u^s(N|k))$$

should be less than or equal to zero. This implies existence of $u^s(N|k)$ such that $s(x(k), u(k)) \leq -l(x(k), u(k))$ and condition (8) holds with $M = 1$ and $\rho = \mathrm{id}$. Approach *(iv)* (MPC without terminal constraint and with zero terminal cost) uses the property (see (Grüne, 2012, Proposition 3.4))

$$V(x(k+1)) - V(x(k)) \leq -\alpha l(x(k), u(k)),$$

where $\alpha \in (0, 1]$ is a constant. Taking a zero terminal cost and requiring a monotonic decrease of V, as in (Grüne, 2012, Proposition 3.4), corresponds to existence of $u^s(N|k)$ such that

$$\begin{aligned} s(x(k), u(k)) &= l(x^*(N|k), u^s(N|k)) - l(x(k), u(k)) \\ &\leq -\rho \circ l(x(k), u(k)), \end{aligned}$$

which implies that (8) holds with $M = 1$ and $\rho < \mathrm{id}$.

Next, we briefly indicate how to construct a shifted input trajectory that verifies the developed stabilizing conditions. To begin with, we opt for using a terminal cost equal to the stage cost for the state, i.e. assume that $l(x, u) = l(x, 0) + l(0, u)$ and set $l_N(x) := l(x, 0)$. Then the MPC supply function becomes:

$$\begin{aligned} s(x(k), u(k)) :=& l(x^s(N+1|k), 0) + l(x^*(N|k), u^s(N|k)) \\ &- l(x^*(N|k), 0) - l(x(k), u(k)) \\ &= l(x^s(N+1|k), u^s(N|k)) - l(x(k), u(k)). \end{aligned} \tag{9}$$

At every time $k \in \mathbb{N}$, given $x(k)$, after $\mathbf{u}^*(k)$ was calculated, we need to check that there exists a $u^s(N|k) \in \mathbb{U}$ such that

$$\begin{aligned} &s(x(k), u(k)) = \\ &l(f(x^*(N|k), u^s(N|k)), u^s(N|k)) - l(x(k), u^*(0|k)) \\ &\leq -\rho \circ l(x(k), u^*(0|k)), \end{aligned} \tag{10}$$

for some $\rho \in \mathcal{K}_\infty$ with $\rho < \mathrm{id}$. If the above condition holds, then the cyclically neutral supply condition also holds.

The above inequality can be further relaxed by exploiting the accumulated supply over the previous M time steps, where the current time must satisfy $k \geq M + 1$, i.e.,

$$\begin{aligned} &\sum_{i=-M+1}^{0} s(x(k+i), u(k+i)) \\ &\leq -\rho \circ l(x(k-M+1), u^*(0|k-M+1)). \end{aligned} \tag{11}$$

Indeed, if we let $M = 1$ in the above inequality, we recover (10).

4. RECURSIVE FEASIBILITY ANALYSIS

The following results are a new addition to (Lazar, 2021). In order to guarantee recursive feasibility, consider the following terminal set characterization for system (1):

$$\mathbb{X}_T := \{x \in \mathbb{X} \ : \ g^q(\mathcal{X}, x) \leq c\},$$

where $c > 0$ is such that $\mathbb{X}_T \subseteq \mathbb{X}$, $\mathcal{X}$ is a proper C–set with gauge function $g(\cdot, \cdot)$ (Blanchini et al., 2015), and $q = 1$ or 2 for ellipsoidal proper C-sets.

Assumption 8. There exists an admissible control law $\kappa : \mathbb{X}_T \to \mathbb{U}$ continuous at the origin and zero at zero such that the set $\mathbb{X}_T$ is control λ–contractive with $\lambda : \mathbb{R}_+ \to \mathbb{R}_+$, $\lambda(0) = 0$ and $\lambda < \mathrm{id}$, for the dynamics (1), i.e., for all $x \in \mathbb{X}_T$ it holds that $g^q(\mathcal{X}, f(x, \kappa(x)) \leq \lambda \circ g^q(\mathcal{X}, x)$.

Then we can formulate the following result.

Theorem 9. Let the hypothesis of Theorem 6 hold, let Assumption 5 hold and consider the nonlinear MPC problem (5) at time $k \in \mathbb{N}$ with prediction horizon $N(k) \geq 2$ and the additional constraint $x(N(k)|k) \in \mathbb{X}_T$, where $\mathbb{X}_T \subseteq \mathbb{X}$ is a terminal set satisfying Assumption 8 for a state–feedback control law $\kappa(x)$. Then the following properties hold:

- If the nonlinear MPC problem (5) with the additional terminal constraint is feasible at time k, then the same problem is feasible at time $k+1$ for any $N(k+1) \geq N(k)$;
- Assume there exists $\sigma \in \mathcal{K}$ such that
$$l(x, \kappa(x)) \leq \sigma \circ g^q(\mathcal{X}, x), \quad \forall x \in \mathbb{X}_T. \tag{12}$$
Then there exists a $N(k+1) \geq N(k)$ such that the negative supply condition (10) holds at time $k+1$.

Proof. Since $x^*(N(k)|k) \in \mathbb{X}_T$, we can construct a feasible shifted sequence

$$\begin{aligned} &\{u^*(1|k), \ldots, u^*(N(k)-1|k), \\ &\quad \kappa(x^*(N(k)|k)), \ldots, \kappa(x(N(k)+N_T|k))\} \end{aligned} \tag{13}$$

for any $N_T \geq 1$, where

$$\begin{aligned} &x(N(k)+N_T|k) = \\ &f(x(N(k)+N_T-1|k), \kappa(x(N(k)+N_T-1|k))) \in \mathbb{X}_T \end{aligned}$$

for all $N_T \geq 1$. Hence, the MPC optimization problem with the terminal constraint added is feasible at time $k+1$ for any $N(k+1) \geq N(k)$.

Moreover, $x^*(N(k)|k) \in \mathbb{X}_T$ implies $g^q(\mathcal{X}, x^*(N(k)|k)) \leq c$. Hence, from inequality (12) it follows that there exists a $N_T \geq 1$ such that

$$\begin{aligned} &l(x(N(k)+N_T|k), \kappa(x(N(k)+N_T|k))) \\ &\leq \sigma \circ g^q(\mathcal{X}, x(N(k)+N_T|k)) \\ &\leq \sigma \circ \lambda^{N_T}(c) \\ &\leq (\mathrm{id} - \rho) \circ l(x(k), u^*(0|k)), \end{aligned}$$

for any $x(k) \neq 0$, which implies condition (10) holds for $N \geq N(k) + N_T$. Above we have used that $\lambda < \mathrm{id}$ and $\sigma \in \mathcal{K}$. Hence, by selecting $N(k+1) = N(k) + N_T - 1$ and time $k+1$ we have that the dissipation inequality (7) holds with $\tilde{V}(x(k))$ instead of $V(x(k))$ corresponding to the extended sequence (13) and with the supply $s(x(k), u(k))$ satisfying (10). □

The above result provides a mechanism for adapting the prediction horizon online such that recursive feasibility

and convergence of the optimal nonlinear MPC cost function are guaranteed (assuming $N(k)$ converges to a constant value in finite time), for an arbitrary positive definite cost function. An alternative way of guaranteeing convergence with a time–varying $N(k)$ is to employ a contractive terminal constraint, as proposed in (Limon et al., 2006), or to resort to time–varying Lyapunov functions. The details of these approaches will be presented in an extended paper.

Observe that the condition (12) is easily satisfied if the terminal set is such that its Minkowski functional is a norm, e.g., an ellipsoidal set. Indeed, since typically $l(x, \kappa(x))$ is upper bounded by a $\mathcal{K}$–function of x in the terminal set, condition (12) holds due to equivalence of norms. For systematic computation of ellipsoidal contractive sets for discrete–time nonlinear systems we refer to the sNMPC toolbox (Eyüboğlu and Lazar, 2022).

5. PRACTICAL STABILIZING NMPC DESIGN

As a conclusion to this extended abstract we propose two practical methods for designing stabilizing NMPC algorithms with arbitrary positive definite stage cost functions.

Time–varying horizon NMPC

- At time $k \in \mathbb{N}$, given $x(k)$, $N(k)$, $l(\cdot,\cdot)$, $\mathbb{X}_T$ and $\kappa(\cdot)$, $\mathbb{X}$ and $\mathbb{U}$ solve the optimization problem (assuming it is feasible):

$$\min_{\mathbf{u}(k)} \sum_{i=0}^{N(k)-1} l(x(i|k), u(i|k))$$

subject to constraints:

$$x(i+1|k) = f(x(i|k), u(i|k)), \quad \forall i \in \mathbb{N}_{[0,N(k)-1]},$$
$$(x(i+1|k), u(i|k)) \in \mathbb{X} \times \mathbb{U}, \quad \forall i \in \mathbb{N}_{[0,N(k)-1]},$$
$$x(N(k)|k) \in \mathbb{X}_T.$$

- Compute $l(x^*(N(k)|k), \kappa(x^*(N(k)|k)))$, where $\kappa(\cdot)$ is the state–feedback control law that renders $\mathbb{X}_T$ contractive and check if

$$l(x^*(N(k)|k), \kappa(x^*(N(k)|k))) < l(x(k), u^*(0|k)).$$

  If the above inequality holds, apply $u^*(0|k)$, set $N(k+1) = N(k)$ and repeat for $k+1$.
- Else, compute $l(x(N(k)+N_T|k), \kappa(x(N(k)+N_T|k)))$ for $N_T = 1, 2, \ldots$ using the dynamics $f(x, \kappa(x))$ until

$$l(x(N(k)+N_T|k), \kappa(x(N(k)+N_T|k))) < l(x(k), u^*(0|k)).$$

  Then apply $u^*(0|k)$, set $N(k+1) = N(k) + N_T$ and repeat for $k+1$.

If the terminal set and local controller $\kappa(\cdot)$ are not available/used, the above algorithm can still be implemented by computing the additional control inputs online, solving additional optimization problems, as suggested in (Lazar, 2021).

Alternatively, the following NMPC implementation can be used, which explicitly enforces the stage cost constraint and utilizes a slack variable s, to minimize the supply function induced by the stage cost. Simulation examples will be provided during the presentation and in a corresponding article.

NMPC with flexible supply constraint

- At time $k \in \mathbb{N}$, given $x(k)$, N, $l(\cdot,\cdot)$, $\mathbb{X}_T$ and $\kappa(\cdot)$, $\mathbb{X}$, $\mathbb{U}$, $\lambda > 0$ and $\varepsilon \in \mathbb{N}_{(0,1)}$ solve the optimization problem (assuming it is feasible):

$$\min_{\mathbf{u}(k), s(k)} \sum_{i=0}^{N-1} l(x(i|k), u(i|k)) + \lambda s(k)$$

subject to constraints:

$$l(x(N|k), \kappa(x(N|k))) - \varepsilon l(x(k), u(0|k)) \leq s(k)$$
$$x(i+1|k) = f(x(i|k), u(i|k)), \quad \forall i \in \mathbb{N}_{[0,N-1]},$$
$$(x(i+1|k), u(i|k)) \in \mathbb{X} \times \mathbb{U}, \quad \forall i \in \mathbb{N}_{[0,N-1]},$$
$$x(N|k) \in \mathbb{X}_T.$$

Convex Approach to Data-Driven Stochastic Optimal Control using Linear Operator Theory ⋆

Umesh Vaidya

* *Department of Mechanical Engineering, Clemson University, Clemson SC 29631 (email: uvaidya@clemson.edu)*

EXTENDED ABSTRACT

The stochastic optimal control problem (SOCP) is a cornerstone of systems and control theory. This problem has received renewed attention with the growing interest in data-driven analytics and control with applications ranging from vehicle autonomy, robotics, transportation networks, power grid, security, and advanced manufacturing. The SOCP is also at the heart of Reinforcement learning (RL), and various algorithms are developed for the data-driven approximation of its solution. For a system in continuous time with continuous state space and control, the solution to SOCP essentially boils down to solving a Hamilton Jacobi Bellman (HJB) equation, which is a nonlinear partial differential equation. In discrete-time, SOCP involves solving the Bellman equation using the principle of dynamic programming. Thus, the Bellman equation can be viewed as the discrete-time counterpart of the continuous-time HJB equation. Given the nonlinear nature of the HJB equation, one of the popular approaches to solving the HJB equation is the iterative approach. In this work, we propose an alternate method for solving SOCP based on the convex formulation of the problem in the dual space of densities. We provide a data-driven solution to the SOCP over an infinite time horizon with continuous-time system dynamics. The dual approach leads to a convex infinite-dimensional optimization problem to be solved for the SOCP. Unlike iterative algorithms for solving HJB equation in the primal domain, the convex formulation in the dual space lends itself to a single-shot approach for solving SOCP. We use a linear operator theoretic framework involving P-F and Koopman operators to provide a novel perspective on the SOCP problem and the computation of its solution using data. We show that the traditional primal formulation of SOCP involving the HJB equation is closely tied to the Koopman operator. Furthermore, the dual convex formulation of the SOCP can be understood naturally through the lenses of duality between the Koopman and P-F operator.

We provide a convex formulation to the SOCP using the linear operator theoretic framework involving P-F and Koopman operators. The linear P-F and Koopman operators are dual and provide a linear lifting of nonlinear system dynamics in the space of density and function (observables), respectively. The dynamical system theory inspires the results, as the duality in SOCP is discovered through duality between the P-F and Koopman operators. The SOCP problem is formulated using P-F operator-based lifting of control system dynamics in the dual density space. This dual approach leads to the infinite-dimensional convex optimization-based formulation of the SOCP. We provide a computational framework based on the data-driven approximation of the P-F operator for the data-driven stochastic optimal control design. The convex formulation of SOCP is made possible by exploiting the P-F operator's linearity, positivity, and Markov properties. Furthermore, we show that the hard constraints on the control input and the state can also be written convexly in the dual formulation. The state constraints will include safety or obstacle avoidance constraints. On the other hand, we establish a connection between the Koopman operator and the HJB equation. This connection allows us to develop a numerical algorithm for the data-driven solution of the HJB equation based on Koopman theory. In particular, we provide an iterative algorithm based on a data-driven approximation of the Koopman operator for solving the SOCP problem in the primal domain. This new algorithm is reminiscent of the generalized policy iteration (GPI) algorithm in RL, and we call it Koopman policy iteration (KPI). Moreover, the interpretation of GPI using the Koopman theory opens up the possibility of exploiting the rich spectral theory of the Koopman operator for data-driven control. It is important to emphasize that the existing iterative algorithm for solving the HJB equation, including our proposed Koopman-based approach, requires an initial control policy to be stabilizing. However, designing stabilizing controller for a stochastic nonlinear system is far from a trivial problem. Our proposed dual approach to SOCP does not suffer from this drawback. The convex optimization problem in our dual framework can be solved as a single shot problem, where almost everywhere, stochastic stabilizability arises as a constraint of this optimization problem. So the data-driven stochastic stabilization will emerge as the particular case of the main result on SOCP.

Algebraic and Path-Based Conditions for Local Network Identifiability

A. Legat, J. M. Hendrickx *

(e-mail: { antoine.legat, julien.hendrickx } @uclouvain.be).

Abstract: This work focuses on the generic identifiability of dynamical networks with partial excitation and measurement: a set of nodes are interconnected by transfer functions according to a known topology, some nodes are excited, some are measured, and only a part of the transfer functions are known. Our goal is to determine whether the unknown transfer functions can be generically recovered based on the input-output data collected from the excited and measured nodes. Introducing the notion of generic local identifiability, we derive a necessary and sufficient algebraic condition, which can be checked efficiently by rank computation. Another notion, generic decoupled identifiability, allows to reflect on a larger network which decouples excitations and measurements. This yields a necessary path-based condition, and a sufficient one.

Keywords: System Identification, Networked Control Systems, Linear Systems.

1. INTRODUCTION

The goal of this work is to recover the local dynamics from the global input-output behavior of a networked system and the knowledge of the network topology.

We consider the identifiability of a network matrix $G(q)$, where the network is made up of n node signals $w(t)$, external excitation signals $r(t)$, measured nodes $y(t)$ and noise $v_1(t), v_2(t)$ related to each other by:

$$\begin{aligned} w(t) &= G(q)w(t) + Br(t) + v_1(t) \\ y(t) &= Cw(t) + v_2(t), \end{aligned} \tag{1}$$

where matrices B and C are binary selections defining respectively the n_B excited nodes and n_C measured nodes, forming sets $\mathcal{B}$ and $\mathcal{C}$ respectively. The nonzero entries of the network matrix $G(q)$ define the network topology: some of them are known and collected in $G^0(q)$, and the others are the unknowns to identify, collected in $G^\Delta(q)$, such that $G(q) = G^0(q) + G^\Delta(q)$.

We assume that the global relation between the excitations r and measurements y has been identified, and that the structure of $G(q)$ is known. From this knowledge, we aim at recovering the unknown entries of $G(q)$.

Networked systems have recently been the object of a significant research effort. The independent identification of all local dynamics in a networked system would require exciting and measuring every single node of the network, which is costly and often impractical. We therefore assume here that we excite and measure different subsets of nodes, and are able to identify the global input-output dynamics going from the excited nodes to the measured nodes.

A recent approach employs graph-theoretical tools to derive identifiability conditions on the graph of the network. Using this approach, Hendrickx et al. (2018); Cheng et al. (2019) address the particular case where all nodes are excited. In the general case of partial measurement *and* excitation, Shi et al. (2021) derive identifiability conditions while exploiting unmeasured noise. In this work, we consider partial measurement and excitation and we introduce the notions of generic local and decoupled identifiability, for which we derive algebraic and path-based conditions.

Assumptions: Consistently with previous works, we assume that $(I - G(q))^{-1}$ is proper and stable, and we consider a single frequency z, so that all transfer functions are modeled simply by a complex value, and the matrices G and $T(G) = (I-G)^{-1}$ are complex matrices rather than matrices of transfer functions.

Genericity: Besides, we say that a network is *generically* identifiable if it is identifiable at all G with same known and zero entries, except possibly those lying on a set of dimension lower than the number of unknown edges. In the remainder of this paper, we say that a property is *generic* if it either holds (i) for *almost all* variables, i.e for all variables except possibly those lying on a lower-dimensional set, or (ii) for no variable.

2. LOCAL IDENTIFIABILITY

First, we remind a notion of identifiability amenable to linear analysis: local identifiability, which corresponds to identifiability provided that $\tilde{G}$ is sufficiently close to G.

Definition 1. The network is *locally identifiable* at G from excitations $\mathcal{B}$ and measurements $\mathcal{C}$ if there exists $\epsilon > 0$ such that for any $\tilde{G}$ with same zero and known entries as G satisfying $||\tilde{G} - G|| < \epsilon$, there holds

$$C\,T(\tilde{G})\,B = C\,T(G)\,B \Rightarrow \tilde{G}^\Delta = G^\Delta, \tag{2}$$

where $\tilde{G}^\Delta$ collects only the entries of $\tilde{G}$ corresponding to unknown edges, just as G^Δ does for G.

Local identifiability is a generic property of the network, and is a necessary condition for identifiability. It is *a priori* a weaker notion, yet no example locally identifiable but not globally identifiable is known to the authors.

2.1 Necessary and sufficient algebraic condition

Linearizing (2) yields a necessary and sufficient condition.

Proposition 2. Exactly one of the two following holds:

(i) the network is generically locally identifiable and for almost all G, there holds
$$C\,T(G)\,\Delta\,T(G)\,B = 0 \Rightarrow \Delta = 0, \tag{3}$$
for all Δ of same dimensions and zero entries as G^{Δ}.
(ii) the network is never locally identifiable and there is no G for which (3) holds $\forall\ \Delta$ with same 0s as G^{Δ}.

Moreover, (3) holds if and only if matrix $K(G)$ is full rank. Expression of $K(G)$ can be found in Legat and Hendrickx (2020), along with an algorithm that efficiently determines generic local identifiability by rank computation of $K(G)$.

The algebraic condition of Proposition 2 allows rapidly testing local identifiability for any given network, but we aim at finding a combinatorial characterization for generic identifiability, that is expressed purely in terms of path-based properties, akin to what was done in the full excitation case e.g. in Hendrickx et al. (2018). This spurs the need for a new notion of identifiability.

3. DECOUPLED IDENTIFIABILITY

We consider a more general notion than local identifiability. It is essentially inspired from (3), where the left and right $T(G)$ are no more equal, hence the name *decoupled*.

Definition 3. A network is *decoupled-identifiable* at (G, G'), with G and G' sharing the same zero and known entries, if for all Δ with same zeros as G^{Δ}, there holds:
$$C\,T(G)\,\Delta\,T(G')\,B = 0 \Rightarrow \Delta = 0. \tag{4}$$

Similarly to local identifiability, decoupled identifiability is a generic property: either it holds for almost all (G, G'), or for no (G, G'). Besides, generic decoupled identifiability is necessary for generic local identifiability, which is itself necessary for generic identifiability. Hence, necessary conditions obtained for generic decoupled identifiability apply to (generic) (local) identifiability as well.

In addition, generic decoupled identifiability of a network is equivalent to generic identifiability of a larger network, constructed by duplicating the initial network, exciting one copy, measuring the other one and adding the unknown edges in the middle. This larger network is called *decoupled network* and is defined in Legat and Hendrickx (2021).

3.1 Necessary path-based condition, and sufficient

Decoupled identifiability allows to reflect on the decoupled network, on which for each unknown edge, one can route a path that starts at an excitation and ends at a measurement. Building on Proposition 2, this approach leads to Theorem 4, which gives a necessary path-condition and a sufficent one, for generic decoupled identifiability.

For ease of presentation, we consider the case where there are exactly $n_B n_C$ unknown edges, i.e. as many as the number of (excitation, measurement) pairs. Transfer functions are referred to as edges, and an *assignation* σ is a function that assigns to each unknown edge a pair (excitation, measure). We say that σ is *connected* if for each unknown edge there is a path from its assigned excitation to its assigned measurement, in which the unknown edge is included.

Theorem 4. If a network is generically decoupled-identifiable, then there is at least one assignation σ such that:

(a) n_C unknown edges are assigned to each excitation
(b) n_B unknown edges are assigned to each measurement
(c) σ is connected
(d) for each excitation b, there are n_C vertex-disjoint paths between the edges assigned to b and measurements $\mathcal{C}$.
(e) for each measurement c, there are n_B vertex-disjoint paths between edges assigned to c and excitations $\mathcal{B}$.

If there is only one such assignation, then this condition is also sufficient for generic decoupled identifiability.

4. DISCUSSION

In Legat and Hendrickx (2021), the intuition is given that a stronger version of Theorem 4 could exist, which would extend path-based conditions of Hendrickx et al. (2018). Specific counter-examples allow to narrow the search for such stronger conditions and a low-level approach gives a more clear understanding of the problem.

Besides, we remind that the necessary condition of Theorem 4 extends to (generic) (local) identifiability, and that no counter-example to sufficiency of generic decoupled and local identifiability is known to the authors.

5. CONCLUSION

We introduced the notion of local generic identifiability, which excludes situations where the set of solutions is discrete. Linearizing this notion gave a necessary and sufficient algebraic condition, which can be checked efficiently by rank computation.

Another new notion, decoupled identifiability, allowed us to reflect on a larger graph that highlights paths between excitations and measurements. This approach led to a necessary path-based condition, and a sufficient one.

Eventually, potential stronger path-based conditions are discussed, supported by specific counter-examples and a low-level approach.

Nash equilibria of the pay-as-bid auction with K-Lipschitz supply functions

EXTENDED ABSTRACT

M. Vanelli * **G. Como** * **F. Fagnani** *

(e-mail: {martina.vanelli,giacomo.como, fabio.fagnani}@polito.it).

Abstract: We model a system made of n asymmetric firms participating in a market in which each firm chooses as its strategy a supply function relating its quantity to its price. Such strategy (Supply function equilibrium) is a generalization of models where firms can either set a fixed quantity (Cournot model) or set a fixed price (Bertrand model). Our goal is to study the pay-as-bid auction in this setting. Under the assumption of K-Lipschitz supply functions, we were capable of determining existence and characterization of Nash equilibria of the game.

Keywords: Supply function equilibrium, Pay-as-bid auction, Discriminatory price auction, Oligopoly, Electricity market

1. INTRODUCTION

The progressive liberalization of electricity markets motivates the need to develop realistic and robust models for the analysis of the strategic bidding problem (Ventosa et al. (2005)). Pricing rules in oligopolistic wholesale electricity auctions are mainly two: the uniform price rule and the pay-as-bid rule (Rassenti et al. (2003), Fabra et al. (2006)). In a uniform price auction, electricity is paid/sold at the market-clearing price, regardless of the offers that bidders actually made. On the other hand, in the pay-as-bid auction (also called discriminatory price auction), the remuneration is the bid price. Uniform price auctions are usually employed in day-ahead markets, while ancillary services markets sometimes adopt pay-as-bid remunerations (e.g, see Müsgens et al. (2014) and Gestore dei Mercati Energetici (GME)).

From a game-theoretic point of view, appropriate models for studying wholesale markets for electricity are Supply Function Equilibrium (SFE) models. With this approach, instead of setting their price bids (Bertrand) or quantities (Cournot), see Mas-Colell et al. (1995), firms bid their choices of supply functions and the predicted outcome is a Nash equilibrium of the game. SFE models were first introduced by Klemperer and Meyer (1989), and then applied to electricity markets by Green and Newbery (1992)). Empirical studies of strategic bidding suggest that the SFE model provides a good approximation of the behavior of large producers (Hortaçsu and Puller (2008); Sioshansi and Oren (2007)).

There is a vast amount of literature directed to the study of SFE outcomes in uniform-price auctions (e.g., David (1993), Baldick and Hogan (2001), Anderson and Philpott (2002), Baldick et al. (2004), Holmberg and Newbery (2010)), but less clear is the behavior of SFE models when discriminatory prices are considered. Our focus is on existence and characterization of Nash equilibria in supply functions with the pay-as-bid remuneration and asymmetric firms. We determine conditions on the strategy space under which existence is guaranteed and best responses can be characterized. Our work is related to Holmberg (2009), where uncertainty is considered. The authors determine conditions on the hazard rate of the demand distribution to ensure existence of Nash equilibria which is in general not guaranteed. We instead study the problem from a deterministic perspective with the goal of determining a tractable model. Although different in the purpose, it is relevant to mention Genc (2009), where supply function equilibria game models are compared for uniform-price and pay-as-bid auctions.

2. MODEL

2.1 Definition of the game

In the general setting, we shall consider:

- a player set $\mathcal{N} = \{1, \dots, n\}$ made of n firms equipped with non-decreasing *cost functions* $C_i(q)$, for $i \in \mathcal{N}$, where q denotes the sold quantity. We assume that C_i is twice continuously differentiable and such that $C_i' \geq 0$ and $C_i'' \geq 0$ for every $i \in \mathcal{N}$. The assumption of convex costs is standard in literature (see Klemperer and Meyer (1989), Green and Newbery (1992));
- a strictly decreasing industry *demand function* $D(p)$, which retuns the aggregate quantity that consumers are willing to buy at a (maximum) unit price p. We define $\hat{p}$ as the price such that $D(\hat{p}) = 0$. We assume that $D \in C^2$ and such that $D' < 0$ and $D'' \leq 0$.

The *strategy* of firm $i \in \mathcal{N}$ is a supply function belonging to an arbitrary subset of the set of non-decreasing continuous functions passing through the origin, i.e.,

$$\mathcal{F} = \{S \in C^0([0, \hat{p}])\,,\ S_i(0) = 0\,,\ S \text{ non-decreasing}\}\,. \quad (1)$$

The supply function S_i returns the quantity $q = S_i(p)$ that the firm is willing to produce at (minimum) unit price p. The *strategy configuration* of the auction combines all

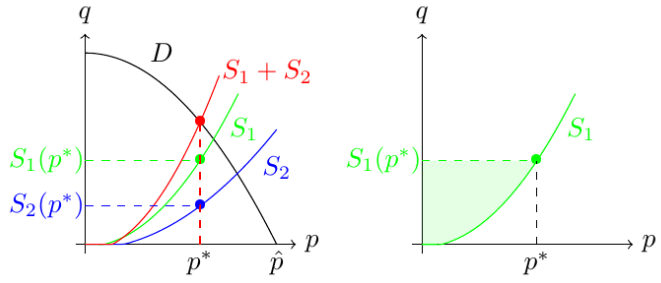

Fig. 1. The equilibrium marginal price (on the left) and the pay-as-bid remuneration (on the right).

strategies, that is, $\mathbf{S} = (S_1, \dots, S_n)$. For a firm $i \in \mathcal{N}$ and a strategy configuration $\mathbf{S}$, we shall refer to the other firms' strategies with $S_{-i} = \{S_j\}_{j \neq i}$.

Given a demand D and a strategy configuration $\mathbf{S}$, the *equilibrium marginal price* is determined as the price that matches total demand and total supply, that is, $p^* \in [0, \hat{p}]$ satisfying

$$D(p^*) = \sum_{i=1}^{n} S_i(p^*)\,. \tag{2}$$

We remark that p^* exists unique in $[0, \hat{p}]$ under the assumptions of a strictly decreasing continuous demand function and increasing continuous supply functions satisfying $S_i(0) = 0$ for all i. The equilibrium marginal price determines the total quantity that will be sold by each firm in the auction, that is, $q_i^* = S_i(p^*)$ for every $i \in \mathcal{N}$. An example of equilibrium marginal price is depicted on the left of Fig.1.

We define the following class of games based on the pay-as-bid remuneration. For a given $\mathcal{A} \subseteq \mathcal{F}$, the *pay-as-bid* (PAB) *auction* is a game with player set $\mathcal{N}$, strategy space $\mathcal{A}$ and utilities, for every $i \in \mathcal{N}$,

$$u_i(S_i, S_{-i}) := p^* S_i(p^*) - \int_0^{p^*} S_i(p)\,\mathrm{d}p - C_i(S_i(p^*))\,, \tag{3}$$

where $p^* := p^*(S_i, S_{-i})$ is the equilibrium marginal price satisfying (2). We shall denote the PAB auction with $\mathcal{U} = (\mathcal{N}, \mathcal{A}, \{u_i\}_{i \in \mathcal{N}})$.

In words, firm i sells $S_i(p^*)$ at the bid price and the final utility is given by the total revenue minus the production cost. We remark that the integral term is the one that makes the difference between the uniform-price auction and the pay-as-bid one. Indeed, notice that, when S_i is differentiable,

$$\int_0^{p^*} pS_i'(p)\,\mathrm{d}p = p^* S_i(p^*) - \int_0^{p^*} S_i(p)\,\mathrm{d}p\,.$$

If the reward were only $p^* S_i(p^*)$, we would be dealing with a uniform price auction, thus obtaining the model in Klemperer and Meyer (1989). Observe that, if S_i is invertible, the total revenue in the pay-as-bid auction equals the integral from 0 to $S_i(p^*)$ of the inverse of S_i, that is, the price function $P_i(q) := S_i^{-1}(q)$ of producer i. The price function assigns to each quantity the marginal price at which firms are willing to sell such quantity for. Therefore, its integral from 0 to q_i^* determines the total pay-as-bid remuneration for firm i for a quantity q_i^*. By considering the formula in (3), we do not need to make any assumption on S_i.

An example of remuneration of the pay-as-bid auction is depicted on the right of Figure 1. When the supply function is S_1 and the equilibrium marginal price is p^*, the total revenue for firm 1 coincides with the green area (the utility is then given by revenue minus costs).

Throughout the analysis, we shall focus on existence and characterization of Nash equilibria of the pay-as-bid auction: an action configuration $\mathbf{S}$ is a (pure strategy) *Nash equilibrium* if, for every $i \in \mathcal{N}$, S_i maximizes the utility given the other firms' strategies. Let $S_{-i} \in \mathcal{A}^{\mathcal{N}\setminus\{i\}}$. We shall refer to the set

$$\mathcal{B}_i(S_{-i}) = \operatorname*{argmax}_{S_i \in \mathcal{A}} u_i(S_i, S_{-i})$$

as the *best response* of firm i to S_{-i}. Then, $\mathbf{S}$ is a Nash equilibrium if and only if $S_i \in \mathcal{B}_i(S_{-i})$ for every $i \in \mathcal{N}$.

2.2 Remarks on the strategy space

In this section, in order to provide the motivation for our work, we shall discuss existence of Nash equilibria in the pay-as-bid auction depending on the choice of the strategy space $\mathcal{A}$.

Let us first observe that, when the supply functions can be generic non-increasing continuous functions, that is, when $\mathcal{A} = \mathcal{F}$ as in (1), the PAB auction admits no Nash equilibria. More precisely, we shall prove that the best-response does not exist.

Proposition 1. Consider the PAB auction with strategy space $\mathcal{A} = \mathcal{F}$ as in (1). Then, for every $i \in \mathcal{N}$ and $S_{-i} \in \mathcal{A}^{\mathcal{N}\setminus\{i\}}$, $\mathcal{B}_i(S_{-i}) = \emptyset$.

Proof. We shall prove that for every feasible supply function $S_i \in \mathcal{A}$, there exists another feasible supply function $\tilde{S}_i \in \mathcal{A}$ yielding to the same equilibrium price and a higher utility. Formally, let S_i be any non-decreasing continuous function yielding to an equilibrium price p^*. We shall then define

$$\tilde{S}_i(p) := S_i\left(\frac{p^2}{p^*}\right)\,.$$

Observe that $\tilde{S}_i(0) = S_i(0)$ and $\tilde{S}_i(p^*) = S_i(p^*)$. Also $S_i(p) \geq \tilde{S}_i(p)$ for all $p \in [0, p^*]$ and, more precisely, $S_i(p) > \tilde{S}_i(p)$ for every $p \in (0, p^*)$ such that $S_i(p) > 0$. Then,

$$u_i(\tilde{S}_i, S_j) > u_i(S_i, S_j)\,.$$

This concludes the proof.

Remark 1. The proof of Proposition 1 suggests that best responses would exist if one could use step functions. However, enlarging the strategy space to discontinuous functions would lead to a number of different technical difficulties. For instance, one has to solve some technical problems in the definition of the game. Indeed, the existence of a unique marginal equilibrium price p^* is not anymore guaranteed. Anyway, even when we technically solve such problem, Nash equilibria might fail to exist.

Thus, we observed that, in the general settings, Nash equilibria might fail to exist. This gives the motivation for the K-Lipschitz assumption, which guarantees existence and characterization of Nash equilibria.

3. RESULTS

3.1 The Lipschitzianity assumption

As previously observed, one of the main issues is that, without any particular restriction on the strategy space, the best response is a step function and existence of Nash equilibria is not guaranteed. Accordingly, the best response does not exist when considering generic continuous supply functions. The problem is solved when considering K-Lipschitz supply functions, for a fixed $K > 0$. Under this assumption, not only best responses do exist, but it is rather simple to determine their structure. As we shall observe, this assumption drastically reduces the dimention of the strategy space.

Let $K > 0$. We recall that a function $S : [0, \hat{p}] \to [0, \infty)$ is *K-Lipschitz* if

$$|S(x) - S(y)| \leq K|x - y|\,, \quad \forall x, y \in [0, \hat{p}]\,,\, x \neq y\,.$$

Let us then define

$$\mathcal{A}_K := \{S \in \mathcal{F}\,, S \text{ is } K\text{-Lipschitz}\}\,. \tag{4}$$

Under the assumption of K-Lipschitz supply functions, that is, $\mathcal{A} = \mathcal{A}_K$, we can characterize best response functions, as showed in the following lemma.

Lemma 1. (Affine best-response). Consider the PAB auction $\mathcal{U}$ with strategy space $\mathcal{A} = \mathcal{A}_K$. Then, for every $i \in \mathcal{N}$ and $S_{-i} \in \mathcal{A}^{\mathcal{N}\setminus\{i\}}$,

$$S_i \in \mathcal{B}_i(S_{-i}) \quad \Rightarrow \quad S_i(p) = K[p - p_i]_+ \tag{5}$$

for some $p_i \in [0, \hat{p}]$.

Proof. Consider a generic function $S_i \in \mathcal{A}_K$ and let p^* denote the equilibrium price such that $D(p^*) = \sum_{j=1}^n S_j(p^*)$. We shall prove the statement by construction, that is, we provide a strategy $\tilde{S}_i \in \mathcal{A}_K$ of the form in (5) that gives a greater or equal utility than S_i. More precisely, we construct $\tilde{S}_i$ of the form in (5) that passes through the same p^* as S_i, that is, $\tilde{S}_i(p) = K[p - p_i]_+$ with

$$p_i := p^* - \frac{S_i(p^*)}{K}\,.$$

The K-Lipschitzianity of S_i combined with the assumption that $S_i(0) = 0$ guarantees that $p^* - \frac{S_i(p^*)}{K} \geq 0$ and thus ensures the existence of $p_i \geq 0$. An example is shown in Fig. 2 for S_1 and S_2 as in Fig. 1 and $K = 3$. We remark that $\tilde{S}_i \in \mathcal{A}_K$.

We shall now prove that $S_i(p) \geq \tilde{S}_i(p)$ for all $p \in [0, p^*]$. First, notice that, for $p \in [0, p_i]$, the inequality is trivial since $S_i(p) \geq \tilde{S}_i(p) = 0$. Let $p \in (p_i, p^*]$. Then, the inequality is satisfied as

$$\begin{aligned} S_i(p^*) - S_i(p) = |S_i(p^*) - S_i(p)| &\overset{(1)}{\leq} K|p^* - p| = K(p^* - p) \\ &= K(p^* - p_i) - K(p - p_i) \\ &= \tilde{S}_i(p^*) - \tilde{S}_i(p) \\ &= S_i(p^*) - \tilde{S}_i(p) \end{aligned}$$

where (1) is guaranteed by the K-Lipschitz property of S_i.

To sum up, we observed that $S_i(p) \geq \tilde{S}_i(p)$ for all $p \in [0, p^*]$ and $S_i(p^*) = \tilde{S}_i(p^*)$. Therefore,

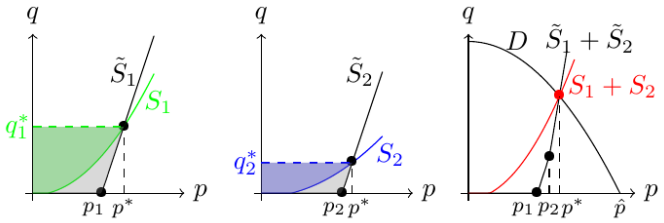

Fig. 2. Explanation of Lemma 1 (see Remark 2).

$$\begin{aligned} u_i(S_i, S_{-i}) &= p^* S_i(p^*) - \int_0^{p^*} S_i(p)dp - C_i(S_i(p^*)) \\ &\leq p^* \tilde{S}_i(p^*) - \int_0^{p^*} \tilde{S}_i(p)dp - C_i(\tilde{S}_i(p^*)) \\ &= u_i(\tilde{S}_i, S_{-i})\,. \end{aligned}$$

More precisely, it holds that, $\forall\, p \in [0, p^*]$,

$$\int_0^{p^*} S_i(p)\,\mathrm{d}p = \int_0^{p^*} \tilde{S}_i(p)\,\mathrm{d}p \quad \Leftrightarrow \quad S_i(p) = \tilde{S}_i(p)\,,$$

which implies that $u_i(S_j, S_i) = u_i(S_j, \tilde{S}_i)$ if and only if $S_i \equiv \tilde{S}_i$. This concludes the proof.

Remark 2. Lemma 1 is illustrated in Fig. 2. Consider two generic supply functions S_1 and S_2 as in Fig.1. Notice that when playing $\tilde{S}_1(p) = K[p - p_1]_+$ for p_1 as in figure, firm 1 receives a higher utility than the one obtained by playing S_1. Indeed, the remuneration increases (colored areas), while the equilibrium price does not change, thus yielding to the same sold quantity. The same happens for firm 2 when playing $\tilde{S}_2(p) = K[p - p_2]_+$ instead of S_2. Then, for any supply S_i, it is possible to construct another supply $\tilde{S}_i$ yielding to a higher utility. Thus, best responses must have such form.

Lemma 1 yields a fundamental simplification in our problem. Indeed, according to (5), every Nash equilibrium $\mathbf{S}^*$ necessarily exhibits the form

$$S_i^*(p) = K[p_i - p^*]_+$$

for suitable values $p_i \in [0, \hat{p}]$. In particular, this yields a complexity reduction from an infinite-dimensional strategy space to a finite-dimensional one. In order to find Nash equilibria, we can indeed further restrict the strategy space to considering just functions as in (5), which are parametrized by just one parameter, that is, $p_i \in [0, \hat{p}]$, for $i \in \mathcal{N}$. We can then define a restricted game $\mathcal{U}^r = (\mathcal{N}, \mathcal{A}^r, \{u_i^r\}_{i\in\mathcal{N}})$, where $\mathcal{A}^r = [0, \hat{p}]$ and the utilities are functions of p_i and $p_{-i} = \{p_j\}_{j\neq i}$, that is, for $i \in \mathcal{N}$,

$$\begin{aligned} u_i^r(p_i, p_{-i}) := &\, p^* K[p^* - p_i]_+ - \frac{(K[p^* - p_i]_+)^2}{2K} \\ &- C_i\left(K[p^* - p_i]_+\right) \\ \text{s.t.:} \quad K[p^* - p_i]_+ &= D(p^*) - \sum_{j\neq i} K[p^* - p_j]_+\,. \end{aligned} \tag{6}$$

We can now state the following corollary that formalizes what previously observed, which is a direct consequence of Lemma 1.

Corollary 1. The set of Nash equilibria of the PAB auction $\mathcal{U}$ coincides with the set of Nash equilibria of the restricted game $\mathcal{U}^r$.

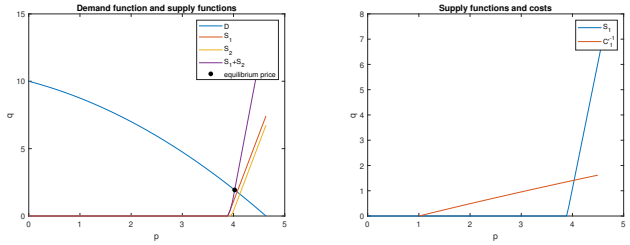

Fig. 3. The unique equilibrium **S** for Example 1

Therefore, it is sufficient to study the restricted game $\mathcal{U}^r$ to determine the entire set of Nash equilibria of the game $\mathcal{U}$. In the next section, we shall prove that the game $\mathcal{U}_r$ admits at least one Nash equilibrium.

3.2 Existence and characterization of Nash equilibria

In this section, we shall prove that the restricted game $\mathcal{U}_r$ admits at least one Nash equilibrium. According to Corollary 1, the Nash equilibrium of the restricted game $\mathcal{U}_r$ corresponds to a Nash equilibrium of the PAB auction $\mathcal{U}$ with strategy space $\mathcal{A}_K$. Therefore, the PAB auction $\mathcal{U}$ with strategy space $\mathcal{A}_K$ admits Nash equilibria that can be characterized in the same way.

Theorem 1. Consider the PAB action with strategy space $\mathcal{A} = \mathcal{A}_K$ as in (4). Then, there exists at least one Nash equilibrium **S** of the form $S_i(p) = K[p - p_i]_+$ for $i \in \{1, 2\}$ and $p_i \in [0, \hat{p}]$.

To prove the statement, we show that the utility function in (6) is quasi-concave in p_i. Quasi-concavity is proved using the fact that the utility is concave in the stationary points. This property, combined with the compactness and convexity of $[0, \hat{p}]$ and the continuity of u_i^r, permits to apply Proposition 20.3 in Osborne and Rubinstein (1994) (pp. 19-20) which guarantees existence of pure-strategy Nash equilibria.

Let us conclude with an example.

Example 1. Let $K = 10$, $D(p) = -\frac{1}{4}p^2 - p + 10$, $C_1(q) = \frac{1}{30}q^3 + q^2 + q$ and $C_2(q) = \frac{1}{30}q^3 + \frac{3}{2}q^2 + 2q$. Then, there exists a unique equilibrium $S = (S_1, S_2)$ where

$$S_1(p) = 10[p - 3.89]_+$$
$$S_2(p) = 10[p - 3.96]_+$$

as shown in Fig. 3

4. CONCLUSION

We considered a supply function equilibrium model with pay-as-bid remuneration and asymmetric firms. Existence of an equilibrium is ensured if we restrict the strategy space to K-Lipschitz supply functions. In such setting, a characterization of Nash equilibria is given.

Further work comprehends conditions for uniqueness of Nash equilibria. Also, we intend to include uncertainty in our model. Motivated by the current structure of electricity markets, we aim to study the concatenation of a uniform-price auction and a pay-as-bid one, modeled as a two-stage game.

Abstract: We review Linear-Matrix-Inequality criteria for various notions of stability and performance for discrete-time autonomous (state/output) linear systems. Here we discuss analogues of all these ideas for a certain class of time-varying discrete-time, state/output linear systems, where output-stability requires that the Z-transform of the output sequence be in a weighted Bergman space over the unit disk rather than in the usual Hardy space over the unit disk.

Keywords: stability, time-varying system, linear matrix inequality, weighted Bergman space

1. INTRODUCTION

Here $\mathcal{X}$ (the state space) and $\mathcal{Y}$ (the output space) are Hilbert spaces and we suppose that we are given an output pair $(C, A) \in \mathcal{L}(\mathcal{X}, \mathcal{Y}) \times \mathcal{L}(\mathcal{X})$ generating a state/output linear system

$$\Sigma = \Sigma_{C,A}: \begin{cases} x(j+1) &= Ax(j) \\ y(j) &= Cx(j), \end{cases} \quad j \in \mathbf{Z}_+,$$

there are various notions of stability:

(1) Σ is *internally stable*:

$$x(0) \text{ arbitrary } \Rightarrow \lim_{j\to\infty} \|x(j)\| = 0,$$

i.e., A is *strongly stable:* $\lim_{j\to\infty} \|A^j x_0\| = 0$ for each $x_0 \in \mathcal{X}$.

(2) Σ is *internally exponentially stable*, i.e.,

$$\exists\, \rho < 1,\ M < \infty \text{ so that } \|x(j)\| \le M\rho^j \|x(0)\|.$$

Equivalent conditions are:

(2a) A is similar to a strict contraction operator: $\exists$ an invertible X on $\mathcal{X}$ so that $\|X^{-1}AX\| < 1$.

(2b) A has spectral radius strictly less than 1:

$$\rho_{\rm sp}(A) := \lim_{j\to\infty} \|A^j\|^{\frac{1}{j}} < 1.$$

(2c) The inverse linear pencil $L(\lambda)^{-1} = (I - \lambda A)^{-1}$ exists and is uniformly bounded on the closed unit disk.

(3) Σ is *output stable*, i.e.,

$$x(0) \text{ arbitrary} \Rightarrow \{y(j)\}_{j\ge 0} \in \ell^2_{\mathcal{Y}}.$$

We note that the state/output-signal map is given explicitly by the *observability operator* $\mathcal{O}^{\circ}_{C,A}: \operatorname{col}[CA^j]_{j\ge 0}$ being bounded as an operator from $\mathcal{X}$ to $\ell^2_{\mathcal{Y}}$. We prefer to work with the Z-transformed version of the observability operator $\mathcal{O}^{\circ}_{C,A}$ given simply by

$$\mathcal{O}_{C,A}: x \mapsto \sum_{j=0}^{\infty} (CA^j x)\lambda^j.$$

Conditions equivalent to output-stability of the output pair (C, A) are:

(3a) The observability operator $\mathcal{O}_{C,A}$ is bounded as an operator from $\mathcal{X}$ to $H^2_{\mathcal{Y}}$.

(3b) The observability gramian $\mathcal{G}_{C,A} = \mathcal{O}^*_{C,A}\mathcal{O}_{C,A}$ exists as a bounded operator on $\mathcal{X}$, and is given by the strongly convergent infinite series

$$\mathcal{G}_{C,A} = \sum_{j=0}^{\infty} A^{*j} C^* C A^j.$$

While there seems to be no known Linear-Matrix-Inequality (LMI) criterion for the property (1) (except in the finite-dimensional case), there are LMI criteria for the notions (2), (3):

(2) Exponential stability holds if and only if there is a bounded positive definite $H \succ 0$ such that

$$H - A^* H A \succ 0. \tag{1}$$

(3) Output stability holds if and only if there is a bounded positive semi-definite $H \succeq 0$ on $\mathcal{X}$ satisfying the Stein inequality

$$H - A^* H A \succeq C^* C. \tag{2}$$

Specializing to the special case where $\mathcal{X} = \mathcal{Y}$ and $C = I_{\mathcal{X}}$, we arrive at the following statement: *Given $A \in \mathcal{L}(\mathcal{X})$, A has the property that $\sum_{j=0}^{\infty} \|A^j x\|^2 < \infty$ for any $x_0 \in \mathcal{X}$ if and only if $\exists\ H \succeq 0$ so that $H - A^* H A \succeq I_{\mathcal{X}}$.* Since the right-hand side of this last equation is strictly positive definite, we see that its solution H must also be strictly positive definite. Then a rescaling of this latter inequality finally gets us back to (1). We conclude that *exponential stability* for the state operator A is equivalent to output stability for the output pair $(I_{\mathcal{X}}, A)$, a fact presumably which one can also see directly.

Whether or not A is strongly stable (the *internal stability* property (1) above) plays a key role in the finer structure of the solution set for inequality (2), as illustrated in the following result.

Theorem 1. Suppose that the output pair (C, A) is output stable, so the inequality (2) has a positive semidefinite solution H. Then:

(1) The observability gramian $H = \mathcal{G}_{C,A}$ is the minimal positive semidefinite solution of (2) and satisfies (2) with equality:
$$H - A^*HA = C^*C. \tag{3}$$
(2) If A is strongly stable, then $H = \mathcal{G}_{C,A}$ is the unique solution of the equality (3).
(3) Suppose that there exists $H' \succ 0$ such that $H' - A^*H'A \succ 0$ (equivalently, A is similar to a strict contraction). Then conversely, if $H = \mathcal{G}_{C,A}$ is the unique solution of (3), then A is strongly stable.

Our goal here is to discuss recent work of the authors (see Ball-Bolotnikov (2013) and the more comprehensive treatment Ball-Bolotnikov (2022)) on a certain class of time-varying discrete-time state/output linear systems. In the definition of output stability, rather than requiring that the Z-transform $\widehat{y}(\lambda) = \sum_{j=0}^{\infty} y_j\lambda^j$ of the output sequence $\{y(j)\}_{j\geq 0}$ be in the Hardy space H^2 (i.e., that $\sum_{j=0}^{\infty}\|y(j)\|^2 < \infty$), we require that $\widehat{y}(\lambda)$ be in a prescribed weighted Bergman space over the unit disk. Our motivation comes from operator theory (the study of the model theory for various classes of hypercontraction operators on a Hilbert space), but related problems with a more engineering motivation have been studied in a continuous-time setting in the work of Partington and collaborators (see e.g. Jacob-et-al (2018)).

2. WEIGHTED BERGMAN SPACES

We note that the Z-transform of the space $\ell^2_{\mathcal{Y}}$ which has a prominent role in the discussion of the previous section is the Hardy space $H^2_{\mathcal{Y}}$

$$H^2_{\mathcal{Y}} = \{f(\lambda) = \sum_{j=0}^{\infty} f_j\lambda^j : \sum_{j=0}^{\infty}\|f_j\|^2_{\mathcal{Y}} < \infty\}.$$

The classical Bergman space $\mathcal{A}_2$ (here taken with values in the coefficient Hilbert space $\mathcal{Y}$) consists of holomorphic $\mathcal{Y}$-valued functions on the unit disk which are square-integrable with respect to area measure:

$$\mathcal{A}_{2,\mathcal{Y}} = \{f(\lambda) = \sum_{j=0}^{\infty} f_j\lambda^j : \int_{\mathbf{D}}\|f(\lambda)\|^2_{\mathcal{Y}}dA(\lambda) < \infty\}$$

where the area integral can also be expressed in terms of Taylor-series coefficients:

$$\|f\|^2_{\mathcal{A}_{2,\mathcal{Y}}} = \sum_{j=0}^{\infty}\frac{1}{j+1}\|f_j\|^2_{\mathcal{Y}}$$

More generally, for any natural number $n \geq 2$ we may consider the space $\mathcal{A}_{n,\mathcal{Y}}$ consisting of $\mathcal{Y}$-valued holomorphic functions on $\mathbf{D}$ having finite weighted area integral

$$\|f\|^2_{\mathcal{A}_{n,\mathcal{Y}}} = \frac{1}{\pi}\int_{\mathbf{D}}\|f(\lambda)\|^2_{\mathcal{Y}}(n-1)(1-|\lambda|^2)^{n-2}dA(\lambda)$$

or in terms of Taylor coefficients

$$\|f\|^2_{\mathcal{A}_{n,\mathcal{Y}}} = \sum_{j=0}^{\infty}\mu_{n,j}\|f_j\|^2_{\mathcal{Y}}$$

where $\mu_{n,j} = \frac{j!}{n(n+1)\cdots(n+j+1)}$ are reciprocal binomial coefficients. All these spaces embed into a family of spaces with continuous index ρ restricted only by $1 < \rho < \infty$ where

$$\|f\|^2_{\mathcal{A}_\rho} = \frac{1}{\pi}\int_{\mathbf{D}}\|f(\lambda)\|^2_{\mathcal{Y}}dA_\rho(\lambda)$$

and $dA_\rho(\lambda) = (\rho-1)(1-|\lambda|^2)^{\rho-2}dA(\lambda)$ or equivalently by

$$\|f\|^2_{\mathcal{A}_\rho} = \sum_{j=0}^{\infty}\mu_{\rho,j}\|f_j\|^2_{\mathcal{Y}}$$

with $\mu_{\rho,j} = \frac{j!}{\rho(\rho+1)\cdots(\rho+j-1)} = \frac{j!\Gamma(\rho)}{\Gamma(\rho+j)}$ where Γ is the usual gamma function meromorphic on the whole complex plane $\mathbf{C}$ with simple poles at the negative integers $-1, -2, \ldots$ which satisfies the interpolation conditions $\Gamma(n) = (n-1)!$. Still more generally, following Ball-Bolotnikov (2013), we introduce *admissible weights* $\omega = \{\omega_j\}_{j\geq 0}$ satisfying admissibility conditions

$$\omega_0 = 1, \quad 1 \leq \frac{\omega_j}{\omega_{j+1}} \leq M \text{ for all } j \text{ for some } M < \infty. \tag{4}$$

A useful consequence of (4) is that the sequence $\{\omega_j^{-1}\}_{j\geq 0}$ is nondecreasing:

$$1 = \omega_0^{-1} \leq \omega_1^{-1} \leq \cdots \leq \omega_j^{-1} \leq \omega_{j+1}^{-1} \leq \cdots. \tag{5}$$

We then define a generalized weighted Bergman space $\mathcal{A}_{\omega,\mathcal{Y}}$ to consist of all $\mathcal{Y}$-valued functions on $\mathbf{D}$ with finite $\mathcal{A}_{\omega,\mathcal{Y}}$-norm, where

$$\|\sum_{j=0}^{\infty} f_j\lambda^j\|^2_{\mathcal{A}_{\omega,\mathcal{Y}}} = \sum_{j=0}^{\infty}\omega_j\|f_j\|^2_{\mathcal{Y}}.$$

One can show that $\mathcal{A}_{\omega,\mathcal{Y}}$ is a reproducing kernel Hilbert space with reproducing kernel of the form

$$K_{\mathcal{A}_{\omega,\mathcal{Y}}}(\lambda,\eta) = k_\omega(\lambda,\eta)I_{\mathcal{Y}}$$

where the scalar-valued kernel k_ω is given by

$$k_\omega(\lambda,\eta) = \sum_{j=0}^{\infty}\omega_j^{-1}\lambda^j\overline{\eta}^j.$$

We assume that $k_\omega(\lambda,\eta) \neq 0$ for λ, η in the unit disk $\mathbf{D}$. We can then expand the inverse function $\frac{1}{k_\omega}$ into a series of the form

$$\frac{1}{k_\omega}(\lambda,\eta) = \sum_{j=0}^{\infty}c_j\lambda^j\overline{\eta}^j.$$

We shall also occasionally need the *shifted kernel function*: for $\kappa = 1, 2, \ldots$, we define

$$k_\omega^{(\kappa)}(\lambda,\eta) = \sum_{j=0}^{\infty}\omega_{j+\kappa}^{-1}\lambda^j\overline{\eta}^j.$$

We shall need the additional hypothesis concerning the coefficients $\{c_j\}_{j\geq 0}$ above:

$$\sum_{j=0}^{\infty}|c_j| < \infty. \tag{6}$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Let us also introduce a quick and dirty functional calculus for functions of the form $f(\lambda,\eta)=\sum_{j=0}^{\infty} f_j\lambda^j\overline{\eta}^j$. For S,T,H operators on $\mathcal{X}$, we define

$$f(S,T)[H]=\sum_{j=0}^{\infty} f_j S^j H T^{*j}\in\mathcal{L}(\mathcal{X}) \tag{7}$$

whenever the series converges. We shall apply this functional calculus with f equal to the following functions:

$$f=\frac{1}{k_\omega},\quad f=\frac{k_\omega^{(\kappa)}}{k_\omega}\text{ for }\kappa=1,2,\dots. \tag{8}$$

3. NOTIONS OF WEIGHTED STABILITY

Associated with an output pair $(C,A)\in\mathcal{L}(\mathcal{X},\mathcal{Y})\times\mathcal{L}(\mathcal{X})$ is the weighted state/output linear system

$$\Sigma_\omega=\Sigma_{\omega,C,A}\colon\begin{cases} x(j+1) &= \dfrac{\omega_j}{\omega_{j+1}}Ax(j),\\ y(j) &= Cx(j).\end{cases}$$

Solving the recursions leads to

$$\begin{aligned} x(j) &= \omega_j^{-1}A^jx(0),\\ y(j) &= \omega_j^{-1}CA^jx(0).\end{aligned}$$

There are various possibilities for notions of stability for such an autonomous time-varying system but it is not clear which ones are useful and analyzable. For example one might formulate *internal stability* of Σ_ρ (or ω-strong stability of the operator A) to mean that $\lim_{j\to\infty}x(j)=0$ whenever $\{x(j)\}_{j\ge0}$ is a state trajectory of Σ_ω, or equivalently, *A is ω-strongly stable* in the sense that $\lim_{j\to\infty}\omega_j^{-1}A^jx_0=0$ for all $x_0\in\mathcal{X}$, but we shall introduce below another notion of *ω-strong stability* for A which appears to be more useful. We focus here on:

(2-ω) Σ_ω is *internally ω-exponentially stable*, i.e.,

$$\exists\rho<1,\ M<\infty\text{ so that }\|x(j)\|\le M\rho^j\|x(0)\|,$$

or A is *ω-exponentially stable:* $\exists\rho<1$, $M<\infty$ so that

$$\omega_j^{-1}\|A^jx_0\|\le M\rho^j\|x_0\|\,\forall x_0\in\mathcal{X}.$$

An equivalent condition is:

(2b-ω) A has ω-spectral radius less than 1, i.e.,

$$\rho_{\omega,\mathrm{sp}}(A):=\limsup_{j\to\infty}\left\{\omega_j^{-\frac{1}{j}}\|A^j\|^{\frac{1}{j}}\right\}<1.$$

(3-ω) Σ_ω is *ω-output stable,* i.e.,

$$x(0)\text{ arbitrary }\Rightarrow\sum_{j=0}^{\infty}y(j)\lambda^j\in H^2_\omega.$$

Equivalent conditions are:

(3a-ω) the *ω-observability operator*

$$\begin{aligned}\mathcal{O}_{\omega,C,A}:\ x\mapsto C\big(\sum_{j=0}^{\infty}\omega_j^{-1}\lambda^jA^j\big)x\\ = Ck_\omega(\lambda I_{\mathcal{X}},A^*)x\end{aligned}$$

maps $\mathcal{X}$ boundedly into $H^2_{\omega,\mathcal{Y}}$.

(3b-ω) The weighted observability gramian

$$\mathcal{G}_{\omega,C,A}=\mathcal{O}^*_{\omega,C,A}\mathcal{O}_{\omega,C,A}$$

is a bounded operator on $\mathcal{X}$.

We conjecture: $A\in\mathcal{L}(\mathcal{X})$ is *ω-exponentially stable* if and only if the output pair $(C,I_{\mathcal{X}})$ is ω-output stable.

The LMI criterion for ω-output stability is as follows.

Theorem 2. The output pair $(C,A)\in\mathcal{L}(\mathcal{X},\mathcal{Y})\times\mathcal{L}(\mathcal{X})$ is ω-output stable if and only if there exists $H\in\mathcal{L}(\mathcal{X})$ so that

$$H\succeq A^*HA\succeq0, \tag{9}$$

$$\frac{k_\omega^{(\kappa)}}{k_\omega}(A^*,A)[H]\succeq0\text{ for }\kappa=1,2,\dots,\text{ and} \tag{10}$$

$$\frac{1}{k_\omega}(A^*,A^*)[H]\succeq C^*C. \tag{11}$$

Note that replacing C^*C with $I_{\mathcal{X}}$ gives a criterion for ω-exponential stability for A, assuming the validity of the conjecture just preceding Theorem 2.

The statement of the analogue of Theorem 1 requires a strengthening of the notion of *strong stability* to a notion of *ω-strong stability: Given an operator A on the Hilbert space $\mathcal{X}$, we say that A is* ω-strongly stable *if*

$$\lim_{N\to\infty}A^{*N}\left(\frac{k_\omega^{(N)}}{k_\omega}(A^*,A^*)[I_{\mathcal{X}}]\right)A^N=0$$

in the strong operator topology.

Then we have the following result.

Theorem 3. (See Section 3 in Ball-Bolotnikov (2013).) Suppose that (C,A) is an ω-stable output pair.

(1) Then $H=\mathcal{G}_{\omega,C,A}$ is the minimal positive semidefinite solution of inequality (11) and itself satisfies this inequality with equality:
$$\frac{1}{k_\omega}(A^*,A^*)[H]=C^*C\text{ for }H=\mathcal{G}_{\omega,C,A}. \tag{12}$$
(2) Suppose that $H=I_{\mathcal{X}}$ satisfies all the inequalities (9), (10), (11). Then $\mathcal{G}_{\omega,C,A}\preceq I_{\mathcal{X}}$, i.e., the ω-observability operator $\mathcal{O}_{\omega,C,A}$ is a contraction.
(3) The ω-observability gramian $\mathcal{G}_{\omega,C,A}$ is equal to the identity $I_{\mathcal{X}}$ (i.e., the ω-observability operator $\mathcal{O}_{\omega,C,A}$ is isometric) if and only if (i) (C,A) satisfies inequalities (9), (10) and equality (12), and (ii) A is ω-strongly stable.

Remark. When we specialize the general admissible weight ω to one of the standard weights μ_n $(n=1,2,\dots)$, Theorems 2 and 3 simplify considerably:

- The infinite set of inequalities (10) holds automatically and one is left only with the two inequalities (9), (11).
- μ_n-strong stability is the same as strong stability.
- One can add a uniqueness statement to item (1) in Theorem 3: *for the case where $\omega=\mu_n$ for some $n=2,3,\dots$, $\mathcal{G}_{\mu_n,C,A}$ is the unique solution to (11) if and only if A is strongly stable.*

When (9) and (11) hold with $H=I_{\mathcal{X}}$ and $C=0$, then A is said to be an *n-hypercontraction* in the operator theory literature (see e.g. Agler (1985)). We expect that recent operator-theory work of Olofsson (2015) should adapt to provide a sharpening of Theorems 2 and 3.

Abstract: The foundations of classical Algebraic Geometry and Real Algebraic Geometry are the Nullstellensatz and Positivstellensatz. Over the last two decades the basic analogous theorems for matrix and operator theory (noncommutative variables) have emerged. This paper concerns commuting operator strategies for nonlocal games, recalls NC Nullstellensatz which are helpful, extends these, and applies them to a very broad collection of games.
The main results of this procedure are two characterizations, based on Nullstellensatz, which apply to games with perfect commuting operator strategies. The first applies to all games and reduces the question of whether or not a game has a perfect commuting operator strategy to a question involving left ideals and sums of squares. Previously, Paulsen and others translated the study of perfect synchronous games to problems entirely involving a $*$-algebra. The characterization we present is analogous, but works for all games. The second characterization is based on a new Nullstellensatz we derive in this paper. It applies to a class of games we call torically determined games, special cases of which are XOR and linear system games. For these games we show the question of whether or not a game has a perfect commuting operator strategy reduces to instances of the subgroup membership problem.

Keywords: Nonlocal Games, Operator Algebras, Noncommutative Algebraic Geometry

1. EXTENDED ABSTRACT

A nonlocal game describes a test performed between a verifier and k players, in which the verifier tests the players' ability to produce correlated responses without communicating. In a round of the game the verifier sends questions to the players and the players return responses to the verifier. The list of questions and responses is then scored according to a function known by both the verifier and the players before the game began. By convention, the score achieved lies in the interval $[0, 1]$. The players cooperate to try and achieve the highest possible score, with the challenge that the players can't communicate while the game is in progress and so don't know the questions sent to other players.

The optimal score the players can achieve on a nonlocal game $\mathcal{G}$ depends on the resources the players share. If the players share only classical randomness the optimal score they can achieve in expectation is called the the classical value of the game, denoted $\omega(\mathcal{G})$. If players share an arbitrary state in a (possibly infinite dimensional) Hilbert space and can make commuting measurements on it the optimal score they can achieve is called the commuting operator value of the game, denoted $\omega^*_{\rm co}(\mathcal{G})$. The supremum value achievable by players who make commuting measurements on a state in a finite dimensional entangled space is called the quantum value, denoted $\omega^*_{\rm q}(\mathcal{G})$. These three values can all differ, though the inequalities $\omega(\mathcal{G}) \leq \omega^*_{\rm q}(\mathcal{G}) \leq \omega^*_{\rm co}(\mathcal{G})$ are always satisfied.

Starting roughly in this century the classical subject of real algebraic geometry has been extended to matrix and operator (noncommutative) variables. Here inequalities and equalities are explained by being equivalent to algebraic formulas, often involving Sums of Squares (**SOS**). These go under the names of **Positivstellensatz** for inequalities and **Nullstellensatz** for equations. Of course finding quantum strategies for games leads to many such noncommutative (**NC**) inequalities and equalities.

In this paper we describe how the well developed NC real algebraic geometry theory applies and integrates with nonlocal games and commuting operator strategies for them. We show a connection between NC Nullstellensatz and whether or not a nonlocal game has a perfect commuting operator solution (i.e., $\omega^*_{\rm co}(\mathcal{G}) = 1$). This connection gives a new algebraic characterization which applies to all nonlocal games with commuting operator value exactly equal to one. This characterization provides a unified algebraic framework through which several previous results concerning the commuting operator value of nonlocal games can be understood. For a large class of games it also reduces the question of whether or not a game has perfect commuting operator value to an instance of the subgroup member-

ship problem, providing a potential starting point for the investigation of several yet-to-be studied families of games.

For context, Positivstellensätze have long played a major role in the study of nonlocal games in that they are behind the standard Navascués et al. (2008); Doherty et al. (2008) upper bound on the commuting operator value of a game. Underlying this bound is one of the earliest NC Positivstellensätze, Helton and McCullough (2004). This paper turns its attention to developing the analogous NC real algebraic geometry which bears on perfect games.

In the remainder of this abstract we introduce some new terminology, review some previous results concerning the commuting operator value of nonlocal games, and then give formal statements of some of our main results.

1.1 Algebraic Description of Commuting-Operator Strategies

A commuting operator strategy for a nonlocal game is a description of how players can use commuting operator measurements to map questions sent by the verifier to responses. Formally, a (commuting operator) strategy can be specified by a Hilbert space $\mathcal{H}$, a state $\psi \in \mathcal{H}$ which is shared by the players and projectors $\{E(\alpha)_a^i\}$ acting on $\mathcal{H}$, where α ranges over all players, i ranges over all questions, and a ranges over all responses. The projector $E(\alpha)_a^i$ can be read as "the projector corresponding to player α giving response a to question i".

Because the Hilbert space $\mathcal{H}$ on which they act is arbitrary, it is difficult to reason about the $E(\alpha)_a^i$ directly. Instead we introduce the universal game algebra $\mathscr{U}$, a $*$-algebra generated by variables $e(\alpha)_a^i$ which satisfy the same relations as the projectors $E(\alpha)_a^i$, for example, that $e(\alpha)_a^i$ and $e(\beta)_b^j$ commute for any $\alpha \neq \beta$.[1] Commuting operator strategies can then be specified by tuples (π, ψ), consisting of a $*$-representation π mapping $\mathscr{U}$ to bounded operators on a Hilbert space $\mathcal{H}$, along with a state $\psi \in \mathcal{H}$. When specified in this way, it is understood that projectors $E(\alpha)_a^i$ are given by $\pi(e(\alpha)_a^i)$ and that ψ gives the state shared by the players.

1.2 Other Characterizations of Perfect Commuting-Operator Strategies

Several other papers have considered the problem of deciding whether or not a game has a perfect commuting operator strategy and given criteria which determine the existence of perfect commuting operator strategies for specific families of nonlocal games. We review some of those families of games and the associated characterizations below.

- Linear systems games are two player games based around system of m linear equations on n variables. In Cleve et al. (2017) it was shown that deciding existence of a perfect commuting operator strategy for a binary linear systems game was equivalent to solving an instance of the word problem on a group called the solution group of the game.
- XOR games are k player games which, similarly to linear system games, test satisfiability of a system of m binary equations on kn variables. In Watts and Helton (2020) it was shown that deciding the existence of a perfect commuting operator strategy for an XOR game was equivalent to solving an instance of the subgroup membership problem on a group called the game group.
- Synchronous games are two player nonlocal games which include "consistency-checks", where Alice and Bob are sent the same question and win iff they send the same response. Other than these consistency checks, the questions and winning responses involved in a synchronous game are arbitrary. In Paulsen et al. (2016) it was shown that there was a perfect commuting operator strategy for a coloring game iff a $*$-algebra associated with a single player's operators could be represented into a C^*-algebra with a faithful trace. In Helton et al. (2017) and Kim et al. (2018) this was generalized to synchronous games.

1.3 Our Results

The main results of this paper are two theorems giving algebraic characterizations of games with perfect commuting operator strategies.

A key concept introduced on the way to proving these theorems is the notion of a game being determined by a set of elements $\mathcal{F} \subseteq \mathscr{U}$. Formally we say a game $\mathcal{G}$ is determined by a set of elements $\mathcal{F}$ if, for any commuting operator strategy (π, ψ), we have that (π, ψ) is a perfect commuting operator strategy for $\mathcal{G}$ iff $\pi(f)\psi = 0$ for all $f \in \mathcal{F}$. We also note that any game $\mathcal{G}$ is naturally determined by two sets of elements. The first, $\mathcal{N}$, consists of elements corresponding to projectors onto responses which obtain a score less than 1 on questions asked by the verifier, while the second, $\mathcal{Y}$, consists of elements $y-1$ with each element y corresponding to projectors onto responses which obtain a score of exactly 1.

Our first major theorem follows from combining the notion of sets of elements which determine a game with a result in noncommutative algebraic geometry known as a Nullstellensatz. To state the result formally, let $\mathfrak{L}(\mathcal{X})$ denote the left ideal of $\mathscr{U}$ generated by $\mathcal{X}$ for any set of elements $\mathcal{X} \subseteq \mathscr{U}$ and $\mathrm{SOS}_{\mathscr{U}}$ denote sums of squares in the algebra $\mathscr{U}$. Then the following result holds:

Theorem 1. For a nonlocal game $\mathcal{G}$ determined by a set $\mathcal{F} \subseteq \mathscr{U}$ the following are equivalent:

(i) $\mathcal{G}$ has a perfect commuting operator strategy;
(ii) $-1 \notin \mathfrak{L}(\mathcal{F}) + \mathfrak{L}(\mathcal{F})^* + \mathrm{SOS}_{\mathscr{U}}$.

Theorem 1, combined with the natural determining sets $\mathcal{N}$ and $\mathcal{Y}$, gives a fully algebraic characterization of nonlocal games with perfect commuting operator strategies. This characterization is analogous to the characterization of synchronous games given in Helton et al. (2017), but works for all games. For the special case of synchronous games we show that the characterizations of Theorem 1 and Helton et al. (2017) are equivalent.

The second major theorem focuses on a general class of games on which Theorem 1 can be simplified further. A

[1] The $*$-algebra $\mathscr{U}$ is isomorphic to a group algebra and has appeared before in other contexts. For example, in Lupini et al. (2020) an algebra closely related to $\mathscr{U}$ was denoted $\mathcal{A}(X, A)$.

game $\mathcal{G}$ is called a torically determined game if there exists a group G with $\mathscr{U} \cong \mathbb{C}[G]$ and $\mathcal{G}$ is determined by a set of elements

$$\mathcal{F} = \{\beta_i g_i - 1\} \tag{1}$$

with each $\beta_i \in \mathbb{C}$ and $g_i \in G$. We call the elements $\beta_i g_i$ clauses of $\mathcal{F}$, and let $\mathscr{H} = \{\beta_i g_i\}$ be the set of all the clauses of $\mathcal{F}$. We give the following characterization of torically determined games with perfect commuting operator strategies:

Theorem 2. Let $\mathcal{G}$ be a game torically determined by a set of elements $\mathcal{F}$ with clauses $\mathscr{H}$. Then $\mathcal{G}$ has a perfect commuting operator strategy iff the following equivalent criteria are satisfied:

(i) $-1 \notin \mathfrak{L}(\mathcal{F}) + \mathfrak{L}(\mathcal{F})^*$;
(ii) The subgroup H of $\mathscr{U}$ generated by $\mathscr{H} \cup \mathscr{H}^*$ meets $\mathbb{C}$ only in 1.

Condition (i) makes it clear Theorem 2 can be viewed as a version of Theorem 1 for torically determined games which holds without the SOS term. Additionally, condition (ii) reduces the characterization of perfect commuting operator strategies in terms of $*$-algebras given in Theorem 1 to one entirerly in terms of groups. In the paper we show that both linear systems games and XOR games are torically determined games, and that Theorem 2 recovers the algebraic characterizations of these games given in Cleve et al. (2017); Watts and Helton (2020) respectively. We also show that Theorem 2 lets us extend the algebraic characterization of both XOR and binary linear systems games to more general games based on linear equations Mod r for any integer r. [2]

Both Theorems 1 and 2 allow new algorithms for identifying nonlocal games with perfect commuting operator strategies. We will discuss one such algorithm, based on Gröbner bases, and give some sample applications. We note that, unlike the upper bounds coming from the ncSoS hierarchy, these Gröbner bases algorithms can both prove a game has commuting operator value strictly less than 1 and identify some games with commuting operator value exactly equal to 1. [3]

Abstract:
Input-to-state stability is characterised by admissibility for linear systems, governed by strongly continuous semigroups. Yet, in some applications semigroups may fail to be strongly continuous with respect to the norm of the underlying Banach space. Typical examples are given by shift-semigroups and the Gauß–Weierstraß semigroup on spaces of bounded continuous functions as well as dual semigroups. This requires a suitable theory for this general setting within the framework of so-called bi-continuous semigroups, including proper admissibility concepts. Our contribution mainly focuses on non-trivial variants of results from the classical case. For instance, the recently shown fact that the generator of a strongly continuous semigroup is only admissible if it is a bounded operator, fails for bi-continuous semigroups.

Keywords: input-to-state stability, semigroups of operators, bi-continuous semigroup, admissibility, maximal regularity

1. INTRODUCTION

Input-to-state stability (ISS) is a notion well-understood for control systems modelled by ordinary differential equations, or delay equations. Its infinite-dimensional counterpart, more precisely, in the context of dynamics governed by partial differential equations, is less understood, despite intensive research efforts in the recent 15 years. The so-far existing theory as well as a listing of remaining challenges, such as for instance the existence of ISS Lyapunov functions, is nicely summarized in the recent survey Mironchenko and Prieur (2020), also see Dashkovskiy and Mironchenko (2013), Mironchenko and Wirth (2018), and Karafyllis and Krstic (2019). Clearly, difficulties in the infinite-dimensional situation arise due to the many facets of well-posedness for partial differential equations, but also because of the presence of control acting through the boundary in contrast to distributed controls.

Although ISS has proved successful as a concept for large classes of nonlinear systems, already in comparably simple finite-dimensional examples, one cannot expect standard ISS estimates of the form

$$\|x(t)\|_X \leq \beta(\|x(0)\|,t) + \gamma(\|u\|_{\infty,[0,t]}), \qquad t>0, \quad (1)$$

for inputs $u \in L^\infty(0,\infty;U)$ and corresponding states $x(t) \in X$. Here X and U denote Banach spaces, $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}$, where $\mathcal{KL}, \mathcal{K}$ refer to standard Lyapunov classes. The mapping $(u, x(0)) \mapsto x(t))$ can be viewed as solution operator for given (boundary) inhomogeneity u and initial values $x(0)$. The notion of integral ISS on the other hand describes estimates of the form

$$\|x(t)\|_X \leq \beta(\|x(0)\|,t) + \gamma\Big(\int_0^t \mu(\|u(s)\|_U)\mathrm{d}s\Big), \ t>0, \ (2)$$

with $\gamma, \mu \in \mathcal{K}$. While these notions are rather trivially seen to be equivalent for finite-dimensional linear systems $\dot{x}(t) = Ax(t) + Bu(t)$, the situation in general infinite dimensions remains a notorious open question.

More precisely, if A generates a strongly continuous semigroup $(T(t))_{t\geq 0}$ on the Banach space X, and $B \in \mathcal{L}(U, X_{-1})$, with X_{-1} being the completion of X with respect to $(\lambda I - A)^{-1}$ for some λ in the resolvent set $\rho(A)$ of A, then we ask whether the (mild) solution

$$x(t) = T(t)x_0 + \int_0^t T_{-1}(t-s)Bu(s)\mathrm{d}s, \qquad (3)$$

to the problem

$$\dot{x} = Ax + Bu, \qquad x(0) = x_0, \qquad (4)$$

with $x_0 \in X$, satisfies the ISS estimate (1) or (2), respectively. Here $T_{-1}(t)$ denotes the extension of $T(t)$ to the space X_{-1} which exists uniquely as a bounded operator. Note that here the notion of (integral) ISS in particular includes the property that the solution $x(t)$ lies in the space X, which is non-trivial as a-priori $x(t)$ only lies in X_{-1}, which is also the space on which (4) has to be understood. In fact, if $x(t)$ lies in X for all given input functions from the space $L^\infty(0,\infty;U)$, inequality (1) follows automatically. On the other hand, it is not hard to see that integral ISS always implies ISS for linear systems of the above form, which leaves us with the open question

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Does ISS of a linear system imply integral ISS?

Although several situations, under additional assumptions on the strongly continuous semigroup and the spaces X and U, see e.g. Jacob et al. (2018, 2019), are known, this question in its full generality remains open until today. Recently, in Jacob et al. (2022), an example was provided showing the answer is no, if only continuous input functions are considered. This example is pathologic in the way that $B = A_{-1}$, which can be interpreted as the "worst input operator" one may choose. Still, the question whether L^∞-ISS implies L^∞-integral ISS remains untouched by the example. In the same paper, a relation between ISS (or admissibility respectively) and maximal regularity for abstract evolution equations was revealed. More precisely, it was shown that ISS of $B = A_{-1}$ is equivalent to maximal regularity of A, if both notions are considered with respect to the continuous X-valued functions.

This contribution aims to pave the way for a corresponding theory if the strong continuity of the semigroup is dropped. Moreover, we want to study the above central question on ISS for this more general class as well as the relation to maximal regularity with respect to continuous and essentially bounded functions. In particular, we want to explain why the definitions of ISS respectively admissibility and maximal regularity depend on the considered function classes in a subtle way.

1.1 A motivating example

A first attempt to answer the above mentioned question on ISS in the negative is given by the following example, which is standard in semigroup theory.

Consider the space $X = \ell^\infty$ of bounded, complex-valued sequences $(a_n)_{n\in\mathbb{N}}$ with the supremum norm $\|\cdot\|_\infty$. The operators defined by

$$T(t)(x_n)_{n\in\mathbb{N}} := (\mathrm{e}^{-nt}x_n)_{n\in\mathbb{N}}, \qquad t \geq 0,$$

clearly define a semigroup of bounded linear operators on X, which fails to be strongly continuous. As the dual semigroup of a strongly continuous semigroup on ℓ^1, it is clear that $(T(t))_{t\geq 0}$ is bi-continuous with respect to the weak* topology with generator A given by

$$D(A) = \{(x_n)_{n\in\mathbb{N}} \in \ell^\infty \colon (nx_n)_{n\in\mathbb{N}} \in \ell^\infty\},$$
$$A(x_n)_{n\in\mathbb{N}} = (-nx_n)_{n\in\mathbb{N}}.$$

It is not hard to see that the following facts hold.

- $B = A_{-1}$ is ISS, but
- $B = A_{-1}$ is not integral ISS

with respect to inputs u in $L^\infty(0,\infty;X)$. Note that the corresponding statement changes significantly if we replace the space ℓ^∞ by c_0; then $B = A_{-1}$ is not ISS. This is a consequence of a recent result Jacob et al. (2022) stating that L^∞-ISS for $B = A_{-1}$ for a strongly continuous semigroup already implies the boundedness of the generator.

On the first glance, this result seems to resolve the question posed in the introduction completely. A closer look, however, reveals that the considered function space $L^\infty(0,\infty;X)$ does not match the natural setting we encounter for bi-continuous semigroups.

2. NOTIONS AND PRELIMINARIES

We call a triple $(X, \|\cdot\|, \tau)$ a sequentially complete Saks space if $(X, \|\cdot\|)$ is a Banach space, τ is a coarser Hausdorff locally convex topology than the $\|\cdot\|$-topology such that $(X,\tau)'$ is norming, and if $\|\cdot\|$-bounded τ-Cauchy sequences are convergent. In our motivating example $(\ell^\infty, \|\cdot\|_\infty, \sigma(\ell^\infty,\ell^1))$ is the sequentially complete Saks space. Bi-continuous semigroups on a sequentially complete Saks space $(X, \|\cdot\|, \tau)$ were introduced by Kühnemund (2001, 2003) as exponentially bounded semigroups in the space of bounded linear operators $\mathcal{L}(X)$ on X which are (only) τ-strongly continuous and locally sequentially τ-equicontinuous on $\|\cdot\|$-bounded sets. The precise definition looks as follows.

Definition 1. Let $(X, \|\cdot\|, \tau)$ be a sequentially complete Saks space. A family $(T(t))_{t\geq 0}$ in $\mathcal{L}(X)$ is called *τ-bi-continuous semigroup* if

(i) $(T(t))_{t\geq 0}$ is a *semigroup*, i.e. $T(t+s) = T(t)T(s)$ and $T(0) = \mathrm{id}$ for all $t, s \geq 0$,
(ii) $(T(t))_{t\geq 0}$ is *τ-strongly continuous*, i.e. the map $T_x \colon [0,\infty) \to (X,\tau)$, $T_x(t) := T(t)x$, is continuous for all $x \in X$,
(iii) $(T(t))_{t\geq 0}$ is *exponentially bounded*, i.e. there exist $M \geq 1$, $\omega \in \mathbb{R}$ such that $\|T(t)\| \leq Me^{\omega t}$ for all $t \geq 0$,
(iv) $(T(t))_{t\geq 0}$ is *locally bi-equicontinuous*, i.e. for every sequence $(x_n)_{n\in\mathbb{N}}$ in X, $x \in X$ with $\sup_{n\in\mathbb{N}} \|x_n\| < \infty$ and $\tau\text{-}\lim_{n\to\infty} x_n = x$ it holds that

$$\tau\text{-}\lim_{n\to\infty} T(t)(x_n - x) = 0$$

locally uniformly for all $t \in [0,\infty)$.

In order to interpret the (mild) solution (3) there are some adaptations needed in the bi-continuous setting. The generator of a τ-bi-continuous semigroup is defined similar to the one of a $\|\cdot\|$-strongly continuous semigroup, namely, by

$$Ax := \tau\text{-}\lim_{t\to 0^+} \frac{T(t)x - x}{t},\ x \in D(A),$$

where the domain $D(A)$ consists of all $x \in X$ such that this τ-limit exists and $\sup_{t\in(0,1]} \frac{\|T(t)x-x\|}{t} < \infty$. The notion of the extrapolation space X_{-1} and the extrapolated semigroup $(T_{-1}(t))_{t\geq 0}$ was transferred by Budde and Farkas (2019) to the bi-continuous setting and the semigroup $(T_{-1}(t))_{t\geq 0}$ becomes a bi-continuous semigroup with generator A_{-1} on the sequentially complete extrapolated Saks space $(X_{-1}, \|\cdot\|_{-1}, \tau_{-1})$. The integral appearing in (3) is in general not a Bochner integral (in X_{-1}) anymore due to the extrapolated semigroup being only τ_{-1}-strongly continuous. However, one may regard this integral as a Pettis integral in X_{-1} w.r.t. the τ_{-1}-topology under the constraint that $U = X$, $B \in \mathcal{L}(X; X_{-1})$ is in addition τ-τ_{-1}-continuous and the inputs u belong to the space $C_{\tau,b}([0,t];X)$ of τ-continuous $\|\cdot\|$-bounded functions from $[0,t]$ to X. Now, the operator B is called *$C_{\tau,b}$-admissible* for $t > 0$ if this τ_{-1}-Pettis integral belongs to X, and it turns out that the $C_{\tau,b}$-admissibility of $B = A_{-1}$ is equivalent to

$$\int_0^r T(r-s)f(s)\mathrm{d}s \in D(A)$$

for all $f \in C_{\tau,b}([0,t];X)$ and all $r \in [0,t]$. If B is $C_{\tau,b}$-admissible for all $t > 0$, then we call B $C_{\tau,b}$-admissible.

Looking at the space $C_{\tau,b}([0,t];X)$ and aiming for a corresponding result to Jacob et al. (2022) in the bi-continuous framework, one realizes that the definition of L^∞-admissibility needs an adaptation as well. Namely, due to the functions in $C_{\tau,b}([0,t];X)$ being only τ-continuous they may not be $\|\cdot\|$-strongly measurable and therefore it is not guaranteed that the inclusion $C_{\tau,b}([0,t];X) \subset L^\infty(0,t;X)$ holds. Thus one has to replace the $\|\cdot\|$-strong measurability by τ-strong measurability and so the space $L^\infty(0,t;X)$ by

$$L^\infty_\tau(0,t;X) := \mathscr{L}^\infty_\tau(0,t;X)/\mathscr{N}.$$

where $\mathscr{L}^\infty_\tau(0,t;X)$ is the space of functions $f\colon [0,t] \to X$ which are τ-strongly measurable and essentially $\|\cdot\|$-bounded, and $\mathscr{N}$ is the space of functions in $\mathscr{L}^\infty_\tau(0,t;X)$ which vanish Lebesgue almost everywhere. If τ coincides with the $\|\cdot\|$-topology, then this space coincides with $L^\infty(0,t;X)$.

Definition 2. Let $(X,\|\cdot\|,\tau)$ be a sequentially complete Saks space and $(T(t))_{t\geq 0}$ a τ-bi-continuous semigroup on X. Let $t_0 > 0$ and $F(0,t_0;X)$ be a space of functions on $[0,t_0]$ with values in X such that the convolution

$$(T * f)(t) := \int_0^t T(t-s)f(s)\,\mathrm{d}s$$

is a well-defined τ-Pettis integral in X for any $t \in [0,t_0]$. We say that $(T(t))_{t\geq 0}$ satisfies *F-maximal regularity for* t_0 if for all $f \in F(0,t_0;X)$ it holds that $(T*f)(t) \in D(A)$ for all $t \in [0,t_0]$ and $A(T*f) \in F(0,t_0;X)$. We say that $(T(t))_{t\geq 0}$ satisfies *F-maximal regularity* if it satisfies F-maximal regularity for all $t_0 > 0$.

3. RESULTS

3.1 A theorem on maximal regularity w.r.t. $\|\cdot\|_\infty$-norms

It is well-known that maximal regularity with respect to continuous functions is rare for strongly continuous semigroup generators. This is due to Baillon's result given in Baillon (1980), which even holds if the considered semigroup is not strongly continuous.

Theorem 1. (Baillon's result on maximal regularity). Let A be the generator of a analytic semigroup on a Banach space X such that A satisfies $C([0,t];X)$-maximal regularity. If A is unbounded, then X contains an isomorphic copy of c_0.

The phenomenon observed in Section 1.1, however, is not accidental, as the following result shows.

Theorem 2. Let A generate a strongly continuous semigroup on a Banach space X and suppose that the adjoint A' satisfies $C([0,t];X)$-maximal regularity. Then X' contains ℓ^∞.

However, as mentioned above, maximal regularity and admissibility with respect to functions in $C([0,t];X)$ or $L^\infty([0,t];X)$ is not the natural setting as the continuity/measurability relates to the wrong topology. Instead, the spaces $C_{\tau,b}([0,t];X)$ and $L^\infty_\tau(0,t;X)$ should be used.

The ultimate goal of these considerations is to approach a statement of the following form, which is inspired by the corresponding result for strongly continuous semigroups, Jacob et al. (2022).

Conjecture 3. Let $(X,\|\cdot\|,\tau)$ be a sequentially complete Saks space. and $(T(t))_{t\geq 0}$ a τ-bi-continuous semigroup on X with generator $(A, D(A))$ such that $0 \in \rho(A)$. Then the following assertions are equivalent:

(a) A_{-1} is L^∞_τ-admissible.
(b) $\mathrm{Fav}(T) = D(A)$ and $(T(t))_{t\geq 0}$ satisfies the $C_{\tau,b}$-maximal regularity.
(c) $D(A) = X$ and $A\colon (X,\gamma) \to (X,\gamma)$ is continuous.

Here, L^∞_τ-admissibility is defined analogously to $C_{\tau,b}$-admissibility, $\mathrm{Fav}(T)$ denotes the Favard space of T and $\gamma = \gamma(\|\cdot\|,\tau)$ the mixed topology introduced by Wiweger (1961), see Cooper (1978) as well. If τ coincides with the $\|\cdot\|$-topology, then γ coincides with the $\|\cdot\|$-topology too. So, if true, then this conjecture generalises the mentioned result from Jacob et al. (2022). In order to achieve this, we have developed a corresponding theory of sun dual spaces for bi-continuous semigroups in Kruse and Schwenninger (2022); a tool that was pivotal in the norm-strongly continuous case. These results, which are of interest in their own right, extend works by van Neerven (1992).

A non-linear internal model principle for observers ⋆

Jochen Trumpf * **Johannes Nüssle** **

* *Australian National University (e-mail: Jochen.Trumpf@anu.edu.au)*
** *e-mail: nuessle@johannesnuessle.de*

Keywords: observer theory, internal model principle, non-linear observers, behaviours, non-linear systems theory

1. EXTENDED ABSTRACT

State observer design for non-linear systems is concerned with the question of how to construct a dynamical system, the *observer*, that takes as input both the input u and the output y of a given non-linear control system

$$\begin{aligned} \dot{x} &= f(x,u,t), \\ y &= h(x,u,t), \end{aligned} \tag{1}$$

and produces as its output an estimate $\hat{x}$ of the state variable x. The notation in (1) is deliberately generic since many variations of this problem are studied in the literature that differ in terms of the spaces that the variables x, u, and y live in, the assumed properties of the functions f and h, or the notion of what constitutes a good estimate $\hat{x}$ of x.

One way to approach this problem is to make the Ansatz

$$\dot{\hat{x}} = f(\hat{x},u,t) + \Delta(\hat{x},u,y,t), \tag{2}$$

where the *internal model term* $f(\hat{x},u,t)$ simulates the observed system, or *plant*, (1) and the *correction term* $\Delta(\hat{x},u,y,t)$ is zero along trajectories of (1). In the linear context this idea dates back to Luenberger (1964), and in the non-linear context at least to Kou (1973), see also Thau (1973). In the case where $x, \hat{x} \in \mathbb{R}^n$ and where we are seeking an asymptotic observer, the problem is now to construct a correction term $\Delta(\hat{x},u,y,t)$ such that the *observer error* $e := \hat{x} - x$ fulfils

$$\lim_{t\to\infty} e(t) = 0 \tag{3}$$

for all (admissible) choices of $x(0)$, $\hat{x}(0)$ and u.

The significance of $\Delta(\hat{x},u,y,t)$ being zero along trajectories of (1) is that, together with uniqueness of solutions, it implies the *tracking property*

$$\hat{x}(0) = x(0) \implies \hat{x}(t) = x(t) \text{ for all } t. \tag{4}$$

In other words, the behaviour (set of trajectories) of the observer (2) contains the behaviour (set of trajectories) of the plant (1), i.e. an *internal model* of the plant.

An obvious question now is to what extent such an internal model plus correction term design is *necessary*. If we have a general asymptotic observer

$$\dot{\hat{x}} = \hat{f}(\hat{x},u,y,t) \tag{5}$$

for which (3) holds, does the right hand side $\hat{f}$ *always* split as in (2)? An affirmative answer to such a question is called an *internal model principle for observers*. Note that such a result depends on the classes of plants and observers under consideration as well as on the notion of what constitutes a good estimate.

For linear systems, several such internal model principles were proved in Trumpf et al. (2014), covering the most common notions of good estimate: asymptotic, dead-beat, and exact observers. See also the even more general results in Blumthaler and Trumpf (2014). In the linear case, observers do not necessarily contain *full* internal models of the plant but internal models of significant parts of the plant behaviour. For the details see Trumpf et al. (2014) or Blumthaler and Trumpf (2014).

In this work, we will present a general internal model principle for observers formulated in a purely set theoretic generalisation of behavioural observer theory. We show that the historic focus on the linear case has somewhat obscured what is in essence a surprisingly simple theory, at least once the manifold implications of linearity have been disentangled and only the strictly necessary components kept and generalized. We recover the known linear results as special cases of our general result and also derive a novel internal model principle for non-linear kinematic systems on differentiable manifolds. To our best knowledge, this is the first non-linear internal model principle for observers in the literature.

Our theory proceeds from the observations that (3) defines an equivalence relation on the set of state trajectories, i.e. a notion of which pairs of trajectories are *close* to each other, and that sets of trajectories form a *poset* (partially ordered set) under set inclusion. We define the *saturation* of a given behaviour (set of trajectories) as the set closure under the closeness relation and use this concept to define what we call the *radical set* associated with a given behaviour (set of trajectories). The space of saturations of behaviours is a poset under set inclusion. We show that the space of radical sets also carries a natural poset structure. The case where the poset of saturations and the poset of radical sets are isomorphic via the natural isomorphism is of particular interest. We say that the poset of radical sets admits *local poset sections* in this case. This property holds for linear systems as well as for kinematic systems on differentiable manifolds.

⋆ This research is supported by the Australian Research Council Discovery Project DP190103615: "Control of Network Systems with Signed Dynamical Interconnections".

The general internal model principle for observers now states that if the poset of radical sets admits local poset sections and if the radical sets of behaviours are well-founded (the latter is a standard property in the theory of posets that implies the existence of minimal elements) then any non-intrusive, observable observer behaviour contains a minimal element of the radical set of the plant behaviour.

Focusing on the case of asymptotic observer design, for linear systems the minimal element of the radical set is unique and equals the anti-stabilizable part of the plant behaviour, cf. (Trumpf et al., 2014, Theorem 5.6). We show that for kinematic systems on differentiable manifolds the radical set only contains the plant behaviour. It follows that any asymptotic observer for a non-linear kinematic system on a differentiable manifold contains a full internal model of the plant.

Abstract: We consider Dynamic programming equations associated to discrete time stochastic control problems with continuous state space, which arise in particular from monotone time discretizations of Hamilton-Jacobi-Bellman equations. We develop and study several numerical algorithms for solving such equations, combining tropical numerical methods and stochastic dual dynamic programming methods. We also compare these algorithms with the point based methods for solving Partially Observable Markov Decision Processes (POMDP).

Keywords: Stochastic Control, Hamilton-Jacobi-Bellman equations, Stochastic Dual Dynamic Programming, Tropical algebra, Partially Observable Markov decision processes.

1. INTRODUCTION

We consider the following stochastic control problem with discrete time and a possibly discounted additive payoff, either with a finite or infinite horizon T. At each step $t \in [\![0,T]\!]$, the state $\mathbf{X_t} \in \mathbb{X} \subset \mathbb{R}^n$ follows the following dynamics

$$\mathbf{X_{t+1}} = f_t^{\mathbf{W_{t+1}}}(\mathbf{X_t}, \mathbf{U_t}) \ ,$$

where $(\mathbf{W_t})_{t\in[\![0,T]\!]}$ is a sequence of random variables with values in some measurable set $(\mathbb{W}, \mathcal{W})$, and $(\mathbf{U_t})_{t\in[\![0,T]\!]}$ is an *adapted* sequence of (random) decisions or controls with values in some measurable set $(\mathbb{U}, \mathcal{U})$. The state is fully observed, and we may be in the hazard-decision framework in which *adapted* means that, for all t, $\sigma(\mathbf{U_t}) \subset \sigma(\mathbf{X_0}, \mathbf{W_1}, \ldots, \mathbf{W_{t+1}})$. We may also be in the decision-hazard framework, in which *adapted* means that, for all t, $\sigma(\mathbf{U_t}) \subset \sigma(\mathbf{X_0}, \mathbf{W_1}, \ldots, \mathbf{W_t})$. At each time t, the decision maker is receiving the reward

$$r_t^{\mathbf{W_{t+1}}}(\mathbf{X_t}, \mathbf{U_t}) \ ,$$

and at the final time, if any, the decision maker receives the final reward $\psi(\mathbf{X_T})$. Then, the decision maker aims to maximize his total expected reward:

$$\mathbb{E}\left[\sum_{t=0}^{T-1} r_t^{\mathbf{W_{t+1}}}(\mathbf{X_t}, \mathbf{U_t}) + \psi(\mathbf{X_T})\right] \ .$$

Such a problem is also called a multi-stage optimization problem. In the sequel, we shall assume that the random variables $\mathbf{W_{t+1}}$ are independent and with finite support $\mathbb{W}$. The law of $\mathbf{W_{t+1}}$ may depend on t. In the decision-hazard framework, we may also consider the case where the law of $\mathbf{W_{t+1}}$ depends on $(\mathbf{X_t}, \mathbf{U_t})$, which is equivalent to consider the general framework of Markov decision processes, with some given transition probabilities $T_t^{u_t}(x_t, x_{t+1}) = P(\mathbf{X_{t+1}} = x_{t+1} \mid \mathbf{X_t} = x_t, \mathbf{U_t} = u_t)$, such that $T_t^{u_t}(x_t, \cdot)$ has a finite support. In the hazard-decision framework, we can assume that the law of $\mathbf{W_{t+1}}$ depends on $\mathbf{X_t}$, but it cannot depend on $\mathbf{U_t}$. The discrete probability law of $\mathbf{W_{t+1}}$ will be denoted by $p_t^{x_t,u_t}(w) = P(\mathbf{W_{t+1}} = w \mid \mathbf{X_t} = x_t, \mathbf{U_t} = u_t)$ in the first case, and by $p_t^{x_t}(w) = P(\mathbf{W_{t+1}} = w \mid \mathbf{X_t} = x_t)$ in the second case.

By the dynamic programming approach (see Bellman (1984)), the value function of the above problem is the function V_0 obtained from the solution to the following recurrence equation:

$$V_T = \psi \quad \text{and} \quad \forall t \in [\![0, T-1]\!], V_t = \mathfrak{B}_t\left(V_{t+1}\right) \ , \qquad (1)$$

where $\mathfrak{B}_t$ is the associated Bellman operator from the set of extended real functions over $\mathbb{X}$ ($\overline{\mathbb{R}}^{\mathbb{X}}$), to itself. This operator can be written as the composition of three different operators among the following ones which are operating on functions from either $\mathbb{X}$, $\mathbb{X} \times \mathbb{U}$, $\mathbb{X} \times \mathbb{U} \times \mathbb{W}$ or $\mathbb{X} \times \mathbb{W}$ to $\overline{\mathbb{R}}$:

⋆ Sponsor and financial support acknowledgment goes here. Paper titles should be written in uppercase and lowercase letters, not all uppercase.

$$\begin{aligned}
\mathcal{Q}_t(\phi)(x,u,w) &= r_t^w(x,u) + \phi\big(f_t^w(x,u)\big),\\
\mathcal{M}_t^{(1)}(Q)(x,w) &= \max_{u\in\mathbb{U}} Q(x,u,w),\\
\mathcal{E}_t^{(2)}(Q)(x) &= \mathbb{E}\Big[Q(x,\mathbf{W_{t+1}})\Big] = \sum_{w\in\mathbb{W}} p_t^x(w)Q(x,w),\\
\mathcal{E}_t^{(1)}(Q)(x,u) &= \mathbb{E}\Big[Q(x,u,\mathbf{W_{t+1}}) \mid \mathbf{X}_t = x, \mathbf{U}_t = u\Big]\\
&= \sum_{w\in\mathbb{W}} p_t^{x,u}(w)Q(x,u,w),\\
\mathcal{M}_t^{(2)}(Q)(x) &= \max_{u\in\mathbb{U}} Q(x,u)\ ,
\end{aligned}$$

in which we use the convention $+\infty-\infty=-\infty$. Indeed, in the hazard-decision case, we have $\mathfrak{B}_t = \mathcal{E}_t^{(2)}\circ\mathcal{M}_t^{(1)}\circ\mathcal{Q}_t$ and in the decision-hazard case, we have $\mathfrak{B}_t = \mathcal{M}_t^{(2)}\circ\mathcal{E}_t^{(1)}\circ\mathcal{Q}_t$.

The above discrete time Bellman equation (1) can also be obtained after some semi-Lagrangian time discretization of a Hamilton-Jacobi-Bellman equation, see Falcone and Ferretti (2014), or any monotone time discretization. The dynamic programming approach suffers from the "curse of dimensionality", since one would need to compute for all $t \in [\![0,T]\!]$ the value function V_t on all the state space $\mathbb{X}$, and any grid-based discretization would need a number of values exponential in the dimension n of the state space $\mathbb{X}$. Several methods have been proposed in the litterature to bypass the obstruction of curse of dimensionality. We shall only cite the ones related to the present work: the tropical numerical methods developped in the context of Hamilton-Jacobi equations (McEneaney (2007); McEneaney et al. (2011); Qu (2014); Akian and Fodjo (2018)), the tree-structured algorithm developped recently by Alla et al. (2019), and the stochastic dual dynamic programming method developped in the context of discrete time stochastic control (Pereira and Pinto (1991); Philpott et al. (2013)).

Here, we consider a general algorithm inspired by both tropical numerical methods and SDDP algorithm and which can be seen as a generalization of the algorithms proposed in Philpott et al. (2013); Baucke et al. (2018)). Moreover, we show that in the case of the dynamic programming equation associated to a partially observable Markov Decision Process (POMDP), it is similar to the so called point based algorithms developped in Pineau et al. (2003); Kurniawati et al. (2008); Shani et al. (2013).

2. TROPICAL NUMERICAL METHOD FOR LIPSCHITZ PRESERVING BELLMAN OPERATORS

The following algorithm is introduced in more details in Akian et al. (2020).

We assume that the map r_t^w takes its values in $\mathbb{R}\cup\{-\infty\}$, to handle constraints in state and control. We also assume that r_t^w is bounded from above, which will imply that the Bellman operator preserves the set of upper bounded function from $\mathbb{X}$ to $\mathbb{R}\cup\{-\infty\}$. For any function ϕ from a set Y to $\mathbb{R}\cup\{-\infty\}$, the support of ϕ will be the set of $y\in Y$ such that $\phi(y)\in\mathbb{R}$. The constraints determined by the support of r_t^w and the support of the final reward ψ induce a sequence of sets $X_t\subset\mathbb{X}$, $t\in[\![0,T]\!]$, such that any sequence V_t, $t\in[\![0,T]\!]$, satisfying (1) is such that the support of V_t is included in X_t.

It is well known that Bellman operators are order preserving and nonexpansive for the sup-norm. Since $\mathbb{X}$ is an infinite set, we shall need the following stronger property:

Assumption 1. There exists a sequence $\mathcal{L}_t$, $t\in[\![0,T]\!]$, of compact subsets of the set of functions from $\mathbb{X}$ to $\mathbb{R}\cup\{-\infty\}$, endowed with the uniform convergence topology, such that, for all $t\in[\![0,T-1]\!]$, the Bellman operator $\mathfrak{B}_t$ sends $\mathcal{L}_{t+1}$ into $\mathcal{L}_t$.

Compact subsets $\mathcal{L}_t$ can be obtained by taking the set of functions from $\mathbb{X}$ to $\mathbb{R}\cup\{-\infty\}$, that are L_t-Lipschitz continuous (for some given norm of $\mathbb{R}^n$) on their compact support X_t, or any closed subset of this set. In Akian et al. (2020), Assumption 1 is proved to be satisfied for these particular sets $\mathcal{L}_t$, for some constants L_t, under some technical conditions similar to the ones that are generally assumed in the proofs of convergence of SDDP algorithm. Another important property assumed to apply SDDP algorithm (in the above context of a maximization problem) is that the control set is polyhedral, that the reward functions are polyhedral and concave with respect to state and control, and that the dynamics are affine with respect to state and control. In that case the value function can be approximated by the finite infimum of affine functions, and the computation of appropriate affine functions can be done by solving some Linear Programs. In what follows, we describe a general algorithm which does not necessarily need this property. What will be needed however is the following assumption which is satisfied again by the above particular sets.

Assumption 2. The subsets $\mathcal{L}_t$ of Assumption 1 are lattices for the pointwise partial order: for all $t\in[\![0,T]\!]$, and $\phi,\phi'\in\mathcal{L}_t$, there exists a supremum (least upper bound) of ϕ and ϕ' in $\mathcal{L}_t$, that we shall denote by $\phi\vee\phi'$ and an infimum (greatest lower bound) of ϕ and ϕ' in $\mathcal{L}_t$, that we shall denote by $\phi\wedge\phi'$.

Note that the set $\mathcal{C}_t$ of concave functions that are L_t-Lipschitz continuous on their compact support X_t is stable by the infimum operation, so that the pointwise infimum in the set of all functions coincides with the infimum in $\mathcal{C}_t$. It is not stable by the pointwise supremum, but the supremum in $\mathcal{C}_t$ exists and coincides with the concave hull of (the least concave map greater than) the pointwise supremum.

The Tropical Dynamic Programming (TDP) algorithm of Akian et al. (2020) (which generalizes Philpott et al. (2013); Baucke et al. (2018)) consists in the iterative construction of two approximations of the value function V_t, one from above and one from below. At each iteration k, the upper approximation, denoted $\overline{V}_t^k$, is obtained as the infimum (in $\mathcal{L}_t$) of a finite set $\overline{F}_t^k$ of basic functions and the lower approximation, denoted $\underline{V}_t^k$, is obtained as the supremum (in $\mathcal{L}_t$) of a finite set $\underline{F}_t^k$ of basic functions. Basic functions for the upper and lower approximations are taken respectively in subsets $\underline{\mathbf{F}}_t$ and $\overline{\mathbf{F}}_t$ of $\mathcal{L}_t$, that is we have $\overline{F}_t^k\subset\overline{\mathbf{F}}_t$ and $\underline{F}_t^k\subset\underline{\mathbf{F}}_t$. Note that the approximations $\overline{V}_t^k$ and $\underline{V}_t^k$ are parametrized by the sets $\overline{F}_t^k$ and $\underline{F}_t^k$, which means that we never store the values of these functions on a grid of $\mathbb{X}$. The sets of basic functions $\overline{F}_t^k$ and $\underline{F}_t^k$ are increasing with respect to iteration number

k, so that $\overline{V}_t^{k+1} \leq \overline{V}_t^k$ and $\underline{V}_t^{k+1} \geq \underline{V}_t^k$. These sets are computed using a sequence of state-action-noise, which is itself computed using the previous sequence of functions.

Starting with an initial state x_0 and emptysets, or appropriate singleton sets $\underline{\phi}_{t+1}^0$ and $\overline{\phi}_{t+1}^0$, the algorithm solving the Bellman equation in the hazard-decision framework consists at each step $k \geq 0$ in the following two phases:

- **Forward phase:** Compute a new (deterministic) trajectory $(x_t^k)_{t\in[\![0,T]\!]}$ starting in x_0 as follows. For $t = 0, \dots, T-1$, do:

  For each $w \in \mathbb{W}$, compute an optimal control u_t^w for $\overline{V}_{t+1}^k$ at x_t^k:
  $$u_t^w \in \arg\max_{u\in\mathbb{U}} \mathcal{Q}_t(\overline{V}_{t+1}^k)(x_t^k, u, w) \ . \tag{2}$$
  Compute the noise $w_t \in \mathbb{W}$ which maximizes the future gap
  $$w_t \in \arg\max_{w\in\mathbb{W}} \big(\overline{V}_{t+1}^k - \underline{V}_{t+1}^k\big)\big(f_t^w(x_t, u_t^w)\big).$$
  Compute the next state associated to the above noise and optimal control:
  $$x_{t+1}^k = f_t^{w_t}(x_t^k, u_t^{w_t}) \ .$$
- **Backward phase:** For $t = T, T-1, \dots, 0$, select for both upper and lower approximations, one new basic function $\overline{\phi}_t \in \overline{\mathbf{F}}_t$ (resp. $\underline{\phi}_t \in \underline{\mathbf{F}}_t$) and add it to the corresponding set: $\overline{F}_t^{k+1} := \overline{F}_t^k \cup \{\overline{\phi}_t\}$ and $\underline{F}_t^{k+1} := \underline{F}_t^k \cup \{\underline{\phi}_t\}$.

  If $t = T$, the new basic functions are chosen such that
  $$\overline{\phi}_T \geq \psi \quad \text{and} \quad \overline{\phi}_T(x_T^k) = \psi(x_T^k).$$
  and symmetrically
  $$\underline{\phi}_T \leq \psi \quad \text{and} \quad \underline{\phi}_T(x_T^k) = \psi(x_T^k).$$
  If $t < T$, the new basic functions are chosen such that
  $$\overline{\phi}_t \geq \mathfrak{B}_t\left(\overline{V}_{t+1}^{k+1}\right)$$
  $$\overline{\phi}_t(x_t^k) = \mathfrak{B}_t\left(\overline{V}_{t+1}^{k+1}\right)(x_t^k).$$
  and symmetrically
  $$\underline{\phi}_t \leq \mathfrak{B}_t\left(\underline{V}_{t+1}^{k+1}\right)$$
  $$\underline{\phi}_t(x_t^k) = \mathfrak{B}_t\left(\underline{V}_{t+1}^{k+1}\right)(x_t^k),$$
  where for all t, k, we denote $\overline{V}_t^k = \inf \overline{F}_t^k$ and $\underline{V}_t^k = \sup \underline{F}_t^k$.

For the decision-hazard framework, the only difference is in the forward phase, in which one computes an optimal control u_t independent of w:
$$u_t \in \arg\max_{u\in\mathbb{U}} \mathcal{E}_t^{(1)}(\mathcal{Q}_t(\overline{V}_{t+1}^k))(x_t^k, u) \ .$$
If $\mathcal{L}_t$ is the set of L_t-Lipschitz continuous functions on their compact support X_t, for some given norm $\|\cdot\|$ of $\mathbb{R}^n$, then a typical example of a set of basic functions $\underline{\mathbf{F}}_t$ is the set of functions $x \in X_t \mapsto a - L_t\|x - x_0\|$ with $a \in \mathbb{R}$ and $x_0 \in X_t$. Then $-\underline{\mathbf{F}}_t$ is also a good candidate for $\overline{\mathbf{F}}_t$. If $\mathcal{L}_t$ is the set of concave L_t-Lipschitz continuous functions on their compact support X_t, then one can replace $\overline{\mathbf{F}}_t$ by the set of L_t-Lipschitz continuous affine maps restricted to X_t. This is what is done in the SDDP like algorithms of Philpott et al. (2013); Baucke et al. (2018).

Theorem 3. (Akian et al. (2020)). Let V_t be the solution of the Bellman equation (1). For all $t \in [\![0, T]\!]$, the sequences $\left(\underline{V}_t^k\right)_{k\in\mathbb{N}}$ and $\left(\overline{V}_t^k\right)_{k\in\mathbb{N}}$ converge uniformly to two functions $\underline{V}_t^*$ and $\overline{V}_t^*$ of $\mathcal{L}_t$ which satisfy $\underline{V}_t^* \leq V_t \leq \overline{V}_t^*$. Moreover, we have that $\overline{V}_t^*(x_t^*) = V_t(x_t^*) = \underline{V}_t^*(x_t^*)$ for every accumulation point x_t^* of the sequence $(x_t^k)_{k\in\mathbb{N}}$. In particular $\overline{V}_0^*(x_0) = V_0(x_0) = \underline{V}_0^*(x_0)$.

The above algorithm and theorem are defined and stated in Akian et al. (2020) under some technical assumptions which ensure that Assumptions 1 and 2 hold for the set $\mathcal{L}_t$ of L_t-Lipschitz continuous functions with compact support X_t. However, the algorithm and proof only use the properties stated in these assumptions.

3. POINT BASED ALGORITHMS FOR POMDP

One way to solve a partially observable Markov decision Problem (POMDP) is to introduce, for each time t, the belief state b_t that is a probability distribution among the elements of the state space, given the information available at time t. The value function and an optimal strategy can then be obtained by solving the dynamic programming equation of a Markov decision process over the belief state space with perfect information. This gives in particular an optimal strategy which only depend on the belief state at the current time.

We recall this dynamic programming equation in the discounted infinite horizon case, for which point based algorithm were introduced (see Pineau et al. (2003); Kurniawati et al. (2008); Shani et al. (2013)). Assume that the state space is equal to $[n] := \{1, \dots, n\}$, so that the belief space is the simplex $\Delta_n = \{b \in \mathbb{R}_+^n \mid \sum_i b_i = 1\}$, which is a compact subset of $\mathbb{X} = \mathbb{R}^n$. Assume also that the observation space $\mathbb{O}$ and the control space $\mathbb{U}$ are finite sets. For all $o \in \mathbb{O}$ and $u \in \mathbb{U}$, let us denote by $\mathcal{M}^{u,o}$ the $n \times n$ matrix with entries
$$\mathcal{M}_{xx'}^{u,o} = P(\mathbf{o_{t+1}} = o, \mathbf{X_{t+1}} = x' \mid \mathbf{X_t} = x, \mathbf{U_t} = u) \ ,$$
and let us any belief state as a row $1 \times n$ vector. Then, the dynamics of the belief state is given by:
$$\mathbf{b_{t+1}} = \tau^{\mathbf{o_{t+1}}}(\mathbf{b_t}, \mathbf{u_t}) \quad \text{with} \quad \tau^o(b, u) = \frac{b\mathcal{M}^{u,o}}{b\mathcal{M}^{u,o}\mathbf{1}} \ .$$
We also have
$$P(\mathbf{o_{t+1}} = o \mid \mathbf{b_t} = b, \mathbf{U_t} = u) = p^{b,u}(o) := b\mathcal{M}^{u,o}\mathbf{1} \ .$$
Denoting $\gamma < 1$ the discount factor, the dynamic programming equation of the POMDP is the fixed point equation
$$V = \mathfrak{B}(V)$$
with $\mathfrak{B} = \mathcal{M} \circ \mathcal{E} \circ \mathcal{Q}$ for the following operators
$$\mathcal{Q}(\phi)(b, u, o) = R(b, u) + \gamma\phi\big(\tau^o(b, u)\big),$$
$$\mathcal{E}(Q)(b, u) = \sum_{o\in\mathbb{O}} p^{b,u}(o) Q(b, u, o),$$
$$\mathcal{M}(Q)(b) = \max_{u\in\mathbb{U}} Q(b, u) \ ,$$
in which $R(b, u) = b\, r(\cdot, u) = \sum_{x\in[n]} b_x r(x, u)$. The above Bellman operator has same form as the one of previous section in the decision-hazard framework, but for some special dynamics. The observation process $\mathbf{o_t}$ play the role

of the noise process $\mathbf{W_t}$. Both belong to finite sets. So we can apply the TDP algorithm as soon as we found some appropriate sets $\mathcal{L}_t$. It is well known that the value function of a POMDP is a bounded convex Lipschitz continuous function over the simplex Δ_n. The bound and the Lipschitz constant (with respect to the ℓ_1 norm on the simplex) are both equal to $L = R_{\max}/(1-\gamma)$, where $R_{\max}$ is the sup-norm of the reward function r. The point based algorithms developped in (Pineau et al. (2003); Kurniawati et al. (2008); Shani et al. (2013)) consist in approximating the value function from below by a supremum of linear maps and from above by either an infimum of functions of the form $b \mapsto a + L\|b - b_0\|_1$ or by the convex hull of such functions. Both methods can be seen as a particular case of the TDP algorithm, up to some improvements, and a generalization to the infinite horizon case. Such a generalization consists in gathering (at each iteration k) all the improvements into the same approximate value function $\overline{V}^k$ or $\underline{V}^k$, and in stopping the trajectory (x_t^k) at a time T such that $\left(\overline{V}^k - \underline{V}^k\right)(x_T^k) \leq \epsilon$.

In Smith and Simmons (2005), an analysis of the point based algorithm is done, only under the assumption that the algorithm stops. Moreover, in Fehr et al. (2018), it is proved that the Bellman operator $\mathfrak{B}$ preserves the set of Lipschitz continuous functions over the simplex, but the Lipschitz constant can become very large for some $\gamma > 1/2$.

We can show however that the set $\mathcal{L}$ of functions on the simplex which are bounded by L and can be extended in a positively homogenous and L-Lipschitz continuous map on the positive cone $\mathbb{R}^n_+$ is preserved by the Bellman operator of the POMDP. This set is compact for the uniform convergence topology, so it satisfies Assumption 1. It also satisfies Assumption 2. This allows us to construct a variant of point based algorithm for which a convergence result similar to Theorem 3 up to ϵ is possible.

Keywords: Linear quadratic control, distributed reinforcement learning, zeroth-order optimization, connectivity, stationary points

AMS Classification: 49N10

Reinforcement learning for control systems with unknown or complex system models has attracted considerable attention recently. Particularly, there have been exciting advances on reinforcement learning for the (centralized) linear quadratic regulator problem that adopt an optimization viewpoint for algorithm design and theoretical analysis. Specifically, it has been shown that the LQR cost, when viewed as a function of the controller's feedback gain, is a gradient dominated function with a connected domain, and model-free reinforcement learning algorithms based on zeroth-order gradient estimation can achieve fast convergence to the globally optimal solution. Motivated by such success, this work attempts to investigate model-free reinforcement learning of two other linear quadratic control problems from an optimization viewpoint: i) decentralized linear quadratic control, ii) linear quadratic Gaussian control.

We first study distributed reinforcement learning of decentralized linear quadratic control. We consider a group of N agents interacting with a discrete-time linear dynamical system. Each agent only has access to partial state observations, local actions and local costs. The group of agents are connected by a communication network. The goal for each agent is to learn a local control policy by interacting with the linear system and by exchanging information with its neighbors in the network, so that the infinite-horizon averaged global cost will be minimized.

We propose a Zero-Order Distributed Policy Optimization algorithm (ZODPO) that learns local control policies in a distributed fashion. ZODPO leverages the ideas of policy gradient, zeroth-order optimization and consensus algorithms. ZODPO operates on two timescales: The fast timescale iterations proceed at the same pace with the discrete-time linear system, while each iteration on the slow timescale carries out one stochastic gradient descent update. At the beginning of each slow timescale iteration, each agent will generate a random perturbation and apply the perturbed control policy to the system. Then we let the system evolve for a sufficiently long period, during which each agent will accumulate local costs and run a consensus-based method on the fast timescale for estimating the global objective value. At the end of the slow timescale iteration, each agent constructs a zeroth-order partial gradient estimator and carries out a stochastic gradient descent update.

Further, we investigate the nonasymptotic performance of ZODPO for linear static local controllers. We show that, as long as the algorithmic parameters are properly chosen, all intermediate control policies $(\mathsf{K}(1), \ldots, \mathsf{K}(T_G))$ generated by ZODPO will stabilize the system with high probability. In addition, we derive a bound for the sample complexity of ZODPO, defined as the number of samples needed to approach a stationary point with arbitrary precision: In order to achieve

$$\frac{1}{T_G}\sum_{s=1}^{T_G} \|\nabla J(\mathsf{K}(s))\|^2 \leq \epsilon$$

for a sufficiently small tolerance $\epsilon > 0$, ZODPO requires a sample complexity of

$$\Theta\left(\frac{n_K^3}{\epsilon^4}\max\left\{n\beta_0^2, \frac{N}{1-\rho_W}\right\}\right).$$

Here n_K denotes the dimension of the controller parameter K, n denotes the dimension of the global state, β_0 is a constant determined by the system, and ρ_W captures the rate of consensus via the communication network. To the best of our knowledge, this is the first sample complexity

result for reinforcement learning of decentralized linear quadratic control.

We complement our theoretical results with numerical experiments on a multi-zone HVAC system test case.

Note that our theoretical results for ZODPO can only guarantee that a stationary point can be approached. This limitation is closely related to the fact that the optimization landscape of partially observable linear quadratic control with static output feedback lacks good structural properties that can facilitate convergence to the globally optimal point. This motivates us to analyze the optimization landscape of the linear quadratic Gaussian problem, which considers the optimal control of partially observable linear systems by dynamic controllers.

Specifically, we adopt an optimization viewpoint and reformulate the continuous-time linear quadratic Gaussian problem as an optimization problem. We parametrize a dynamic controller by its system matrices $(A_\mathsf{K}, B_\mathsf{K}, C_\mathsf{K})$. The objective function is the infinite-horizon quadratic cost, and the feasible region is the set of full-order dynamic controllers that can internally stabilize the plant.

We first characterize the connectivity of the feasible region of the LQG optimization problem. We prove that the feasible region can be disconnected, but has at most two path-connected components. Moreover, when the feasible region is disconnected, its two path-connected components are diffeomorphic under a similarity transformation $(A_\mathsf{K}, B_\mathsf{K}, C_\mathsf{K}) \mapsto (TA_\mathsf{K}T^{-1}, TB_\mathsf{K}, C_\mathsf{K}T^{-1})$ for any invertible T with $\det T < 0$, and this similarity transformation also preserves the objective value. This brings positive news to gradient-based local search algorithms for the LQG problem, since it makes no difference to search over either path-connected component even if the feasible region is disconnected. We further show that if the plant can be stabilized by a reduced-order dynamic controller, then the feasible region is always connected; this sufficient condition for connectivity becomes necessary when the plant is single-input or single-output.

We then investigate structural properties of the stationary points and the globally optimal points of the LQG cost function. It is known that the LQG cost is invariant under similarity transformations on the dynamic controller. As a consequence of this symmetry, the globally optimal solutions to the LQG problem are not unique, not isolated, and can be disconnected in the state-space domain. For a class of LQG problems, we show that the set of globally optimal solutions forms a submanifold with two path-connected components. When characterizing the set of stationary points, the notion of minimal controllers (controllable and observable controllers) plays an important role. We show it is likely that there exist many strictly suboptimal stationary points of the LQG cost function, and these stationary points are always non-minimal. We even provide an example of a saddle point that has a vanishing Hessian. In contrast, we prove that all minimal stationary points are globally optimal solutions to the LQG problem. These minimal stationary points are identical up to similarity transformations. This is expected from the classical result that the globally optimal LQG controller is unique in the frequency domain. Our analysis implies that if local search iterates converge to a critical point that corresponds to a controllable and observable controller, then the algorithm has found a globally optimal solution to the LQG problem. These results reveal rich yet complicated optimization landscape properties of the LQG problem, and shed light on the algorithm design and performance analysis of model-free policy gradient methods for solving the LQG problem.

Application of Generalized Functions in Optimal Control

Erik I. Verriest *

* *Georgia Institute of Technology, Atlanta, GA 30332 USA (e-mail: erik.verriest@ece.gatech.edu).*

Abstract: A new spin is given on the classical optimal control problem with piecewise differentiable dynamics and performance index with respect to the state variables. While in each domain of differentiability, the necessary conditions for optimality are easily established, their interpretation at the boundaries between domains is not well-understood. In this paper we show that in order to make sense of the Euler-Lagrange equation at this interface one needs to transcend the classical theory of Schwartz distributions and make suitable extensions to allow for the questionable behavior of impulses multiplied by discontinuities, and the notion of partial derivatives at a discontinuity. Such a theory has been developed, in the Colombeau, Oberguggenberger and Rosinger theory of Generalized Functions in 1990, going back to ideas from Nonstandard Analysis (NSA). We develop an alternative NSA based approach applicable to impulsive dynamics and optimal control.

Keywords: Generalized Functions, Optimal Control

1. INTRODUCTION

At the Boulder AMS Conference in 1990, R. Hermann presented a talk on the Colombeau, Oberguggenberger and Rosinger theory of generalized functions and predicted that it would revolutionize mathematical physics and system theory in the 21-st century (Hermann (1994)). This has not happened, perhaps because the details involved on the extended Schwartz distribution theory are not very transparent. In this paper, the theory is revisited, and it is shown that it has indeed a distinctive merit.

Assume that the state space, for simplicity embedded in $\mathbb{R}^n$, is partitioned in two domains, Ω_+ and Ω_-, separated by the interface $\Omega_0 = \{\, x \,|\, g(x) = 0 \,\}$. A standard optimal control problem is to find the control and trajectory for a system governed by the dynamics $\dot{x} = f(x,u)$, in going from an initial state, x_0, to a desired final state, x_f, while minimizing some performance index, say $J = \int_0^T L(x,u)\,\mathrm{d}t$, with T fixed for simplicity. In the hybrid problem, L and f are smooth functions of the arguments in each domain, but are discontinuous at Ω_0. The optimal trajectory from a given state $x_0 \in \Omega_-$ to a given final state $x_f \in \Omega_+$ must cross the interface an odd number of times. Let's focus here on the case having one such crossing. Transversality requires that $[\nabla g f_-]_{t_-}[\nabla g f_+]_{t_+} > 0$, where $t_- = t_i - \epsilon$ and $t_+ = t_i + \epsilon$ for $\epsilon \xrightarrow{>} 0$. Crossing time and crossing state are a priori unknown.

Classically, the solution is found stepwise: First, establish the necessary conditions for optimality in Ω_-: The optimality condition relates u_- to x_- and λ_- implicitly. In principle one can express u explicitly so that the state equation and the Euler-Lagrange equation (EL), $\dot{\lambda}_- = -\left(\frac{\partial H_-}{\partial x}\right)^\top$, where $H_-(x,u,\lambda) = L(x,u) + \lambda^\top f$ is the Hamiltonian, leaves $2n$ coupled ODE's for x_- and λ_-. The initial condition, x_0, provides n initial conditions for these equations. Augmenting with the n unknown parameters, $\lambda_0 = \lambda_-(0)$, the solution of these $2n$ ODE's can be specified in parameterized form as $x_-(t;\lambda_0)$, with $x_-(0;\lambda_0) = x_0$, for the states, and the co-states $\lambda_-(t;\lambda_0)$. Likewise, in the domain Ω_+, the necessary conditions lead to the $2n$ coupled ODE's, parameterized by say $\lambda_+(t_f) = \lambda_f$, which are as yet unknown. This leads to the parameterized form of the n states $x_+(t) = x(t;\lambda_f)$ and the n co-states $\lambda_+(t;\lambda_f)$.

This yields two families of trajectories: One starting from x_0 and parameterized by n parameters in λ_0. The other family, $x_+(t;\lambda_f)$, ends at x_f and is likewise parameterized by the n parameters in λ_f. Continuity of the state at the interface requires that for some time τ, $x_-(\tau;\lambda_0) = x_+(\tau;\lambda_f)$, which provides n equations, but introduces another variable: τ. However, at the interface $x_i = x_-(\tau) = x_+(\tau) \in \Omega_0$ the equation $g(x_-(\tau)) = 0$ determines this τ in principle. This still leaves n unknowns in the problem. One solves for these n remaining parameters by *optimization*.

But, a close inspection of the problem reveals that the *information present in the Euler-Lagrange equation of the optimal problem has not been exhausted*. By separately solving the EL equation in both domains, the EL equation *across* the interface has not been used. Since λ_- and λ_+ may differ on $g(x) = 0$, it means that the derivative of λ must be impulsive across the interface. Thus the right-hand-side of the EL is impulsive as well. But there are several problems with this. The right-hand side of the EL equation is specified as the gradient with respect to x. If x were smooth, Schwartz's distribution theory tells us how to relate the impulse with argument x to the impulse with argument t, but here $\dot{x}$ is not continuous across the interface. Likewise the right hand side also involves a product of distributions with respect to x with functions that are necessarily discontinuous. Such objects are not allowed in

Schwartz's distribution theory. This is the essence of the *Schwartz impossibility theorem*, relating to the fact that the set of distributions does not have the structure of an algebra. See Oberguggenberger (1992). Consequently, the needed interpretation of the EL completely fails in the classical Schwartz sense at the interface.

2. KRYLOV-SPACE

The way out of this impasse is to use the framework of generalized functions with a well-defined multiplicative structure, such as outlined in Grosser et al (2001). We propose a new definition of generalized functions, one that can handle the interpretative problems of $\delta(x(t))$ and $\phi(t)\delta(t)$ respectively when x is not differentiable and ϕ is not continuous. Non-standard analysis (NSA) provides an answer, but seems more complicated than it needs to be (Goldblatt (1998). In previous work Hyun and Verriest (2016, 2017) we developed an axiomatic approach from the ground up. This was introduced for the purpose of placing *causality*, understood in the sense of a cause leading to an effect, back in hybrid system theory. While in the linear theory, the reachability problem is investigated using impulsive inputs (the cause) creating jumps in the state (the effect), in the nonlinear case hybrid systems are modeled at their jumps solely by the effects, e.g., $x(t_+) = \phi(x(t_-), p)$, where the p may be some control parameters. In the cited thesis, the objective was to put the impulses back in the continuous dynamical equation, but properly model the dynamic behavior in our sense. This theory borrowed also from the generalized function theory of Colombeau (1985), which has found widely acceptance in mathematical physics. See also Oberguggenberger (1992).
Within our *post-Schwartzian generalized function theory*, we were able to obtain a clear understanding of this singular behavior of the EL equation $\dot{\lambda} = -H_x^\top$, across the interface, which we called the *generalized Euler-Lagrange equation* (GEL). The results then lead to a precise formula for the jump $\Delta\lambda$ in the co-states across the interface $g(x) = 0$ in terms of the co-states just before and just after the Ω_0 crossing (Zhou and Verriest (2022)). The upshot of this is now that the *GEL provides n additional equations* precisely in the remaining parameters. Hence the GEL can be used instead of solving the classical parameter optimization problem. Solving nonlinear equations is computationally more straightforward. This information has not been exploited in problems involving singularities in optimal control before.

3. SCHWARTZ DISTRIBUTION THEORY AND BEYOND

The Schwartz distribution theory centers on $\mathcal{D} = C_0^\infty(\mathbb{R})$, the space of C^∞ functions with compact support. The space of distributions is then defined as the dual space $\mathcal{D}'$. A distribution $\tilde{f} \in \mathcal{D}'$ is *regular* if there exists $f \in L_{1,loc}$, the space of locally integrable functions, such that

$$\forall \phi \in \mathcal{D}, \quad \tilde{f}(\phi) = \int_{\mathbb{R}} f(x)\phi(x)\,\mathrm{d}x.$$

Let $\mathcal{D}'_{reg}$ denote the space of *regular distributions*. Then $\mathcal{D}'_{reg} \subset \mathcal{D}'$ and $\forall f, g \in L_{1,loc}$ it holds that $\tilde{f} = \tilde{g} \Leftrightarrow f = g$ a.e.. In contrast, the *evaluation functional*, $\sigma_t : C_0^\infty \to \mathbb{R} : \phi \mapsto \phi(t)$, is usually denoted as $\int_{\mathbb{R}} \delta_t(x)\phi(x)\,\mathrm{d}x$, however the δ_t known as Dirac-delta's are not functions.
For $D \in \mathcal{D}'$, the *distributional derivative* is defined by $D' : \mathcal{D}' \to \mathcal{D}' : D \to (\phi \mapsto -D(\phi'))$. For $\tilde{f} \in C^1 \cap L_{1,loc}$, we get $\widetilde{(f')} = (\tilde{f})'$. For smooth functions $f \in C^\infty$ and $D \in \mathcal{D}'$, we define $fD : C_0^\infty \to \mathbb{R} : \phi \mapsto D(f\phi)$, and note that $fD \in \mathcal{D}'$. Furthermore, $(fD)' = f'D + fD'$, and $\forall g \in L_{1,loc}$, $f\tilde{g} = \widetilde{(fg)}$.
The *support of a distribution* is the complement of the largest open set on which the distribution vanishes. Let $\mathcal{D}'_M = \{D \in \mathcal{D}' \operatorname{supp} D \subseteq M\}$ for any measurable subset of $\mathbb{R}$. Let D_M denote the *restriction* of the distribution D. Desirable properties for a restriction are:
i) $\forall D \in \mathcal{D}'$ and measurable M, $D_M \subseteq \mathcal{D}'_{\mathrm{cl}\,M}$, and D_M linear and idempotent.
ii) $\forall f \in L_{1,loc}$ and measurable M, if $f_M = \chi_M f$, with χ_M the indicator function of M, then $\widetilde{f_M} = (\tilde{f})_M$.
iii) $\forall \phi \in C_0^\infty$, $\forall D \in \mathcal{D}'$ and measurable M it holds that $\operatorname{supp}\phi \subseteq M \Rightarrow D_M(\phi) = D(\phi)$ and $\operatorname{supp}\phi \cap M = \emptyset \Rightarrow D_M(\phi) = 0$.
iv) M_i pairwise disjoint with $M = \cup M_1$, it holds that $D_M = \sum D_{M_i}$ and $(D_{M_i})_{M_j} = 0$ if $i \neq j$.
If $\operatorname{supp} D = \{t\}$, then there exists $N \in \mathbb{N}$, and $\alpha_i \in \mathbb{R}$; $i = 0, \ldots, n$ such that $D = \sum_{i=0}^N \alpha_i \delta_t^{(i)}$ and $\sum_{i=0}^N \alpha_i \delta_t^{(i)} = 0 \Leftrightarrow \alpha_i = 0$, for $i = 0, \ldots, N$.
As the conditions (i) to (iv) cannot be satisfied together, Trenn (2009) defined an appropriate subspace of *piecewise regular distributions* that allows (i) to (iv) to be satisfied.

$$\mathcal{D}'_{pw\,reg} = \{\tilde{f} + \sum_{t\in T} D_t \,|\, f \in L_{1,loc}, T \subset \mathbb{R}, \text{locally finite}\},$$

where $D_t \in \mathcal{D}'_{\{t\}}$. It is shown in (Trenn (2009)) that $\mathcal{D}'_{pw\,reg} \subset \mathcal{D}'$, the representation is unique, (i) to (iv) are satisfied, and for measurable $M \subset \mathbb{R}$, $D = \tilde{f} + \sum_T D_t$ implies $D_M = \widetilde{f_M} + \sum_T \chi_M(t)\,\mathrm{d}t$.
For $D \in \mathcal{D}'_{pw\,reg}$, define $D[t] = D_{\{t\}}$ as D_t if $t \in T$ and zero else. Then $D[\cdot] = \sum_T D_t$ is the *impulsive part* of the distribution D.
Multiplication with piecewise smooth functions is well-defined (Trenn (2009)).
The class of piecewise smooth distributions is then defined and with the differentiation and multiplication defines an associative differential algebra. In Trenn (2009) it was argued that $\widetilde{\chi_{[t,\infty)}}\,\delta_t = \delta_t$ for all t corresponds with a causality condition, rendering the Cauchy initial value problem of an algebraic differential equation unique. While successful in switched behaviors with impulses (Trenn and Willems (2012)), the application of this multiplication to the Euler-Lagrange equation in multi-mode optimal control is inconsistent with the solution method that computes the set of optimal solutions in each domain, parameterized by the interface condition, and then determines the optimal parameters. This stems from the fact that the Euler-Lagrange and state equations constitutes a two-point boundary value problem and not an initial value problem. Hence *causality is not a concern*, and the solutions in the above extension of $\mathcal{D}'_{pw\,reg}$ will not solve the problem. The way out is to enlarge the set of distributions in the nonstandard sense. Indeed, Todorov (1990) proved the existence of a nonstandard function ${}^*\delta \in {}^*C_0^\infty$, such

that for all $\phi \in C^0$

$$\int_{^*\mathbb{R}} {}^*\delta(x)\, {}^*\phi(x)\, \mathrm{d}x = \phi(0).$$

This means that pointwise evaluation of a generalized distribution is possible. The next section uses some notions of non-standard analysis, see Goldblatt (1998). Essentially, just as Cantor's description of the reals is done by considering equivalence classes of Cauchy sequences of rationals, the hyperreals or non-standard reals are definable as equivalence classes (under a different equivalence relation) of sequences of reals. A sequence in $\mathbb{R}^{\mathbb{N}}$ will be denoted by $\{r_n\}_n$ or $\{r_n\}$.

4. KRYLOV SPACE

We review the formal construction in Hyun and Verriest (2017).

4.1 Krylov Hyperreals

The set of hyperreals, $^*\mathbb{R}$, defined in NSA is too large to be easily manageable. The redundancy of infinitesimals prevents the space from having a constructive property such as having a countable basis generating the hyperreals as a vector space over a field, $\mathbb{R}$. Therefore, we construct a countably infinite basis, which generates a reduced extension of the reals, denoted as $\mathbb{K}$.

Definition 1: Let $\alpha > 1$. A sequence $\langle r_n \rangle$ is called a $\mathbb{K}_i$-sequence if there exists $s \in \mathbb{R}$ such that $r_n = (\frac{1}{\alpha^{in}})s$ for all $n \in \mathbb{N}$.
This geometric form of the sequence is reminiscent of linear algebra where it would be called a Krylov sequence. We'll denote it by $\langle \frac{1}{\alpha^i}; s \rangle$. A set $\{x \in \mathbb{R} \,|\, x \text{ is a } \mathbb{K}_i\text{−sequence}\}$ is called $\mathbb{K}_i$ space. Thus $x \in \mathbb{K}_i$ means there exists $s \in \mathbb{R}$ such that $x = \langle \frac{1}{\alpha^i}; s \rangle$.
$\mathbb{K}_i$ is a one-dimensional vector space over $\mathbb{R}$ with property

$$\mathbb{K}_0 = \mathbb{R}, \quad \mathbb{K}_i \subset \mathrm{hal}(0),\ \forall i \in \mathbb{N} \setminus \{0\},$$

where $\mathrm{hal}(0) = \{\, b \in {}^*\mathbb{R} | b \text{ is infinitesimal} \,\}$ is the *halo* of zero, as defined in NSA. A convenient basis for $\mathbb{K}_i$ is the element $e_i = \left\langle (\frac{1}{\alpha})^i; 1 \right\rangle$. With the product defined above, we have $e_i \cdot e_j = e_{i+j}$ for all $i, j \in \mathbb{Z}$. With addition, the set $\mathbb{K}^N = \{x \in {}^*\mathbb{R} \,|\, x = \sum_{i=0}^{N} s_i e_i,\ \{s_n\}_{i=0}^{N} \subset \mathbb{R}\}$ is the direct sum vector space $\oplus_{i=0}^{N} \mathbb{K}_i$ with basis $\{e_i\}_{i=0}^{N}$.
The set $\mathbb{K} = \{x \in {}^*\mathbb{R} \,|\, x = \sum_{i=0}^{\infty} s_i e_i,\ \{s_n\}_{i=0}^{\infty} \in \ell_1\}$ is called the Krylov hyperreal space. In fact $\mathbb{K}$ is also a commutative ring, and the representation of $x^* \in \mathbb{K}$ with coordinates s_i is unique up to equivalence in $^*\mathbb{R}$. There are elements in the hyperreal space that are not elements of $\mathbb{K}$. However, the Krylov space is large enough to contain the reals and the infinitesimals. Given $t^* \in \mathbb{K}$ with representation $\{s_i\}_i \in \ell_1$, we shall refer to s_0 as the *sensible* time of t^*, and s_k, $k > 0$ as the *insensible* time of t^* with $1/\alpha^k$ as convergence rate.

4.2 Krylov Functions

Definition 2: A hyperreal function is a mapping $F : {}^*\mathbb{R} \to {}^*\mathbb{R}$ such that there exists a sequence $\{f_n\}_n \subset \mathbb{R}^{\mathbb{N}}$ an $t^* \in {}^*\mathbb{R}$ and $\sigma_{t^*} F \stackrel{\text{def}}{=} \langle f_n(t_n) \rangle$.
The restriction of F to the Krylov space $\mathbb{K}$ is called a *Krylov function*. We start with sequences of smooth real valued functions of the form $\langle h, S_\alpha h, S_\alpha^2 h, \ldots \rangle$ denoted as $\langle S_\alpha : h \rangle$, where $h : \mathbb{R} \to \mathbb{R}$ and S_α is the scaling operator, $\sigma_t(S_\alpha x) = \sigma_{\alpha t} x$, and take the closure under componentwise addition and multiplication

$$\langle S_\alpha; f \rangle + \langle S_\beta; g \rangle = \langle f + g, S_\alpha f + S_\beta g, S_\alpha^2 f + S_\beta^2 g, \ldots \rangle$$
$$\langle S_\alpha; f \rangle \cdot \langle S_\beta, g \rangle = \langle fg, S_\alpha f \cdot S_\beta g, S_\alpha^2 f \cdot S_\beta^2 g, \ldots \rangle.$$

Let σ_t be the evaluation functional on the class of regular functions $\forall t \in \mathbb{R} : \sigma_t h = h(t)$. The evaluation of a hyperfunction $\langle h_n \rangle$ at $t^* = \langle \gamma; t \rangle \in {}^*\mathbb{R}$ is the hyperreal $\langle h_1(t), h_2(\gamma t), h_3(\gamma^2 t), \ldots \rangle$ The Krylov space is the space of (equivalence classes) of such functions. A regular function, h is embedded in the space generated by Krylov sequences as the class of $\langle 1; h \rangle$. The idea is that a function of the form $f^* = \langle 1; f \rangle + \langle S_\alpha; g \rangle$ is a hyperfunction converging to f in a precise way determined by the rate α and shape g. The above defined hyperreal valued function is said to be in the halo of f, while f is the shadow of f^*. More generally, we have $\sigma_{\langle \beta; t \rangle} \langle f_0, f_1, f_2, \ldots \rangle = \langle f_0(t), f_1(\beta t), \ldots \rangle$, and $\sigma_{\langle 1; t_0 \rangle + \langle \beta; s_0 \rangle} \langle 1; f \rangle = \langle f(t_0 + s_0), f(t_0 + \beta s_0), f(t_0 + \beta s_0^2), \ldots \rangle$. The right limit of a regular function at t_0 is the shadow, $f(t_0+)$, if $s_0 > 0$ and $0 < \beta < 1$.

Consider now $u \in C^1(-1, 1))$, with $\lim_{t \to -1} u(t) = 0$, $\lim_{t \to 1} u(t) = 1$, and extend it to a $C^0(\mathbb{R})$ function, h, with $h(t) = 0$ for $t < -1$ and $h(t) = 1$ for $t > 1$. Then h is a model for the Heaviside function, which is defined as the generalized function $H_h = \langle S_\alpha; h \rangle$. If $t \in \mathbb{R}$, then $H_h(t)$ is the classical Heaviside function for all h. Evaluation at the infinitesimal time $\langle \frac{1}{\alpha}; \overline{t} \rangle$ gives $\sigma_{\langle \frac{1}{\alpha}; \overline{t} \rangle} \langle S_\alpha; h \rangle = \langle h(\overline{t}), \ldots, h(\overline{t}), \ldots \rangle = \langle 1; h(\overline{t}) \rangle$. On a microscopic scale, there are infinitely many Heaviside functions. Consequently, H_h^2 and H_h differ in insensible time, as they respectively give $h^2(\overline{t})$ and $h(\overline{t})$.
Similarly we can define H_h^+ by letting $h(t) = 0$ for $t \in (-1, 0]$ and $h(t) = 1$ for $t \in [0, 1)$. The derivative of H_h^+ is represented by the sequence $DH_h^+ = \langle \alpha; 1 \rangle \langle S_\alpha; Dh \rangle$. With $Dh(t) = h(t) - h(t-1)$, we see that in turn this can be made continuous by a regularization $\delta_{reg} = \langle S_\alpha; Dh \rangle_{reg} = \langle \alpha, 1 \rangle \langle S_\alpha; h_1 \rangle$ with $h_1 = S_\alpha(I - T_{-\alpha})h$. In turn, this gives for $D\delta_{reg}$ the k-th term in the sequence $DS_{\alpha^k}(I - T_\alpha)h = \alpha^k S_{\alpha_k}(I - T_{-\alpha})Dh$. Taking again the regularization $Dh = S_\alpha(I - t_{-\alpha})h$, we find $(D\delta_{reg})_{reg} = \langle \alpha^2; 1 \rangle \langle S_\alpha; S_\alpha(I - T_{-\alpha^2})(I - T_{-\alpha})h \rangle$. It is easily shown by induction that the regularized ℓ-th derivative of the delta corresponds to the generalized function $\langle \alpha^\ell; 1 \rangle \langle S_\alpha; S_{\alpha^\ell} \prod_{i=1}^{\ell} (I - T_{-\alpha^i})h \rangle$.

Alternatively, let $u \in C^\infty((0, 1))$ with again $u(1-) = 1$ and $u(0+) = 0$, and extend it to a Heaviside function. All derivatives are defined and regularization is no longer necessary. In this case the ℓ-th derivative of H_h is represented by $\langle \alpha^\ell; 1 \rangle \langle S_{\alpha^\ell}; D^\ell h \rangle$. Its evaluation at $^*t = \langle \frac{1}{\alpha^k}; \overline{t} \rangle$ is the smooth function $h(\overline{t})$ at level $k = \ell$, and 0 for the other cases.

5. MAIN RESULTS

Let $fg \in C^0$ and $F(t) = f(t) + g(t)H(t)$. The product $F(t)\delta$ is not defined as a Schwartzian distribution, but does in the Krylov sense.

Definition 3 The *impulsivity* of a generalized function ${}^*f$ at a point $t_0 \in \mathbb{R}$ is given by the integral $\int_{t_0-\langle\frac{1}{\alpha};1\rangle}^{t_0+\langle\frac{1}{\alpha};1\rangle} {}^*f(t)\,\mathrm{d}t = \langle \ldots, f_k(\frac{t-t_0}{\alpha^k})\,\mathrm{d}t, \ldots\rangle$.
For δ represented by $\langle\alpha;1\rangle\langle S_\alpha h'\rangle$, we find

$$\int_{\langle\frac{1}{\alpha};1\rangle}^{\langle\frac{1}{\alpha};1\rangle} {}^*\delta(t)\,\mathrm{d}t = \left\langle \ldots, \int_{-\frac{1}{\alpha^k}}^{\frac{1}{\alpha^k}} \alpha^k h'(\alpha^k t)\mathrm{d}t, \ldots \right\rangle = h(1) - h(-1) = 1.$$

It is well known that f is continuous at 0, then $f(t)\delta(t) = f(0)\delta(t)$ for any representation of the Heaviside function.

Theorem 1 The impulsivity of $f(t)\delta_h(t)$ with $f(t) \in C^0_{pw}$ is given by $\langle f\rangle_0 \stackrel{\text{def}}{=} \frac{1}{2}(f(0_-) + f(0_+))$.
Proof: It holds that there exists g and $k \in C^0$ and some $0 < \epsilon \in \mathbb{R}$ such that $f(t) = g(t) + k(t)H_h(t)$. Thus the impulsivity of $f(t)\delta_h(t)$ follows from

$$\begin{aligned}
&\int_{\langle\frac{1}{\alpha};1\rangle}^{\langle\frac{1}{\alpha};1\rangle} (g(t) + k(t)H_h(t))\delta_h(t)\,\mathrm{d}t \\
&= \left\langle \ldots, \int_{-\frac{1}{\alpha^k}}^{\frac{1}{\alpha^k}} \left(g(t) + k(t)h(\alpha^k t)\right)\alpha^k h'(\alpha^k t)\mathrm{d}t, \ldots \right\rangle \\
&= g(0) + \frac{1}{2}k(0)(h^2(1) - h^2(-1)) = \langle f\rangle_0.
\end{aligned}$$

Corollary On the sensible time scale $f(t)\delta(t)$ with $f \in C^0_{pw}$ is equivalent to $\langle f\rangle_0\delta(t)$, and using the shift property $f(t)\delta(t-t_0) = \langle f\rangle_{t_0}\delta(t-t_0)$.

If $x \in C^1$ with $x(t_0) = 0$ and $\dot{x}(t_0) \neq 0$, then it is known that $\delta(x(t) = \frac{\delta(t-t_0)}{|\dot{x}(t_0)|}$. The following theorem generalizes.

Theorem 2 Let $x \in C^1_{pw}(\mathcal{O}(t_0))$ where $\mathcal{O}(t_0)$ is a neighborhood of t_0, where $x(t_0) = 0$. Let x be transversal, i.e., $\dot{x}(0-)\dot{x}(0+) > 0$, then $\delta(x(t)) \approx \frac{\delta(t-t_0)}{\langle|\dot{x}|\rangle_{t_0}}$.
Here, $\langle x\rangle_{t+0}$ is the average $\frac{1}{2}(x(t_0-) + x(t_0+))$.
Proof: Use the fact that $x(t) = (t-t_0)(x_-(t)H(-t) + x_+(t)H(t))$ in a sufficiently small neighborhood of t_0 where $x_\pm \in C^1$ have the same sign. □

The solution of the ODE $\dot{x}(t) = Ax(t)\delta(t)$ is constant for $t > 0$ and $t < 0$. Its behavior at $t = 0$ is retrieved from the sequence of equations $\dot{x}_k(t) = A\alpha^k h'(\alpha^k t x_k(t))$, and leads to $x(0+) = \mathrm{e}^A x(0-)$, which is consistent with Nedeljkov and Oberguggenberger (2012), but differs from Trenn (2009).

Theorem 3 The standard optimal control problem sketched in the Introduction, with discontinuous cost rate and dynamics w.r.t. x has a jump in the costates when the interface is crossed given by

$$\Delta\lambda = -\frac{(\Delta L + \langle\lambda\rangle\Delta f)m}{\langle|m^\top f|\rangle}, \quad m = \left(\frac{\partial g}{\partial x}\right)^\top.$$

Proof: The Euler-Lagrange equation for the optimal control problem is given by

$$\dot{\lambda} = -\frac{\partial L(x,u)}{\partial x}^\top - \lambda^\top f(x,u).$$

Since L and f are discontinuous when $g(x) = 0$, the right hand side of the EL is singular (as function of x). Hence also the left hand side must have a singularity. However, the latter is with respect to the time t. It is therefore necessary to express $\delta(g(x))$ in terms of a delta with respect to time. But precisely because of this dependency, x, and thus also $g(x)$ have a discontinuous derivative when $g(x) = 0$. Thus Theorem 2 applies. Likewise, the singularity in $\frac{\partial f}{\partial x}$ is multiplied by $\lambda^\top$ which has a jump when $g(x) = 0$. Here Theorem 1 applies. Combining and integrating over time in an infinitesimal interval across the discontinuity yields the result. □
The traditional "two-domain" method of solving the problem, keeping the cross-over point and time as parameters to be optimized, is now replaced by a non-linear equation.

Abstract:
The quantification of controllability has gained renewed interest in the context of large, complex network dynamical systems. In some application areas such as computational neuroscience, there is a large interest in modal controllability, which describes the ability of an input to control the modes of a system. In case of a linear system, the modes of the system are given by the left eigenvectors associated with the system matrix. In this work, we identify mode specific and gross metrics for modal controllability for discrete linear time invariant systems. Our metrics are based on energy requirements to move along a given mode and find applications in problems involving selection of driver nodes for minimizing control effort along particular modes of the network. We conclude by studying the properties of the metrics.

Keywords: modal controllability, network control, large scale systems, control energy

1. INTRODUCTION

In recent years, with the development of parallel and decentralized algorithms, there has been a renewed interest in the study of network systems. Such systems appear frequently in the analysis of power grids, infrastructure networks, brain networks, and even social networks. In systems of this scale, simply answering the question of whether a system is controllable or not is not sufficient, as the energy requirements to control such a system can in some cases be impractical, especially when the size of the network is large. To analyze systems from an energy perspective, several measures have been proposed based on spectral properties of controllability gramian, such as minimum eigenvalue(Yan et al. (2012); Pasqualetti et al. (2014)), trace of inverse (Summers et al. (2016)), trace (Summers and Lygeros (2014)), and determinant(Cortesi et al. (2014)) of controllability gramian.

Modal analysis continues to be a strong tool to analyze linear systems. Classically, the study of controllability from a modal perspective involves the identification of controllable and uncontrollable modes. There are two main motivations to consider a modal analysis for large network systems. Firstly, in large networks, the system matrices may not be well-conditioned; therefore, it may be difficult to analyze the system as a whole. Such systems can be divided into modes, and each mode can be analyzed separately. Since each mode has unique conditioning, it is possible to perform a modal analysis. Secondly, in large systems, it is possible that one may be interested in particular modes of the system(for example, the unstable modes or the mode associated with the dominant eigenvalue) and not actually interested in the behavior of the entire system. The overwhelming majority of literature on this topic emphasizes the controllability/lack thereof for the system. Notably, the tests for controllability (Hespanha (2018)), such as Popov-Belevitch-Hautus (PBH) test and Eigenvector test, offer a qualitative measure of controllability. Here, we focus on a quantitative measure for modal controllability, which is important in practical situations due to the limitations of physical components in large scale networks.

To our knowledge, there are two metrics proposed in the literature to measure modal controllability. In Hamdan and Nayfeh (1989), it is proposed that the the cosine of the angle between a mode and the input vector be used as a metric. The argument to use this metric is based on the fact that an increase in the mentioned angle from 0 to 90 degrees leads to a decrease in controllability, with the system losing controllability at an angle of 90 degrees. The authors claims that the use of cosine of the angle is seen as an extension to the PBH test. While this metric accounts for the variance in modal controllability due to the angle between the mode and the input vector, it does not account for the eigenvalue associated with the mode. Due to this, this metric is unable to deal with the analysis of a set of modes. A more recent metric (Pasqualetti et al. (2014)) is based on the ability to maximize the reachability of difficult to reach states. This metric is based on a heuristic and has gained some traction in neuroscience based applications(Gu et al. (2015)).

In this abstract, we define a new metric for modal controllability based on optimal energy requirements to control a system along with a particular mode. We analyze this metric and identify the driver nodes in a network that minimize the energy requirements to move along a mode. We also identify the modes that are the easiest to control

from a given set of driver nodes. Unlike previous metrics, our metric also has a normalization factor that allows the comparison of energy requirements across modes.

The paper is organized as follows. We discuss some preliminary theory in Section 2. We propose our new metric in Section 3. In Section 4, we analyze the metric and study how it varies with varying system parameters. Finally, we conclude in Section 5.

Notation: We denote the set of real numbers by $\mathbb{R}$. $\mathbb{R}^{n\times m}$ denotes the set of matrices of dimension $n \times m$. For any matrix $A \in \mathbb{R}^{n\times m}$, $A' \in \mathbb{R}^{m\times n}$ denotes the transpose of matrix A. We also denote the j^{th} column of A as $\mathbf{a}_j$. The symbol $\mathbf{1}_n$ denotes a vector in $\mathbb{R}^n$, with all entries as 1. We define the norm of a vector $\mathbf{v} \in \mathbb{R}^n$ as $\|\mathbf{v}\| = \sqrt{\mathbf{v}'\mathbf{v}}$.

2. PRELIMINARIES

2.1 Linear Systems Theory

We represent a discrete linear time invariant system (D-LTI system) by

$$\mathbf{x}^+ = A\mathbf{x} + B\mathbf{u}. \tag{1}$$

where, $\mathbf{x} \in \mathbb{R}^n$ represents the state of a system, $A \in \mathbb{R}^{n\times n}$ is the system matrix, and $B \in \mathbb{R}^{n\times m}$ is termed as an input matrix. $\mathbf{u} \in \mathbb{R}^m$ is the control input.

In the special case of networked control systems, the input matrix may be denoted by $B_{\mathcal{K}}$, whose columns correspond to the canonical vectors associated with the input/driver nodes in the network. Further, in network systems, the matrix A represents the adjacency matrix of the network.

If the eigenvalues and both left and right eigenvectors of A can be computed, they contain a lot of information that describes the system in certain circumstances. For example, we may be interested in the dominant eigenvalue, and its associated eigenvector. In a case where the system matrix A is doubly stochastic, the dominant mode is along the vector $\mathbf{1}_n$. Here, controlling the system along this mode could be used to influence the average state of all nodes. As discussed in Bullo (2022), such systems appear in applications such as cyclic pursuit in robotic networks, wireless sensing networks and animal flocking behaviour analysis. For the purpose of modal analysis, the eigenvalues for A must not only be distinct, but A should also be well conditioned. For matrices which have a mixture of both well conditioned and ill conditioned eigenvalues, we limit our methods to the well conditioned eigenvalues.

Assuming A is sufficiently well conditioned, and has distinct eigenvalues, we consider the left eigenvectors of A as the modes of the system, similar to Hamdan and Nayfeh (1989). To guarantee uniformity across modes, we scale the left eigenvectors to ensure their norm is unity.

2.2 Controllability Gramian

The PBH test(Hespanha (2018)) provides a qualitative result, i.e. it does not quantify the difficulty in controlling a system. In large scale systems, a binary answer, of whether or not the system is controllable, may not be sufficient as there may be practical constraints on the input energy. In literature, several metrics have been proposed based on controllability gramian, to quantify the control energy (Müller and Weber (1972); Cortesi et al. (2014)). For the D-TI system described in Equation (1),the controllability gramian is given by

$$W_c(T) = \sum_{\tau=0}^{T} A^\tau BB'(A')^\tau.$$

We note that the minimum energy required to drive a linear system from the origin to a point x_f, in time horizon T is given by

$$E = \mathbf{x}_f' W_c^{-1}(T)\mathbf{x}_f,$$

2.3 Modularity

In our work, we are concerned with the selection of the set of best driver nodes to control a mode, and the set of modes that are easiest to control from a set of inputs. We formulate both problems as set function optimization problems. In this regard, we define modular set function as follows:

Definition 2.1 (Lovász (1983))**.** *Let V be a set. A set function $f : 2^V \to \mathbb{R}$ is said to be modular if and only if for any subset $S \subseteq V$, it can be expressed as*

$$f(S) = a(\phi) + \sum_{i\in S} a(i) \tag{2}$$

for some weight function $a : V \to \mathbb{R}$ and ϕ denoting the null set.

Optimization problems involving the selection of a subset $S \subseteq V$ in order to maximize or minimize a modular function can be solved via a sorting algorithm.

2.4 An extension to Cauchy Schwarz inequality

To motivate our arguments, we use an extension to Cauchy Schwarz inequality.

Lemma 2.1. *Consider a symmetric, positive definite matrix $Q \in \mathbb{R}^{n\times n}$. For any $\mathbf{x} \in \mathbb{R}^n, \|\mathbf{x}\| = 1$, we have*

$$\mathbf{x}'Q\mathbf{x}\mathbf{x}'Q^{-1}\mathbf{x} \geq 1.$$

Proof. Since Q is positive definite and symmetric, it can be diagonalized by an orthogonal matrix (Horn and Johnson (2012)), i.e,

$$Q = P'DP, \quad \text{and}$$
$$Q^{-1} = P'D^{-1}P.$$

where P is orthogonal. Orthogonal matrices preserve norms, so $\|P\mathbf{x}\| = 1$. Let $\mathbf{y} = P\mathbf{x}$. The LHS of our inequality is now reduced to

$$\mathbf{y}'D\mathbf{y}\mathbf{y}'D^{-1}\mathbf{y} = \sum_{i=0}^{n} d_i\mathbf{y}_i^2 \sum_{i=0}^{n} \frac{\mathbf{y}_i^2}{d_i},$$

where d_i is the i^{th} diagonal element of D.
Since Q is positive definite, $d_i > 0$, and since $\|\mathbf{y}\|_2 = 1$, $\sum_{i=1}^{n} \mathbf{y}_i^2 = 1$. Applying Cauchy-Schwarz,

$$\sum_{i=0}^{n} d_i\mathbf{y}_i^2 \sum_{i=0}^{n} \frac{\mathbf{y}_i^2}{d_i} \geq \sum_{i=1}^{n} \frac{\sqrt{d_i}}{\sqrt{d_i}}\mathbf{y}_i^2 = 1.$$

3. PROPOSED METRIC FOR MODAL CONTROLLABILITY

In this section, we propose modal controllability metrics for D-LTI systems.

Theorem 3.1. *Let us consider a discrete time LTI system* (1) *and assume* (A, B) *is controllable. Let* $\mathbf{v}_i$ *be a left eigenvector of* A*, associated with the eigenvalue* λ_i*. Let the optimal energy required to traverse one unit in the direction of* $\mathbf{v}_i$ *be* E_i*, for a time horizon* t*, starting from the origin. Then,*

$$E_i \geq \left(\mathbf{v}_i' BB' \mathbf{v}_i \frac{1-\lambda_i^{2(t+1)}}{1-\lambda_i^2} \right)^{-1}.$$

Proof. The optimal control energy for a system to reach $\mathbf{v}_i$ starting from the origin is given by

$$E_i = \mathbf{v}_i' W_c^{-1}(t) \mathbf{v}_i,$$

where W_c is the controllability gramian. Since (A, B) is controllable, the controllability gramian is symmetric and positive definite. By Lemma 2.1, we have.

$$E_i \mathbf{v}_i' W_c(t) \mathbf{v}_i \geq 1. \tag{3}$$

The controllability gramian, for a time horizon t is given by ,

$$W_c(t) = \sum_{k=0}^{t} A^k BB' (A')^k.$$

Therefore,

$$\begin{aligned} \mathbf{v}_i' W_c(t) \mathbf{v}_i &= \mathbf{v}_i' \left(\sum_{k=0}^{t} A^k BB' (A')^k \right) \mathbf{v}_i \\ &= \sum_{k=0}^{t} \mathbf{v}_i' A^k BB' (A')^k \mathbf{v}_i \\ &= \mathbf{v}_i' BB' \mathbf{v}_i \sum_{k=0}^{t} \lambda_i^{2k}. \end{aligned}$$

The theorem follows from Equation (3) and the above equation. □

Based on this theorem, we define a metric for discrete time systems. We consider the following metric M_i^d to control the i^{th} mode from the given input matrix B, for a time horizon t,

$$M_i^d(t) = \left(\mathbf{v}_i' BB' \mathbf{v}_i \frac{1-\lambda_i^{2(t+1)}}{1-\lambda_i^2} \right)^{-1}.$$

We extend this metric to quantify the difficulty of controlling multiple modes as follows:

Corollary 3.1. *For the setup described in Theorem 3.1, we have*

$$\sum_{i \in \mathcal{T}} E_i \geq \sum_{i \in \mathcal{T}} \left(\mathbf{v}_i' BB' \mathbf{v}_i \frac{1-\lambda^{2(t+1)}}{1-\lambda_i^2} \right)^{-1}.$$

The proof for this statement follows from the theorem, by summing across modes. Subsequently, we define the following metric across modes. For a given set of modes, $\mathcal{T}$ and a time horizon t, we have,

$$M^d(\mathcal{T}, t) = \left(\sum_{i \in \mathcal{T}} \frac{1}{M_i^d(t)} \right)^{-1}.$$

In the limiting case, as $t \to \infty$, when A is stable, we have,

$$\sum_{i \in \mathcal{T}} E_i \geq \sum_{i \in \mathcal{T}} \left(\mathbf{v}_i' BB' \mathbf{v}_i \frac{1}{1-\lambda_i^2} \right)^{-1},$$

where the inequality follows as finite horizon energy control is always higher than the infinite horizon case.

4. DISCUSSION

4.1 Factors affecting the metric

A lower bound for the energy required to control a mode is inversely related to $\mathbf{v}_i BB' \mathbf{v}_i$. Since the eigenvector $\mathbf{v}_i$ is normalized, this term only depends on the magnitude of the columns in the input matrix, and the angle between the column of the input matrix and the eigenvector. This is in line with the PBH test, as when the two vectors are orthogonal, the system is uncontrollable.

Further, a key feature of our metric is the ability to compare the ease of controlling a system across modes. This allows us to study optimization problems where we consider the optimization of the ease of control across a range of modes. Specifically, in the discrete case, we note that modes with eigenvalues closer to unity are easier to control. This is in part due to the natural response of the system. This result is consistent with the findings in Lindmark and Altafini (2018) for the case of continuous time systems.

4.2 Similarity to past metrics

In Hamdan and Nayfeh (1989), the cosine of the angle between an input column and the modal vector is defined as a metric. Our metric is strongly correlated with that metric, but our metric has the added benefit of allowing comparison across modes. Specifically, while considering the modal controllability of the i^{th} mode from the j^{th} input column, if we consider the metric in Hamdan and Nayfeh (1989), it is given by $\cos(\theta)_{ij}$. Whereas our metric for controlling the i^{th} mode from the j^{th} input is :

$$M_i = \frac{\|\mathbf{b}_j\|^2 \cos^2(\theta)_{ij}}{1-\lambda_i^2},$$

where $\mathbf{b}_j$ is the j^{th} input, and λ_i is the eigenvalue associated with the i^{th} mode.

4.3 Similarity to eigenvector centrality

We extend our ideas to linear network systems, by studying the relationship between our metric and the eigenvector centrality measure. In network science, there are several centrality measures (Bullo (2022)) such as degree, pagerank, and eigenvector centrality among others. Specifically we focus on the eigenvector centrality measure. The eigenvector centrality measure computes the influence of a node in a network. In practice, this centrality measure can be represented by the entries of the dominant eigenvector of the adjacency matrix. Specifically, if the dominant

eigenvalue is λ, and the associated eigenvector is $\mathbf{v}$, the centrality measure of the i^{th} node is given by $\mathbf{v}_i$. In the case of linear network systems, each column of the B matrix is a canonical vector. Therefore, our metric for infinite horizon, for the control of the dominant mode from the i^{th} input reduces to

$$M_{dom} = \frac{\mathbf{v}_i^2}{1-\lambda^2}. \tag{4}$$

We show that this is true for a 100 node Erdos-Renyi random network (Erdos et al. (1960)), by plotting M_{dom} against the eigenvector centrality in Fig. 1.

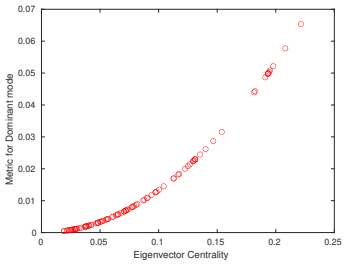

Fig. 1. The eigenvector centrality is related to the metric for the dominant mode for the i^{th} node as input as per Equation (4).

4.4 Modularity of the metrics

We now discuss the modularity properties of our proposed metrics.

Theorem 4.1. *For a given mode i, associated with the eigenvector $\mathbf{v}_i$, the function*

$$f(\mathcal{K}) = \mathbf{v}_i B_{\mathcal{K}} B_{\mathcal{K}}' \mathbf{v}_i \frac{1}{1-\lambda_i^2}.$$

is modular in $\mathcal{K}$.

Proof. Since each column in $B_{\mathcal{K}}$ is a canonical vector of dimension n, $B_{\mathcal{K}} B_{\mathcal{K}}' = \sum_{j\in\mathcal{K}} \mathbf{b}_j \mathbf{b}_j'$, our function reduces to

$$f(\mathcal{K}) = \sum_{j\in\mathcal{K}} \mathbf{v}_i' \mathbf{b}_j \mathbf{b}_j' \mathbf{v}_i \frac{1}{1-\lambda_i^2}.$$

Using Definition 2.1, the function is modular in $\mathcal{K}$. □

4.5 The case of Complex Modes

In general the system matrix A may have both real and complex eigenvalues and eigenvectors. Here, we briefly discuss the equivalent theory for complex modes. Using a similar line of arguments, and replacing the transpose operation with the conjugate transpose operation, the results and inequalities can be extended to modes with both real and imaginary components. For D-LTI systems,

$$M_i^d(t) = \left(\mathbf{v}_i^* B B^* \mathbf{v}_i \frac{1-|\lambda_i|^{2(t+1)}}{1-|\lambda_i^2|} \right).$$

5. CONCLUSION

We have considered the problem of modal controllability for networked systems. We propose an energy related metrics, for discrete LTI systems, which serves as a lower bound for the control effort required to move along a given mode. We analyze the metric by studying its relationship with existing metrics and other centrality measures, showing that it is closely related to the eigenvector centrality. We also formulate two problems regarding the optimization of the metrics, in an effort to minimize the control effort required for the control of a network along particular modes. Our approach to solve these problems are illustrated using a numerical example using the topology of a power grid.

Abstract: The study of Optimal Polynomial Approximants (OPAs) in weighted Dirichlet-type spaces has seen a great deal of success in the past decade. In more than one variable, not as much is known, and the failure of the famous *Shanks Conjecture* shows that there may be issues with the typical Drury-Arveson approach.
A potential remediation is to recast the multivariable into the noncommutative setting where the deficiencies of the Drury-Arveson space are not found. This paper outlines the introductory ideas behind noncommutative Optimal Polynomial Approximants, as well as a couple of tangible conjectures and potential approaches inspired by classical techniques in the freely noncommutative setting.

Keywords: Optimal Polynomial Approximants, Noncommutative Polynomials, Realizations, Row Ball, Shanks Conjecture, Fock Space

AMS Subject Classification: 47A56, 30H20

1. INTRODUCTION

In the last decade, there has been considerable mathematical literature produced about optimal polynomial approximants in connection with Hilbert spaces of analytic functions (of one or several variables) – Bénéteau and Centner (2021); Bénéteau et al. (2013, 2018, 2016a); Sargent and Sola (2020a,b) to name a few. Recall the Hardy space H^2 is the space of functions $f(z) = \sum_{k=0}^{\infty} a_k z^k$ analytic in $\mathbb{D}$, the unit disk, such that $\|f\|^2 = \sum_{k=0}^{\infty} |a_k|^2 < \infty$. We define an inner-product for H^2 by $\langle f, g\rangle := \sum_{k=0}^{\infty} a_k \overline{b_k}$, where $g(z) = \sum_k b_k z^k$. Given a nonzero function $f \in H^2$ and $n \in \mathbb{N}$, we define the n^{th} **optimal polynomial approximant** (OPA) of $1/f$ in H^2 to be the polynomial q_n that minimizes $\|pf - 1\|$ among all polynomials p of degree at most n. While only presented here in terms of the Hardy space, OPAs have undergone considerable investigation in terms of Dirichlet-type Hilbert spaces.

Another related and highly studied idea are cyclic functions Bénéteau et al. (2016b, 2013, 2015). A function $f \in H^2$ is **cyclic** if $\{pf : p \in \mathbb{C}[z]\}$ is dense in H^2. It turns out that a function f is cyclic if and only if the OPAs q_n of f satisfy $\|q_n f - 1\| \to 0$ as $n \to \infty$. Thus, we can study cyclic functions via OPAs and vice versa.

A strange occurrence in commutative functional analysis in several variables is that while analogues of many classical Hardy space results can be found, their proofs often balloon in complexity or in the use of novel proof techniques. One explanation can be found in Jury and Martin (2020): with the Hardy space in one variable, multiplication by z is the *shift operator* and is an isometry. Moreover, every isometry is unitarily equivalent to a direct sum of shifts and a unitary operator. However, the natural multivariable generalization of the Hardy space is the Drury-Arveson space, where the appropriate analogue of the shift is the Arveson d-shift $S := (S_1, \ldots, S_d)$ with $S_i f = z_i f$. Notably, the Arveson d-shift is no longer a (row) isometry, but rather a (row) partial isometry, which is the source of many defects moving from one to several variables. In Jury and Martin (2020), the authors correctly identify the spiritual successor of the Hardy space shift in several variables: the left free shift on the full Fock space. Their choice is justified by the strength of their conclusions: multivariable generalizations of Hardy space theorems that also persist under compression to commuting variables.

Recall that $\mathbb{C}\langle x\rangle$ is the free algebra in d freely noncommuting indeterminates. We make $\mathbb{C}\langle x\rangle$ into a pre-Hilbert space by choosing the free monoid $\langle x\rangle$ to be an orthonormal basis. That is, if $w_1 = x_{i_1} \ldots x_{i_n}$ and $w_2 = x_{j_1} \ldots x_{j_m}$, then $\langle w_1, w_2\rangle$ equals 1 if $n = m$ and $i_k = j_k$, and it equals 0 otherwise. The **full Fock space** in d-letters $\mathcal{F}_d$ is the completion of $\mathbb{C}\langle x\rangle$ with respect to this inner product. The **left creation operators** $L_1, \ldots, L_d$ are natural analogues of the Hardy space shift in the sense that if $f \in \mathcal{F}_d$, then $L_j f = x_j f$ – naturally, we can also define the *right creation operators* as $R_j f = f x_j$. The **left free shift** is the tuple $L = (L_1, \ldots, L_d)$; L is a row isometry, and given any row isometry, it is isomorphic to the direct sum of copies of L and a row unitary. Moreover, it has been well established in the noncommutative function theory literature Agler

and McCarthy (2015); Popescu (2006, 2010); Jury et al. (2021a,b) as well as in terms of noncommutative reproducing kernel Hilbert spaces Ball et al. (2016) that $\mathcal{F}_d$ is canonically isomorphic to the free Hardy space, $H^2(\mathbb{B}_{\mathbb{N}}^d)$ of noncommutative or free holomorphic functions on a certain noncommutative multivariable open unit ball, $\mathbb{B}_{\mathbb{N}}^d$.

With respect to generalizing OPAs to several variables, as we see from above, the full Fock space is a more faithful multivariable generalization of the Hardy space. Moreover, the recent papers Jury et al. (2021a,b) fully characterize cyclic functions in $\mathcal{F}_d$. A function $f \in \mathcal{F}_d$ is **cyclic (for the left free shift)** if its left polynomial multiples have dense range in $\mathcal{F}_d$ if and only if $f(X)$ is nonsingular for all X in the row ball. That is, the function f has no singularities in the unit ball, a condition that is reminiscent of the situation in the classical Hardy space.

We now arrive at the notion of a noncommutative optimal approximant: given nonzero $f \in \mathcal{F}_d$ and $n \in \mathbb{N}$, the n^{th} left nc optimal polynomial approximant (nc OPA) of $1/f$ is the free polynomial p_n that minimizes the norm $\|pf - 1\|_{\mathcal{F}_d}$ among all free polynomials p of degree at most n. Note that in every practical sense, the theory of left nc OPAs is identical to the theory of right nc OPAs. Taking advantage of the theory of reproducing kernels for NC functions, we arrive at the following natural generalization of a classical result.

Conjecture 1. Suppose f is a free polynomial that is cyclic for the left free shift. If p_n is the (left) nc OPA of $1/f$ and $p_n(\Lambda) = 0$ for some matrix tuple $\Lambda = (\Lambda_1, \ldots, \Lambda_d)$, then $\|\Lambda_1 \Lambda_1^* + \cdots + \Lambda_d \Lambda_d^*\| > 1$.

At the time of writing this abstract, the conjecture above remains open. However, the novel techniques used in investigating the conjecture have already borne fruit in the commutative setting:

Theorem 2. Suppose f is a commutative polynomial that is cyclic for the Drury-Arveson d-shift. If q_n is the n^{th} OPA of $1/f$ in the Drury-Arveson space, then q_n has no zeros in the row ball.

That is, the row ball version of the *Shanks Conjecture* holds.

Noncommutative arguments can often be obtained from single variable proofs by generalizing the proof with "one hand tied behind your back," i.e. making no use of commutativity. These nc arguments often generalize readily to several variables. One distinct occasion where this fails, is when the commutative argument takes advantage of factoring, since in the noncommutative setting factoring is often not possible e.g. $x_1x_2x_1 + x_2$ is irreducible when x_1 and x_2 do not commute. However, the resolution to this problem is something called *stable associativity* – see Cohn (2006). Two free polynomials f and g are **stably associated**, if there exist $m \in \mathbb{Z}^+$ and $P, Q \in \mathrm{GL}_{m+1}(\mathbb{C}\langle x \rangle)$ such that

$$P(f \oplus I_m) = (g \oplus I_m)Q.$$

For example, xy and yx are stably associated. While stable associativity seems like an inconvenience, it does have advantages: every atomic (cannot be decomposed as a nontrivial product of free polynomials) free polynomial f with $f(0) = I$ is stably associated to an irreducible monic linear pencil $\mathcal{L}$. This is incredibly appealing, since monic linear pencils are remarkably well-studied Klep and Volčič (2017); Klep et al. (2016); Helton et al. (2017). If we are able to extend our notions of nc OPAs to matrix valued functions, then every problem can be stated in terms of an affine-linear (matrix-valued) polynomial. Thus, we are led to a pair of questions.

Problem 1. What properties of nc OPAs are preserved under stable associativity?

Problem 2. Can nc OPAs be generalized to matrix-valued free polynomials? If so, what properties are preserved under stable associativity?

Abstract: A recent result in (Incremona et al., 2022) put forward an architecture of internal model based controllers, in which the stabilizer can be fully separated from the internal model. In this paper we propose a parametrized implementation of this controller, which isolates a parameter shaping properties of the exosystem. We show that with this implementation the closed-loop dynamics have an affine dependence on the parameter. As such, the closed-loop system remains stable even under arbitrary variations of the parameter, as long as it remains bounded. We demonstrate that this property is beneficial for adding an adaptation mechanism to adjust parameters of the internal model.

Keywords: Regulator problem, Internal Model Principle, adaptive control.

1. INTRODUCTION

Consider the plant

$$\dot{x}(t) = Ax(t) + Bd(t) + Bu(t), \tag{1}$$

where $x(t) \in \mathbb{R}^n$ is its measurable state, $u(t) \in \mathbb{R}^m$ is a control input, and $d(t) \in \mathbb{R}^m$ is a load (matched) disturbance. We assume that the disturbance is generated by the *exosystem*

$$\begin{cases} \dot{x}_{\rm ex}(t) = A_{\rm ex}x_{\rm ex}(t), \quad x_{\rm ex}(0) = x_{\rm ex,0} \\ d(t) = C_{\rm ex}x_{\rm ex}(t) \end{cases} \tag{2}$$

for known $A_{\rm ex}$, assumed to possess no open left half-place eigenvalues, and $C_{\rm ex}$ and an unknown initial condition $x_{\rm ex,0}$. The control goal is to have an asymptotic rejection of every disturbances of this class, i.e. $\lim_{t\to\infty} x(t) = 0$. This is a particular case of the classical regulator problem, see (Saberi et al., 2000; Isidori, 2017) and the references therein.

The regulator problem can be solved via the use of the internal model principle of Francis and Wonham (1975). A conventional modus operandi is to transplant a model of exosystem (2), known as an *internal model*, into the feedback loop and then stabilize the *augmented system*, comprising both the plant and the internal model. The internal model needs to have the eigenvalues of $A_{\rm ex}$ as its poles, but the choice of its other properties is more flexible and can be adjusted to a concrete architecture. This procedure is well understood in the linear case, even for a more general setup than that described above.

Arguably, one of main shortcomings of the design procedure outlined above is the need to design the stabilizing part of the controller for augmented dynamics. This is not a serious issue if (2) is low dimensional, but might become a problem for more complex exosystems, like those used in repetitive control (Longman, 2010). Moreover, changes in parameters of the internal model necessitate a redesign of the stabilizer. This could substantially complicate the employment of various adaptation methods and deter from the use of high-order models, which could be useful in reducing the sensitivity to small deviations of d from its modeled version (Singhose, 2009).

An alternative approach to incorporate internal models into the feedback loop was put forward in (Incremona et al., 2022). Its essence is the use of an "internal model compensation" element in addition to the internal model itself, inspired by the delay compensation idea in (Mirkin, 2020) for repetitive control. This addition enables a complete separation of the stabilizer, which should be designed only for the unaltered plant (1), from the internal model.

Circumventing the need to deal with augmented dynamics simplifies the design of the stabilizer, it can be a static state feedback in the studied case. Yet the dependence of the resulting controller on parameters of the exosystem is still complex, which hampers adjusting those parameters. The goal of this paper is to propose an alternative implementation of the controller of (Incremona et al., 2022), in which parameters of the exosystem that shape its properties, like oscillation frequencies, can be isolated. The proposed architecture simplifies the controller implementation and, more importantly, substantially simplifies the dependence of the closed-loop dynamics on those parameters. Specifically, we show that the dependence of the closed-loop system on those parameters is affine. As a result, the closed-loop stability is maintained even if parameters of the internal model are tuned, provided they remain bounded.

This result paves the way to incorporating adaptation mechanisms, whose purpose is to tune the model to uncertain / changing exosystems. We demonstrate the usefulness of the proposed

architecture by presenting an adaptation mechanism, which ensures the global convergence and asymptotic attenuation of a given class of disturbances under arbitrary unknown parameters of the disturbance model.

Notation Given a full column rank matrix $M \in \mathbb{R}^{n\times m}$, its left inverse is denoted as $M^{\#} \in \mathbb{R}^{m\times n}$, so $M^{\#}M = I$. We use the compact notation

$$\left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right] := D + C(sI - A)^{-1}B$$

for transfer functions in terms of their state-space realizations. The lower linear-fractional transformation

$$\mathcal{F}_{\mathrm{l}}\left(\begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{21} & \Phi_{22} \end{bmatrix}, \Omega\right) := \Phi_{11} + \Phi_{12}\Omega(I - \Phi_{22}\Omega)^{-1}\Phi_{21},$$

see (Zhou et al., 1996, Ch. 10) for its properties.

2. PARAMETRIZATION OF THE INTERNAL MODEL

We start with fixing the structure of the control law in the form

$$u = M(v + R_{\mathrm{stab}}x). \tag{3}$$

Here M is an internal model, whose poles coincide with those of exosystem (2), R_{stab} is a stabilizer, whose purpose is naturally to stabilize the closed-loop system, and v is a signal that can be used to introduce a reference signal. We assume that

$\boldsymbol{\mathcal{A}_1}$: $M(\infty) = I$ and $M^{-1} \in H_\infty$,

which is required by the design procedure of (Incremona et al., 2022) and entails no loss of generality (it does not affect poles).

A key component of the proposed approach is a special parametrization of the internal model in the form

$$\begin{aligned} M^{-1}(s) &= \left[\begin{array}{c|c} A_0 & B_0 \\ \hline C_{01} & I \end{array}\right] + \Theta \left[\begin{array}{c|c} A_0 & B_0 \\ \hline C_{02} & 0 \end{array}\right] \\ &= \mathcal{F}_{\mathrm{l}}\left(\left[\begin{array}{c|cc} A_0 & B_0 & 0 \\ \hline C_{01} & I & I \\ C_{02} & 0 & 0 \end{array}\right], \Theta\right) \end{aligned} \tag{4}$$

for a real parameter Θ and a Hurwitz A_0. In the SISO case this implies that we assume that the denominator of $M(s)$ is an affine function of parameters and its numerator is Hurwitz and does not depend on these parameters. In general, Θ shapes the spectrum of A_{ex} in (2). To see that, note that

$$\begin{aligned} M(s) &= \mathcal{F}_{\mathrm{l}}\left(\left[\begin{array}{c|cc} A_0 - B_0C_{01} & B_0 & -B_0 \\ \hline -C_{01} & I & -I \\ C_{02} & 0 & 0 \end{array}\right], \Theta\right) \\ &= \left[\begin{array}{c|c} A_0 - B_0(C_{01} + \Theta C_{02}) & B_0 \\ \hline -C_{01} - \Theta C_{02} & I \end{array}\right], \end{aligned}$$

which follows from (Zhou et al., 1996, Lem. 10.3). This naturally leads to the assumption that

$\boldsymbol{\mathcal{A}_2}$: $A_{\mathrm{ex}} = A_0 - B_0(C_{01} + \Theta C_{02})$ and $C_{\mathrm{ex}} = -C_{01} - \Theta C_{02}$,

which shall guarantee that the internal model solves the regulator problem.

Representation (4) is related to the representation of an exosystem in (Nikiforov, 1997). A difference is that we *assume* this form of the internal model, whereas it was derived in (Nikiforov, 1997, Lem. 3.1) as an asymptotic model for a general SISO exosystem.

To provide a flavor of this structure, consider a couple of simple examples. First, if $d(t) = a\sin(\omega t + \phi)$ with a known frequency $\omega > 0$ and unknown amplitude a and phase ϕ, then a general internal model satisfying $\boldsymbol{\mathcal{A}_1}$ is $M(s) = \phi(s)/(s^2 + \omega^2)$ for an arbitrary second-order Hurwitz and monic polynomial $\phi(s)$. In this case

$$M^{-1}(s) = \frac{s^2}{\phi(s)} + \frac{\Theta}{\phi(s)} = \mathcal{F}_{\mathrm{l}}\left(\begin{bmatrix} s^2/\phi(s) & 1 \\ 1/\phi(s) & 0 \end{bmatrix}, \Theta\right) \tag{5}$$

under $\Theta = \omega^2$.

The case of two harmonics, say with frequencies $\omega_1 > 0$ and $\omega_2 > 0$, is perhaps less obvious. For example, the sum of two harmonic oscillators as above does not fit into (4), because the parameters (frequencies) affect its numerator as well. But it is not hard to see that $M(s) = \phi(s)/((s^2 + \omega_1^2)(s^2 + \omega_2^2))$ for an arbitrary fourth-order Hurwitz and monic $\phi(s)$ is an admissible choice. It corresponds to

$$\begin{aligned} M^{-1}(s) &= \frac{s^4}{\phi(s)} + \frac{(\omega_1^2 + \omega_2^2)s^2 + \omega_1^2\omega_2^2}{\phi(s)} \\ &= \mathcal{F}_{\mathrm{l}}\left(\left[\begin{array}{c:c} s^4/\phi(s) & 1 \\ \hdashline s^2/\phi(s) & 0 \\ 1/\phi(s) & 0 \end{array}\right], \Theta\right) \end{aligned}$$

under $\Theta = \begin{bmatrix} \omega_1^2 + \omega_2^2 & \omega_1^2\omega_2^2 \end{bmatrix}$, which is in a bijective relation with ω_1^2 and ω_2^2.

3. MAIN RESULTS

Given any internal model M satisfying $\boldsymbol{\mathcal{A}_1}$, the procedure of (Incremona et al., 2022) is to select the stabilizer of the form

$$R_{\mathrm{stab}} = \tilde{R}_{\mathrm{stab}} - \Upsilon,$$

where the "internal model compensation" Υ is any *stable* system such that

$$\Upsilon(s)(sI - A)^{-1}B = I - M^{-1}(s)$$

and $\tilde{R}_{\mathrm{stab}}$ is any controller stabilizing the (non-augmented) plant (1). Possible choices are

$$\Upsilon(s) = (I - M^{-1}(s))(B^{\#}s - B^{\#}A), \tag{6}$$

where $B^{\#}$ is a left inverse of B, and

$$\tilde{R}_{\mathrm{stab}} = K,$$

where $K \in \mathbb{R}^{m\times n}$ is such that $A + BK$ is Hurwitz (the full column rank of B and stabilizability of (A, B) are naturally assumed). This yields the following form of the control law (3):

$$u = M(v + (K - \Upsilon)x). \tag{7}$$

Controller (7) involves two dynamic elements, the internal model M and the internal model compensator Υ. They both have a complex dependence on the model parameter Θ, which hampers studying the effect of this parameter on the closed-loop dynamics. So our first goal is to present (7) in an alternative form, in which the parameter Θ is isolated. This is done by the result below, whose proof is omitted.

Proposition 1. The controller $R : (v, x) \mapsto u$ in (7) can be implemented as $R(s) = \mathcal{F}_{\mathrm{l}}(\Psi, \Theta)$, see Fig. 1(a), where

$$\Psi(s) = \left[\begin{array}{c|c:c:c} A_0 - B_0C_{01} & B_0 & B_K & -B_0 \\ \hline -C_{01} & I & K + C_{01}B_0B^{\#} & -I \\ \hdashline C_{02} & 0 & -C_{02}B_0B^{\#} & 0 \end{array}\right] \tag{8}$$

and $B_K := B_0B^{\#}(A + BK) - (A_0 - B_0C_{01})B_0B^{\#}$.

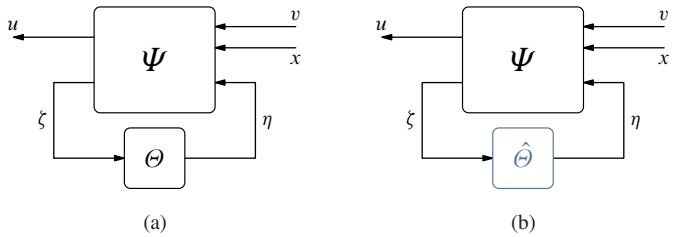

Fig. 1. Implementation of the controller $R : (v, x) \mapsto u$

Plugging this controller into the plant dynamics (1), we have the following expression for the resulting closed-loop system (the proof is also omitted).

Proposition 2. The closed-loop system $T : (v, d) \mapsto (x, u)$ is

$$T = T_v \begin{bmatrix} I & M^{-1} \end{bmatrix} - \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix}, \tag{9}$$

where

$$T_v(s) = \left[\begin{array}{c|c} A + BK & B \\ \hline I & 0 \\ K & I \end{array}\right].$$

Some remarks are in order.

- The effect of the signal v on the closed-loop system, which is $T_v : v \mapsto (x, u)$, is *independent* of the internal model and its shaping parameter Θ. Thus, consistently with the result of (Incremona et al., 2022), we can design v as if no internal model was present in the loop. This could simplify tracking design, as well as facilitates designing an external loop, which may be helpful to handle an unmodeled part of d.
- Straightforward algebra, together with $\boldsymbol{\mathcal{A}_2}$, yields that the signal $d_0 = M^{-1}d$ satisfies

$$\begin{cases} \dot{x}_0(t) = A_0 x_0(t), \quad x_0(0) = x_{\text{ex},0} \\ d_0(t) = C_{\text{ex}} x_0(t). \end{cases} \tag{10}$$

  This is an exponentially decaying function. The stability of T_v implies then that the effect of the disturbance, at least of its part modeled by (2), decays in steady state. Thus, if $\boldsymbol{\mathcal{A}_2}$ holds, i.e. if the internal model M agrees with the exosystem, then the regulator problem is solved in the sense that

$$\lim_{t\to\infty} x(t) = 0 \quad \text{and} \quad \lim_{t\to\infty} (u(t) + d(t)) = 0.$$

4. ADAPTATION MECHANISM FOR UNKNOWN Θ

Advantages of the proposed architecture are even sharper in the case of a varying Θ. Changing one or several parameters in conventional internal model configurations might result in a need to redesign the stabilizer and could thus substantially complicate the analysis. Yet changing Θ in Fig. 1(a) results in the very same closed-loop system as in (9), just with a varying Θ affecting affinely M^{-1} in (4). And the closed-loop system is stable as long as Θ remains bounded. This property paves the way to the design of globally converging adaptation algorithms, in which Θ in the internal model is adjusted to match unknown and possibly varying parameters of the exosystem.

Specifically, assume that Θ is constant, but unknown. Denote by $\hat{\Theta}$ its estimate, to be defined later on. In this case instead of the controller in Fig. 1(a) we implement that in Fig. 1(b), i.e. just replace Θ with its estimate. The following result can be formulated.

Proposition 3. Introduce the signal $e(t) := x(t) - x_v(t)$, where

$$\dot{x}_v(t) = (A + BK)x_v(t) + Bv(t),$$

and let $P = P' > 0$ satisfy $(A + BK)'P + P(A + BK) < 0$ (it exists because $A + BK$ is Hurwitz). The adaptation law

$$\dot{\hat{\Theta}}(t) = B'Pe(t)\zeta'(t), \quad \hat{\Theta}(0) = \hat{\Theta}_0 \tag{11}$$

where ζ is the second output of Φ in Fig. 1(b), guarantees the global boundedness of all signals in the system and the asymptotic regulation in the sense $\lim_{t\to\infty} e(t) = 0$.

Proof (outline). A key observation, which can be shown by straightforward algebra, is that the closed-loop plant satisfies

$$\dot{x}(t) = (A + BK)x(t) + Bv(t) + Bd_0(t) + B\tilde{\Theta}(t)\zeta(t),$$

where $\tilde{\Theta}(t) := \Theta - \hat{\Theta}(t)$ is the parameter mismatch and d_0 satisfies (10). Hence,

$$\dot{e}(t) = (A + BK)e(t) + Bd_0(t) + B\tilde{\Theta}(t)\zeta(t)$$

is independent of v. Because d_0 is exponentially decaying and independent of u, it can be excluded from the stability analysis. Consider the Lyapunov candidate

$$V(t) = e'(t)Pe(t) + \operatorname{tr}(\tilde{\Theta}(t)'\tilde{\Theta}(t))$$

for which, taking into account that $\dot{\tilde{\Theta}} = -\dot{\hat{\Theta}}$,

$$\dot{V}(t) = -e'(t)Qe(t) - 2\operatorname{tr}(\tilde{\Theta}'(t)(\dot{\hat{\Theta}}(t) - B'Pe(t)\zeta'(t))).$$

where $Q = -(A+BK)'P - P(A+BK) > 0$. Hence, (11) yields $\dot{V}(t) = -e'(t)Qe(t) \leq 0$. The result follows then by standard adaptive control arguments, like those in (Lavretsky and Wise, 2013, Ch. 9). □

4.1 Illustrative example

Consider the plant with

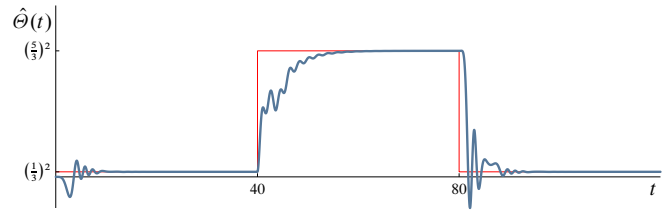
$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

and $d(t) = 0.5\sin(\omega t)$. We model this disturbance by (5) with the Butterworth $\phi(s) = s^2 + \sqrt{2}s + 1$. The state-feedback gain

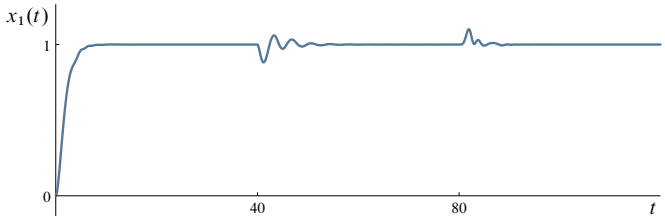
$$K = \begin{bmatrix} -1 & -2 \end{bmatrix},$$

assigning both eigenvalues of $A + BK$ to -1. We choose the the unit step $v(t)$. Finally, in the adaptation law (11) we select $P = 75\left[\begin{smallmatrix} 3 & 1 \\ 1 & 1 \end{smallmatrix}\right]$, which is the solution to the Lyapunov equation $(A + BK)'P + P(A + BK) = -150I < 0$.

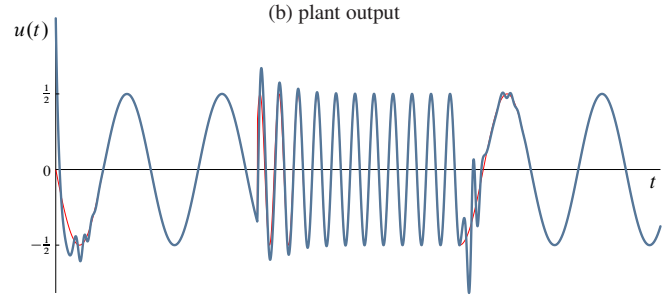
We simulate the resulted closed-loop system for ω switching between $1/3$ and $5/3$ every 40 time units. The estimated parameter $\hat{\Theta}(t) = \hat{\omega}^2(t)$ is shown in Fig. 2(a). Note that it might take (nonphysical) negative values during transients. To prevent this, the adaptation law (11) has to be modified, for example in line with the discussion in (Goodwin and Mayne, 1987). But it eventually always converges to the true value of Θ in this example. The first component of the state, $x_1(t)$, is presented in Fig. 2(b). Its steady state $\lim_{t\to\infty} x_1(t) = 1$ despite harmonic disturbances, which is exactly why we introduced the internal model to the controller. The control signal, shown in Fig. 2(c), expectably converges to $-d(t)$, which is required to cancel the effect of the load disturbance.



(a) estimated disturbance parameter (actual Θ is shown by the thin red line)



(b) plant output



(c) control signal (the additive inverse of $d(t)$ is shown by the thin red line)

Abstract: The adverse effect of increasing penetration of distributed energy resources has resulted in increased vulnerabilities to resilience, defined as the ability of the grid to preserve the original properties under disruptive scenarios which were unforeseen in the traditional power grid. Hence it necessitates the development of accurate and reliable resilience metrics to have deeper insight under any disturbance resulting in modification of structural properties. Especially, considering the critical role of local structure and its inherent underlying geometry makes the impact analysis more challenging. In view of this, the proposed Persistent homology-based resilience enhancement (PHRE) technique utilizes the concept of Topological Data Analysis, particularly Betti numbers (identifying the most vulnerable buses) and persistent homology, extracting the longer-lasting topological features of the graphs through the network filtration at various spatial resolutions characterizing the structural functionality of the network. The proposed PHRE technique is validated using a benchmark system.

Keywords: Betti-number, Grid instability, Persistent homology, Topological analysis

1. INTRODUCTION

The resilience of the power grid Tajer et al. (2021) is referred to as the quantification of the ability of the grid network to maintain its functions under component failures from random errors or external causes. During the design of traditional power grids, the unforeseen vulnerabilities arising from the increasing penetration of renewable energy generations and distributed energy resources were not considered. Hence with the challenging assessment of grid organization, reliable resilience metrices are necessary for the energy systems under various disruptive scenarios, including component failure, various attacks, or natural disasters.

Understanding the structural properties of power networks under disruptive scenarios gives profound insights into their vulnerability. The most explored characteristics of power grid resilience are node degree distribution and mean degree, which are local properties Cuadra et al. (2015) investigated at the level of individual nodes and edges. Incorporating electrical engineering concepts like impedances and power flows Zhu et al. (2014) into the graph, particularly at the local level, then analyzing their impact on grid functionality is a further difficult endeavor. Recent studies Dey et al. (2017), Schultz et al. (2014) suggest that the power grid robustness is associated with its geometry through the network motifs, which are the multi-node sub-graph patterns. However, motifs are inefficient for power networks due to limited applicability to unweighted topological graphs that fail to reflect information about power grid functionality Sánchez-García et al. (2014). Hence the emerging technique called Topological Data Analysis (TDA) Patania et al. (2017), particularly, Persistent Homology (PH) Otter et al. (2017), applicable for weighted topological graphs is explored for the grid analysis since its flexibility of integrating with machine learning approaches.

The extended abstract proposes analysis of the power system resilience through a Persistent Homology-based Resilience Enhancement (PHRE) technique. Network geometry has characterised its structural functionality, and the system's ability to preserve the original network properties for a longer time during disruptive scenarios is enhanced through the PHRE technique for maintaining the resilience standard. The number of one-dimensional holes or the topological loops is identified as the resilience index. The healthier system reports a higher number of holes, and the number drops down drastically for the cascade failures. The PHRE approach analyses the cascade failures triggered by various causes such as voltage instability, overloading, etc., as it is purely based on the network topology and characterizes the functional information of the grid through its underlying geometry.

The extended abstract discusses the main idea of PHRE technique and the representative case study illustrating the implementation on the benchmark IEEE 30 bus system for validating the proposed approach.

2. TOPOLOGICAL DATA ANALYSIS (TDA) AND PERSISTENT HOMOLOGY (PH)

TDA combines various fields, including algebraic topology, data analysis, computational geometry, and statistics.

TDA aims to gain deeper insights into the qualitative characteristics of the data by utilizing the results obtained from its geometry and topology. It is appealing approach for the complex network functionality analysis through some crucial features unveiling the component interactions at multi-scale. These qualitative features are identified through one of the TDA techniques called PH.

PH computes topological features at various spatial resolutions. Consider a weighted graph $G = (V, E, w)$ with V, E, and w denoting the set of vertices, set of edges, and vector of edge weights, respectively. To find the PH of G, the hierarchically nested sequence of subgraphs $G_1 \subseteq G_2 \subseteq \cdots G_n$ with the increased threshold limits on edge weights $\upsilon_1 < \upsilon_2 < \cdots < \upsilon_n$ are obtained, and this stage is referred to as network filtration. Due to the computational efficiency, the Vietoris-Rips (VR) complex Zomorodian (2010) which considers the edge weights as a distance measure between the two nodes forming the given edge is used for network filtration. At a particular weight threshold υ_j the VR complex is defined as

$$\mathrm{VR}_j = \{\varrho \subset V | w_{pq} \leq \upsilon_j \forall p, q \in \varrho\} \tag{1}$$

where the edges with weights $w_{pq} \leq \upsilon_j$ are kept and the remaining edges are discarded to obtain the subgraph G_j with the adjacency matrix $A_{pq} = 1_{w_{pq} \leq \upsilon_j}$. VR_j will contain the k-node subsets of G_j where $k = 1, \cdots, K$ with the pairwise connection with an edge as simplices of dimensions $k-1$. These simplicial complexes aid in approximating the hidden geometric structures of the grid in a combinatorial way.

With VR filtration, $\mathrm{VR}_1 \subseteq \mathrm{VR}_2 \subseteq \mathrm{VR}_n$, the persistent or long-lived features are detected. Persistent features are analyzed through various topological summaries like Betti numbers, persistent diagrams, and persistent barcodes. For each filtration, the Betti numbers are identified such that Betti-0 (β_0) describes the number of connected components, Betti-1 (β_1) reports the number of one-dimensional holes or topological loops, and Betti-2 (β_2) gives the number of two-dimensional holes or topological voids, and so on. For a given filtration, persistent diagrams represent the feature with a point in the Cartesian coordinate system, with 'x' coordinate describing its birth time and 'y' coordinate describing its death time. The longer distance from main diagonal in persistent diagrams is treated as the notion of stronger persistence. Persistent barcodes capture the birth and death instances of the features as a bar.

3. PERSISTENT HOMOLOGY-BASED RESILIENCE ENHANCEMENT (PHRE) TECHNIQUE

A weighted graph $G = (V, E, w)$ describes the topology of the power grid with its buses comprising the set of vertices $V = (\nu_1, \nu_2, \cdots, \nu_n)$, its lines forming the set of edges $E = (\mathrm{e}_1, \mathrm{e}_2, \cdots, \mathrm{e}_m)$ and the edge weights w proportional to line impedances, or, admittances, or, power flows. The adjacent node connectivity is given by weighted adjacency matrix A_{pq} for the nodes p and q as

$$\mathrm{A}_{pq} = \begin{cases} w_{pq} & \forall \mathrm{e}_{pq} \in E, p \neq q \\ 0 & otherwise \end{cases} \tag{2}$$

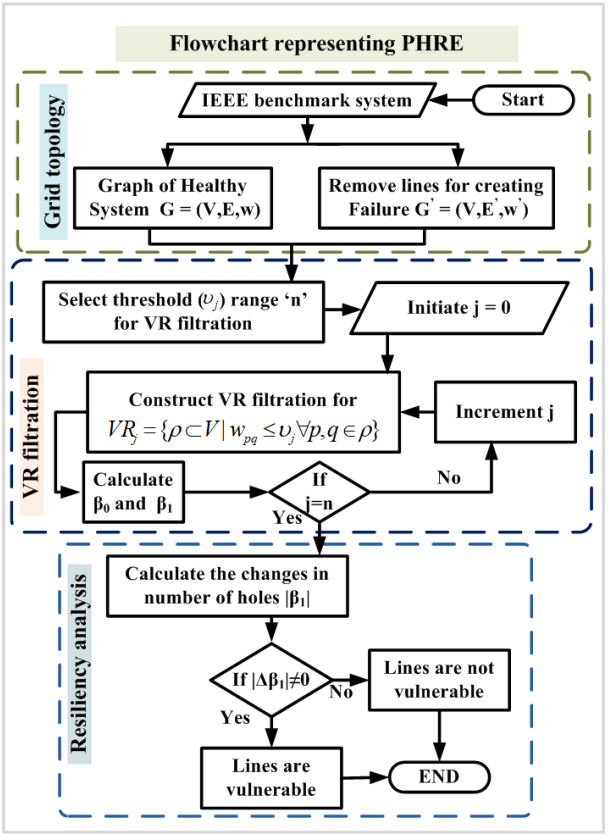

Fig. 1. The flowchart of proposed PHRE technique

The PHRE technique presented in Fig. 1 is applied for investigating the grid resiliency. The network filtration is carried out through VR filtration as explained in 1 for a range of thresholds $\upsilon_j, j = 0, \cdots, n$ imposed on edge weights. To obtain the Betti-0 (β_0) numbers, number of connected components are identified, and the presence of one-dimensional holes are detected to report the Betti-1 (β_1) numbers in the corresponding VR complex.

The blackouts due to cascading failures triggered by events like voltage instability, or overloading results into the change in topology as $G' = (V, E', w)$ whereas E' and w' are reduced set of edges and reduced vector of weights. The VR complices and corresponding betti numbers are identified for the similar range of weight thresholds considered previously. The change in betti numbers $\Delta\beta_0^{\upsilon_j}$ and $\Delta\beta_1^{\upsilon_j}$ for threshold υ_j is calculated as

$$|\Delta\beta_r^{\upsilon_j}| = \left|\beta_r^{b,\upsilon_j} - \beta_r^{f,\upsilon_j}\right| \tag{3}$$

where, $r = (0, 1)$, β_r^b corresponds to the healthy system and β_r^f corresponds to the deformed graph G' for failure.

The change in the number of one-dimensional holes $\left|\Delta\beta_1^{\upsilon_j}\right|$is used as the measure of the grid resiliency. The line outage changes the network topology and the deformation is reflected into the change in Betti numbers. The loss of edges will break the topological loops which results into fall in the number of holes i.e. β_1. If there is fall in the number of holes then the lines are more vulnerable as the outage has caused deformation to the network topology. If the number of holes are remain unchanged then it implies that the lines are not vulnerable.

4. REPRESENTATIVE CASE STUDY

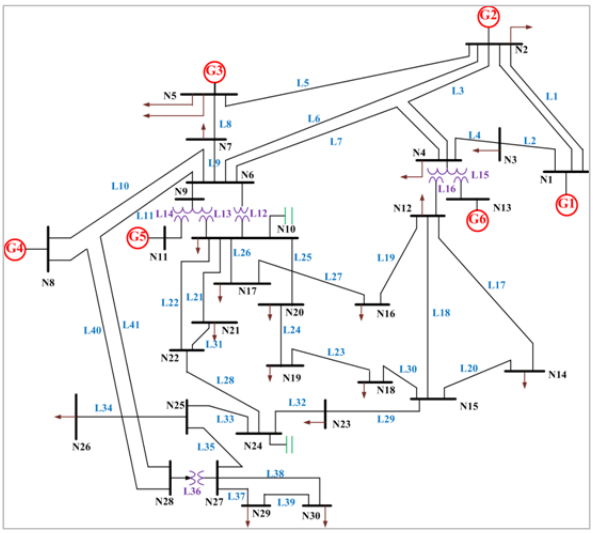

Fig. 2. One line diagram of benchmark IEEE 30 bus system

Benchmark IEEE 30 bus system (Fig.2) with 30 buses and 42 transmission lines of 289.1 MW generation and 283.4 MW load flow capacity Gupta et al. (2015) is considered as representative case study. Topological graph $G = (V, E, w)$ of this network is developed by considering the load and generator buses as the vertices, the transmission lines and transformers as the edges, and the impedance of the corresponding transmission line as edge weight. Two cases comprising base case corresponding to a healthy power grid and failure case corresponding to a cascade failure are discussed to verify the PHRE method.

4.1 Case 1: Base Case

Fig. 3 (h) shows the graph for base.The network filtration is computed with the VR filtration by varying the thresholds from $\upsilon = 0$ to $\upsilon = 0.7$ which are presented in Fig. 3 along with the Betti numbers associated with each complex. Fig. (a) describes the filtration with the threshold $\upsilon = 0$, where all the edges are discarded, and the point cloud of 30 nodes is observed. So the Betti-0 (β_0) = 30 and there are number holes so Betti-1 (β_1) = 0. With the increasing thresholds, more edges are getting included in the complices, and the number of β_0 is decreasing as more and more features are disappearing in the filtration. The one-dimensional holes are computed by tracing the topological loops present in the topology. The first hole appears at the threshold limit υ=0.2. With the further increase in the threshold, the number of holes, i.e., β_1, keeps on increasing. Finally, all edges are included at the threshold $\upsilon = 0.7$, and the last complex illustrates the healthy power grid.

4.2 Case 2: Failure Case

The cascading effect is created by tripping one of the lines from the base case system. The study has been conducted on the cascading scenario discussed in the Gupta et al. (2015) where the cascade has been initiated by tripping the line L21. Then the lines L22 and L29 tripped sequentially, resulting in cascade failure. The cascade scenario is simulated by removing the edges representing the lines L21, L22, and L29 from the graph of the base case. The VR complices are computed in a similar manner as the base case with the same threshold range. The changes in the Betti numbers for the failure case are demonstrated in Table 1. The number of connected components reported by the β_0 decrease with the varying threshold. It is observed that the first hole appears at the threshold $\upsilon = 0.2$, and the number of holes increases with further filtration.

Table 1. Betti numbers associated with VR complices for the cascade failure

Sr. No.	Threshold (υ)	Betti Numbers	
		β_0	β_1
1.	0.0	30	0
2.	0.2	11	1
3.	0.4	4	4
4.	0.6	2	4
5.	0.7	1	4

4.3 Comparative analysis

Table 2. Comparison of Betti numbers associated base case and failure case

Sr. No.	υ	Base Case		Failure Case		$\lvert\Delta\beta_0\rvert$	$\lvert\Delta\beta_1\rvert$
		β_0	β_1	β_0	β_1		
1.	0	30	0	30	0	0	0
2.	0.2	8	1	11	1	3	0
3.	0.4	3	5	4	4	1	1
4.	0.6	1	5	2	4	1	1
5.	0.7	1	6	1	4	0	2

Table 2 summarises the Betti numbers identified for the base case and failure case with the corresponding threshold limits. The variation in connected components (β_0) with the varying threshold for the base case and the failure case is illustrated in Fig. 4. The dynamics of one-dimensional holes (β_1) for various VR complices for the base case and the failure case is demonstrated in Fig. 5. It is observed that for the same threshold value, the number of one-dimensional holes β_1 drop down due to the cascade failure, and the number of β_0 increases as there are deformations in the network topology. Hence it is inferred that the number of holes is more for the healthy system, and during cascade failure, the number of holes drops down due to deformation of the topology. The more drastic change in the one-dimensional holes points out the fact that the corresponding lines are more vulnerable to failures. On the other hand, there may be line outages where the number of holes remains unchanged; such lines are not vulnerable to failure. Hence with the PHRE technique, it is deduced that the number of one-dimensional holes can be used as the measure of the resilience of the system.

5. CONCLUSION

The underlying geometry of power grid plays a vital role in investing its various functional characteristics for the resilience analysis. To gain profound insights into the vulnerability to the grid resilience, the TDA approach, specifically the persistent homology (PH) was explored. The extended abstract proposed an idea of a PHRE technique for analysing the capability of the system to retain its original

properties over a longer period under disruptive scenarios. The PHRE method was validated on the benchmark IEEE 30 bus system. From the results, it was observed that the healthy system reported a higher number of holes, and the cascade failure resulted in a drastic drop in the number of holes. Hence it was concluded that the number of holes or the topological loops might be treated as the measure of the system's ability to retain the resilience standard. The PHRE technique proved advantageous for analysis of cascade failure occurred by various factors, including component failure, overloading, voltage instability due to its relevance with the network geometry for characterizing its functional information.

Abstract: We study a dual decomposition algorithm for a distributed optimization problem with a communication structure corresponding to a hypergraph. We prove that in the case of quadratic objective functions the respective discrete-time dynamical system of a modified dual decomposition algorithm that makes use of the Hessians of the objective functions converges in only one iteration.

Keywords: Large Scale Systems, Optimization: Theory and Algorithms.

1. INTRODUCTION

Real world networks usually consist of a large number of interconnected systems (agents) which communicate with each other in order to achieve a global objective. Many of these objectives can be formulated into distributed optimization problems. Distributed optimization can be traced back to the seminal works of [Tsitsiklis (1984)] and [Bertsekas and Tsitsiklis (1989)]. The most common way of solving distributed optimization problems is to use dual decomposition and first order methods (or subgradients) as in [Kelly et al. (1998)] and [Boyd et al. (2011)].

In this paper we study the discrete-time version of the dual decomposition case of a distributed optimization problem as it was presented in [Samar et al. (2007)]. This algorithm uses a hypergraph communication despite the fact that graph communication is the most commonly used in distributed optimization problems [Yang et al. (2019)]. Hypergraphs were introduced in [Berge (1973)] as a generalization of graphs. The importance of the hypergraph lies in the fact that it allows more than two nodes to be linked in the same edge (hyperedge). As a result, a hypergraph can depict more complex relationships compared to the communication structure of a graph. This different communication structure exists in reality e.g. large online social networks, supply chain management, etc. Various advantages of the hypergraph communication are presented in [Wolf et al. (2016)].

Our main contribution is to show that when the objective functions of the hypergraph distributed optimization problem are quadratic one can construct a dual decomposition based algorithm that converges in only one step, when the Hessians of the objective functions are available. This is in contrast to more classical first order methods where the convergence is asymptotic, i.e., this will involve an infinite number of steps.

An interesting observation is that the communication matrix of the dual decomposition algorithm is the Bolla's Laplacian for hypergraphs [Bolla (1993)]. This observation creates a link with graph based algorithms since they are most commonly described with the use of the graph Laplacian [Yang et al. (2019)]. In our setting the Laplacian communication matrix is also a projection matrix. As a result, the gap between the largest and smallest non zero eigenvalues is zero since both are equal to one. We know from [Duchi et al. (2011)] that a small aforementioned gap can lead to an improved convergence rate. This therefore hints that when the underlying communication topology is designed such that it corresponds to a hypergraph, optimization algorithms with faster convergence rate can be constructed.

The paper is organized as follows: Section 2 presents the mathematical tools that will be used. Section 3 introduces the distributed optimization problem in the hypergraph setting. Finally, in section 4 we present the dual decomposition algorithm along with the proposed modified version where the main results of the paper are associated with the convergence and the optimality of the modified algorithm.

2. PRELIMINARIES

2.1 Notation

The set of real numbers is $\mathbb{R}$. For $x \in \mathbb{R}^n, x \geq 0$ (resp. $x > 0$) means that all components of x are nonnegative (resp. positive). We define the cardinality of a set C as $|C|$. With $\text{vec}(a_i)_{i=1}^n$ we denote the vector obtained by stacking the vectors $a_1, ..., a_n$ into a column vector.

2.2 Convex Analysis

A differentiable function $f : \mathbb{R}^n \to \mathbb{R}$ is said to be convex if $f(x) - f(y) \leq \nabla f(x)^T(x - y)\ \forall\ x, y \in \mathbb{R}^n$. If strict inequality holds then f is a strictly convex function. A function $f : A \subset \mathbb{R}^n \to \mathbb{R}^n$ is locally Lipschitz if for each $x, x_0 \in A$, there exist constant $M > 0$ and $\delta_0 > 0$ such that $||x - x_0|| < \delta_0 \Rightarrow ||f(x) - f(x_0)|| \leq M||x - x_0||$.

2.3 Hypergraphs

A hypergraph (e.g. [Vitaly (2009)]) is a pair $\mathcal{H} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{v_1, ..., v_n\}$ is a finite set of nodes and $\mathcal{E} =$

$\{\mathcal{E}_1, ..., \mathcal{E}_m\}$ is the set of hyperedges. A hyperedge can join any number of nodes and not just two as it is in the case of a graph. The degree of a node in a hypergraph is the total number of hyperedges that are adjacent to this node. The size of a hyperedge $\mathcal{E}_j$, denoted by $|\mathcal{E}_j|$ is the total number of nodes that are adjacent to this hyperedge. We have that $|\mathcal{E}_j| \geq 2, \ \forall \ 1 \leq j \leq |\mathcal{E}|$. We define by D_V the diagonal $|\mathcal{V}| \times |\mathcal{V}|$ matrix whose entries are the degrees of each node and by D_E the diagonal $|\mathcal{E}| \times |\mathcal{E}|$ matrix whose diagonal entries are the sizes of each hyperedge. For a hypergraph $\mathcal{H}$, the incidence matrix denoted by E, is a $|\mathcal{V}| \times |\mathcal{E}|$ matrix whose (i, j)-th entry is given by

$$E_{ij} = \begin{cases} 1, & v_i \in \mathcal{E}_j \\ 0, & \text{otherwise.} \end{cases}$$

The Bolla's Laplacian for hypergraphs denoted by L, is given by

$$L = D_V - E(D_E)^{-1}E^T.$$

2.4 Matrix Theory

For a square matrix $M \in \mathbb{R}^{n\times n}$, $S(M)$ denotes the spectrum of matrix M. A square matrix $P \in \mathbb{R}^{n\times n}$ is called a projection matrix if $P^2 = P$. A square matrix $P \in \mathbb{R}^{n\times n}$ is called an orthogonal projection matrix if $P^2 = P = P^T$. For a projection matrix P its spectrum is $S(P) = \{0, 1\}$. A symmetric matrix M is called positive semidefinite $M \succeq 0$ if $x^T Mx \geq 0$ for every nonzero $x \in \mathbb{R}^n$. If we have strict inequality we say that matrix M is positive definite $M \succ 0$.

3. THE HYPERGRAPH DISTRIBUTED OPTIMIZATION ALGORITHM

We have the following distributed optimization problem with K subsystems

$$\min_{x=[x_1,...,x_K]} \quad \sum_{i=1}^{K} f_i(x_i)$$
$$\text{s.t.} \quad x_i = E_i z \quad i = 1, ..., K \tag{1}$$

where $f_i : \mathbb{R}^{p_i} \to \mathbb{R}$ is the objective function of ith subsystem and is considered to be strictly convex, continuously differentiable with its gradient ∇f_i being locally Lipschitz. The vectors $x_i, \forall \ 1 \leq i \leq K$ denote the variables of the K subsystems. For each subsystem i we have $x_i \in \mathbb{R}^{p_i}$ and we denote the lth component of vector x_i as x_i^l. We assume that all the components of all the variables appear in the variables of other subsystems [1] (i.e. they are coupling variables). We assume there are N different groups of coupling variables, with the variables in each group required to be equal. The components of vector $z \in \mathbb{R}^N$ give the respective common values in each of these groups. The relationship $x_i = E_i z$ defines the equality constraints ("consistency constraints") among the coupling variables of subsystem i and their respective common values. In particular, E_i is a $p_i \times N$ matrix whose (l, j)-th entry is given by

$$E_i^{lj} = \begin{cases} 1, & \text{if } \ x_i^l = z_j, \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

Hence x_i^j is the coupling variable of the ith subsystem that belongs to the jth group of coupling variables for $i = 1, ..., K$ and $j = 1, ..., N$. The vector of coupling variables is denoted as $x = (x_1, ..., x_K) \in \mathbb{R}^p$, where $p = p_1 + ... + p_K$.

We consider a hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{E})$ to represent the couplings among the variables. In particular, the set of nodes $\mathcal{V}$ is partitioned into $\mathcal{V} = \{\mathcal{V}_1, ..., \mathcal{V}_K\}$ where each node in subset $\mathcal{V}_i$ is associated with a component of variable x_i. Each hyperedge $\mathcal{E}_j$ is associated with a component z_j of vector z. Therefore the hyperedge set $\mathcal{E}$ is associated with the "consistency constraints" among the coupling variables of different subsystems. For the hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{E})$ we have $|\mathcal{V}| = p, |\mathcal{E}| = N$ and incidence matrix $E \in \mathbb{R}^{p\times N}$ where $E = \begin{bmatrix} E_1 \\ \vdots \\ E_K \end{bmatrix}$. The node degree matrix of the hypergraph is $D_V = I_{p\times p}$ and the hyperedge size matrix is $D_E = \text{diag}\{|\mathcal{E}_1|, ..., |\mathcal{E}_N|\}$ where $|\mathcal{E}_j| \geq 2, \forall \ 1 \leq j \leq N$. The relationship $x_i = E_i z, \forall \ 1 \leq i \leq K$ can also be written as $x = Ez$.

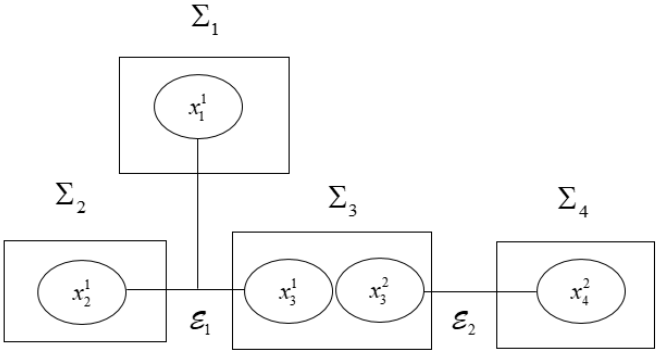

Fig. 1. Hypergraph Communication

It is important to note that this distributed optimization setting can be viewed as a multiple consensus problem, a consensus value must achieved for each hyperedge. The Lagrangian of (1) is

$$\mathcal{L}(x, z, v) = \sum_{i=1}^{K} f_i(x_i) - v^T(x - Ez) \tag{3}$$

where $v \in \mathbb{R}^p$ is the Lagrange multiplier associated with $x = Ez$. The equation (3) can also be written in the form

$$\mathcal{L}(x, z, v) = \sum_{i=1}^{K} (f_i(x_i) - v_i^T x_i) + v^T Ez$$

where v_i is the subvector of v associated with the ith subsystem. The optimality conditions are:

[1] Note that this is without loss of generality as minimization w.r.t. local variables that do not appear in other subsystems can be incorporated within the functions ∇f_i.

$$\frac{\partial L}{\partial x} = 0 \Rightarrow \nabla f_i = v_i \text{ (subsystems interconnections)} \quad (4a)$$
$$\frac{\partial L}{\partial v} = 0 \Rightarrow x = Ez \text{ (primal feasibility)} \quad (4b)$$
$$\frac{\partial L}{\partial z} = 0 \Rightarrow E^T v = 0 \text{ (dual feasibility).} \quad (4c)$$

Example 1. In Figure 1 we have a hypergraph communication with node set $\mathcal{V} = \{1, 2, 3, 4, 5\}$ and hyperedge set $\mathcal{E} = \{\mathcal{E}_1, \mathcal{E}_2\}$. For each node i there is a variable component x_i^j associated with it. Variables $\{x_1^1, x_2^1, x_3^1\}$ are attached to hyperedge $\mathcal{E}_1$ and variables $\{x_3^2, x_4^2\}$ are attached to hyperedge $\mathcal{E}_2$. The node degree matrix, hyperedge size matrix and the incidence matrix are

$$D_V = I_{5\times 5}, D_E = \begin{pmatrix} 3 & 0 \\ 0 & 2 \end{pmatrix} \text{ and } E = \begin{bmatrix} E_1 \\ E_2 \\ E_3 \\ E_4 \end{bmatrix} = \begin{pmatrix} \begin{bmatrix} 1 & 0 \end{bmatrix} \\ \begin{bmatrix} 1 & 0 \end{bmatrix} \\ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \begin{bmatrix} 0 & 1 \end{bmatrix} \end{pmatrix}$$

respectively.

Remark 1. It is important to note that in our setting $E^T E = D_E$.

4. DUAL DECOMPOSITION

In this section we will introduce the discrete-time dual decomposition algorithm and present also a modified version that leads to the main results in the paper.

To find the dual function we first minimize (3) over z, which results in the condition (4c). Then we solve the following subproblems independently for each i given v_i

$$\min_{x_i} f_i(x_i) - v_i^T x_i. \quad (5)$$

Since the objective functions $f_i(x_i)$ are strictly convex, the solution to each subsystem is unique. The dual of the original problem (1) is

$$\max_{v=[v_1,\ldots,v_K]} \sum_{i=1}^{K} q_i(v_i) \quad \text{s.t.} \quad E^T v = 0 \quad (6)$$

where $q_i(v_i) = \min_{x_i}\{f_i(x_i) - v_i^T x_i\}$. A detailed procedure for the extraction of the dual decomposition algorithm is given in [Samar et al. (2007)]. The algorithm is presented below:

Dynamical System

$$E^T v(0) = 0 \quad \text{initial conditions} \quad (7a)$$
$$\nabla f_i(x_i(k)) = v_i(k) \quad \text{optimize subsystems} \quad (7b)$$
$$z(k) = (E^T E)^{-1} E^T x(k) \quad \text{average } x \quad (7c)$$
$$v(k+1) - v(k) = -\rho(x(k) - Ez(k)) \quad \text{update } v \quad (7d)$$

where $k = 0, 1, 2, \ldots$ denotes the iteration number and $\rho > 0$ is the stepsize. Relationship (7b) results from (5). If we substitute (7c) in (7d) we have

$$v(k+1) - v(k) = -\rho(x(k) - E(E^T E)^{-1} E^T x(k)) \Rightarrow$$
$$v(k+1) - v(k) = -\rho Q x(k)$$

where

$$Q = I - E(E^T E)^{-1} E^T. \quad (9)$$

Remark 2. As mentioned in Remark 1, $E^T E = D_E$ and as a result, matrix Q in (9) can be written as $Q = D_V - E(D_E)^{-1} E^T$ since $D_V = I$. Hence matrix Q is the Bolla's Laplacian for the hypergraph considered, [Bolla (1993)]. It is proven in [Samar et al. (2007)] that matrix Q is an orthogonal projection matrix.

Quadratic Case Below we will present the main result of our work. We consider the problem (1) with the objective functions to be $f_i(x_i) = \frac{1}{2} x_i^T A_i x_i + b_i^T x_i + c_i$, $1 \le i \le K$. This problem can also be written in the following form,

$$\min_{x=[x_1,\ldots,x_K]} \frac{1}{2} x^T A x + b^T x + c \quad \text{s.t.} \quad x = Ez \quad (10)$$

where matrix $A = \text{diag}\{A_1, \ldots, A_K\}$ is a block diagonal matrix, each $A_i \in \mathbb{R}^{p_i \times p_i}, 1 \le i \le K$ is a symmetric positive definite matrix. Parameters b and c can be expressed as $b = \text{vec}(b_i)_{i=1}^K$ and $c = \sum_{i=1}^{K} c_i$ respectively. Below we propose a modification of dynamical system (7a)-(7d) which solves the optimization problem (10) in a single iteration.

Dynamical System

$$E^T v(0) = 0 \quad (11a)$$
$$\nabla f_i(x_i(k)) = v_i(k) \quad (11b)$$
$$z(k) = (E^T A E)^{-1} E^T A x(k) \quad (11c)$$
$$v(k+1) - v(k) = -A(x(k) - Ez(k)) \quad (11d)$$

Remark 3. We notice that a main difference of the dynamical system (11a)-(11d) compared to (7a)-(7d) is equation (11c). In equation (7c) we only average the primal variables while in equation (11c) we conduct a weighted averaging, where the weights are determined by the Hessians of the objective functions.

Remark 4. The choice $\rho = A$ in (11d) can be seen as using a non-uniform stepsize among subsystems.

Substituting (11c) in (11d) we have

$$v(k+1) - v(k) = -A(x(k) - E(E^T A E)^{-1} E^T A x(k)) \Rightarrow$$
$$v(k+1) - v(k) = -AQ' x(k)$$

where

$$Q' = I - E(E^T A E)^{-1} E^T A. \quad (13)$$

Lemma 4.1. Matrix Q' in (13) is a projection matrix.

Proof.

We have that

$$\begin{aligned}(Q')^2 =& [I - E(E^T A E)^{-1} E^T A]^2 \\ =& [I - E(E^T A E)^{-1} E^T A][I - E(E^T A E)^{-1} E^T A] \\ =& I - 2E(E^T A E)^{-1} E^T A \\ &+ E(E^T A E)^{-1} E^T A E (E^T A E)^{-1} E^T A \\ =& I - 2E(E^T A E)^{-1} E^T A + E(E^T A E)^{-1} E^T A \\ =& I - E(E^T A E)^{-1} E^T A \\ =& Q'.\end{aligned}$$

As a result, Q' is a projection matrix. The spectrum of Q' is $S(Q') = \{0, 1\}$.

Remark 5. It is important to note that matrix Q' is not symmetric and as a result, not an orthogonal projection matrix.

Using the fact that $\nabla f(x) = Ax+b = v \Rightarrow x = A^{-1}(v-b)$ the algorithm (11a)-(11d) can also be written compactly as follows:

$$E^T v(0) = 0 \tag{15a}$$

$$v(k+1) - v(k) = -AQ'A^{-1}v(k) + AQ'A^{-1}b. \tag{15b}$$

The following theorems present our main results which are associated with the convergence of the modified algorithm in one iteration and the optimality of its equilibrium point.

Theorem 4.2. The algorithm in (11a)-(11d) converges in one iteration.

Proof. We consider the compact form in (15a)-(15b). By considering an iteration to find $v(k+2)$ we have

$$\begin{aligned} v(k+2) =& (I - AQ'A^{-1})v(k+1) + AQ'A^{-1}b \\ =& (I - AQ'A^{-1})((I - AQ'A^{-1})v(k) + AQ'A^{-1}b) \\ &+ AQ'A^{-1}b \\ =& (I - AQ'A^{-1})^2 v(k) + (I - AQ'A^{-1})AQ'A^{-1}b \\ &+ AQ'A^{-1}b \\ =& (I - AQ'A^{-1})^2 v(k) + 2AQ'A^{-1}b \\ &- (AQ'A^{-1})^2 b. \end{aligned}$$

We notice that

$$\begin{aligned} (I - AQ'A^{-1})^2 =& (I - AQ'A^{-1})(I - AQ'A^{-1}) \\ =& I - 2AQ'A^{-1} + AQ'A^{-1}AQ'A^{-1} \\ =& I - 2AQ'A^{-1} + A(Q')^2A^{-1} \\ =& I - AQ'A^{-1} \end{aligned}$$

since Q' is a projection matrix which implies $(Q')^2 = Q'$. Similarly for $(AQ'A^{-1})^2$ we have that

$$(AQ'A^{-1})^2 = AQ'A^{-1}AQ'A^{-1} = A(Q')^2A^{-1} = AQ'A^{-1}.$$

As a result,

$$v(k+2) = (I - AQ'A^{-1})v(k) + AQ'A^{-1}b = v(k+1).$$

Therefore by induction $v(k) = v(1)$ for $k \geq 1$, hence the algorithm converges in one iteration.

Theorem 4.3. The algorithm in (11a)-(11d) satisfies the optimality conditions (4a)-(4c) at equilibrium.

Proof. Conditions (4a), (4b) are trivially satisfied at equilibrium from (11b), (11d), respectively. It remains to show that $E^T v = 0$ at equilibrium. Since we have the initial conditions $E^T v(0) = 0$ it is sufficient to show $E^T v(k+1) = E^T v(k)$ for all $k \geq 0$. Premultiplying (11d) by E^T we need to show that

$$E^T A(x(k) - Ez(k)) = 0.$$

This holds since

$$\begin{aligned} E^T A(x(k) - Ez(k)) &= E^T A(I - E(E^T AE)^{-1}E^T A)x(k) \\ &= 0. \end{aligned}$$

Remark 6. It should be noted that if A is diagonal then the iteration in Algorithm (11a)-(11d) decomposes into distributed computations within each hyperedge. If A is block diagonal distributed algorithms that terminate in a finite number of steps can be formulated by communicating the Hessians of the objective functions throughout the network. The development of more efficient distributed computational procedures in this case is part of ongoing work.

Remark 7. The classical first order algorithms usually require less information for their implementation (no Hessians, smaller connectivity) but they converge asymptotically, i.e., they tend to the optimal solution after an infinite number of steps.

5. CONCLUSION

We have considered a distributed optimization problem with coupling constraints formulated by means of a hypergraph. We have shown that when the objective functions are quadratic a modified dual decomposition algorithm, which makes use of the Hessians of the objective functions, can be constructed such that the optimal solution is obtained after one iteration. Future work includes extensions to problems with general convex objective functions where the hypergraph structure is exploited to obtain improved convergence rates.

Abstract: We show that the explicit solution of a data-driven predictive control scheme for deterministic LTI systems may not be as intractable as previously assumed. By comparing the structure of resulting parametric quadratic programs for the data-driven and classical model-based formulation, we analyze similarities and redundancies that ultimately lead to related structures of the respective explicit solutions. More precisely, some observations indicate a one-to-one relationship of these solutions that will be explored in future work. We illustrate this result by a thorough analysis of a simple example.

Keywords: Data-driven control, model predictive control, explicit MPC, parametric optimization

1. INTRODUCTION

Data-driven predictive control (DPC), where the prediction of the systems' behavior is carried out based on collected input-output data instead of a model, is becoming more and more popular (see, e.g., Coulson et al. (2019); Berberich and Allgöwer (2020); Dörfler et al. (2021)). Remarkably, assuming perfect data and linear dynamics, the fundamental lemma by Willems et al. (2005) and variants of it (as proposed by van Waarde et al. (2020) and Markovsky and Dörfler (2020)) allow establishing the equivalence of the data-driven and model-based approach with respect to the resulting control actions.

However, while strongly related, the two approaches lead to different optimal control problems (OCP). In fact, DPC usually results in an OCP with significantly more decision variables than model-based predictive control (MPC, see Rawlings et al. (2017) for an overview). Moreover, MPC typically results in strictly convex OCP while (unmodified) DPC only offers convexity. As a consequence, explicit solutions of the data-driven OCP seem "unattractive" at first sight (Alpago et al., 2020, Section IV.B), even for applications where explicit MPC (Bemporad et al., 2002) is tractable.

We show in this note that the perceived imbalance between DPC and MPC can be resolved in some cases. In fact, while more decision variables indeed typically result in more complex explicit solutions (in terms of the number of regions etc.), this is not the case for deterministic DPC in comparison to its model-based analogue. To see this, we establish a novel and stricter relation between the two approaches, which reveals that the larger number of decision variables merely results in ambiguity rather than more complex explicit solutions. Note that previous approaches to explicit DPC either operate in the statespace, i.e. assume fully measurable states (Sassella et al., 2021), or utilize additional regularization to obtain a strictly convex OCP (Breschi et al., 2021). For our analysis, we will not apply such simplifications or modifications.

The note is organized as follows. In Section 2, we summarize classical MPC and fundamentals of DPC. The analysis of explicit solutions of the corresponding OCPs and the identification of a closer relation between them are carried out in Section 3. We illustrate our findings with an illustrative example in Section 4. Finally, promising directions for future research are discussed in Section 5.

2. FUNDAMENTALS OF MPC AND DPC

2.1 Classical MPC

We briefly summarize classical MPC in a form that is compatible with the data-driven realization in Section 2.2. To this end, we assume that a linear prediction model

$$x(k+1) = Ax(k) + Bu(k) \tag{1a}$$
$$y(k) = Cx(k) + Du(k) \tag{1b}$$

is known. We further assume that input and output constraints are given in terms of polyhedral sets

$$\mathcal{U} := \{u \in \mathbb{R}^m \,|M_u u \leq v_u\}, \mathcal{Y} \quad := \{y \in \mathbb{R}^p \;|M_y y \leq v_y\},$$

which are specified by the matrices $M_{u/y}$ and vectors $v_{u/y}$, respectively. Then, classical MPC (without terminal cost and constraints) can be realized by solving

$$\begin{aligned} \min_{u(k),x(k),y(k)} \; & \sum_{k=0}^{N_f-1} \|y(k)\|_Q^2 + \|u(k)\|_R^2 && (2)\\ \text{s.t.} \quad & x(0) = x_0, \\ & x(k+1) = A\,x(k) + Bu(k), && \forall k \in \{0,...,N_f-2\}, \\ & y(k) = C\,x(k) + Du(k), && \forall k \in \{0,...,N_f-1\}, \\ & (y(k),u(k)) \in \mathcal{Y} \times \mathcal{U}, && \forall k \in \{0,...,N_f-1\} \end{aligned}$$

in every time-step for the current state x_0, where Q and R are assumed to be positive definite weighting matrices and where $N_f \in \mathbb{N}$ denotes the prediction horizon. Now, the OCP (2) is typically condensed into a quadratic program (QP) such that only the inputs remain as decision variables. To this end, one first introduces the sequences

$$\mathrm{u}_f := \begin{pmatrix} u(0) \\ \vdots \\ u(N_f-1) \end{pmatrix} \quad \text{and} \quad \mathrm{y}_f := \begin{pmatrix} y(0) \\ \vdots \\ y(N_f-1) \end{pmatrix}, \tag{3}$$

and the extended weighting matrices $\mathcal{Q} := \operatorname{diag}(Q, \dots, Q)$ and $\mathcal{R} := \operatorname{diag}(R, \dots, R)$ in order to rewrite the cost function as

$$\sum_{k=0}^{N_f-1} \|y(k)\|_Q^2 + \|u(k)\|_R^2 = \|\mathrm{y}_f\|_{\mathcal{Q}}^2 + \|\mathrm{u}_f\|_{\mathcal{R}}^2. \tag{4}$$

We further define the matrices

$$\mathcal{O}_N := \begin{pmatrix} C \\ CA \\ \vdots \\ CA^{N-1} \end{pmatrix} \text{ and } \mathcal{T}_N := \begin{pmatrix} D & & 0 \\ CB & \ddots & \\ \vdots & \ddots & \ddots \\ CA^{N-2}B & \dots & CB \;\; D \end{pmatrix},$$

which we will consider for different N during this note. For $N = N_f$, we then obtain the relation

$$\mathrm{y}_f = \mathcal{O}_{N_f} x_0 + \mathcal{T}_{N_f} \mathrm{u}_f. \tag{5}$$

Finally, substituting (5) into (4) and introducing the augmented matrices $\mathcal{M}_{u/y} := \operatorname{diag}\left(M_{u/y}, \dots, M_{u/y}\right)$ leads to

$$\begin{aligned} \mathrm{u}_f^*(x_0) := \arg\min_{\mathrm{u}_f} \; & \frac{1}{2} \mathrm{u}_f^\top H \mathrm{u}_f + x_0^\top F^\top \mathrm{u}_f \\ \text{s.t.} \quad & G\mathrm{u}_f \le E x_0 + d \end{aligned} \tag{6}$$

with the parameter x_0 as well as

$$\begin{aligned} H &:= 2\mathcal{T}_{N_f}^\top \mathcal{Q} \mathcal{T}_{N_f} + 2\mathcal{R}, & F &:= 2\mathcal{T}_{N_f}^\top \mathcal{Q} \mathcal{O}_{N_f}, \\ G &:= \begin{pmatrix} \mathcal{M}_u \\ \mathcal{M}_y \mathcal{T}_{N_f} \end{pmatrix} & E &:= \begin{pmatrix} 0 \\ -\mathcal{M}_y \mathcal{O}_{N_f} \end{pmatrix}, \\ d &:= \begin{pmatrix} v_u^\top & \dots & v_u^\top & v_y^\top & \dots & v_y^\top \end{pmatrix}^\top. \end{aligned} \tag{7}$$

2.2 DPC using input-output sequences

In contrast to MPC, DPC considers input-output data instead of a model as in (1). More precisely, DPC builds (in its simplest form) on two sequences u_d and y_d as in (3) but of length $N_d \in \mathbb{N}$ that reflect prerecorded system inputs and outputs. We note, at this point, that with slight abuse of notation, we denote both the elements of u_f and u_d with $u(k)$. However, the relationship will always be clear from the context. The same applies to the elements of the sequences y_f and y_d. Now, in order to realize DPC by means of u_d and y_d, the sequences have to carry enough information about the systems' dynamics. This condition can be fulfilled if the output sequence y_d is consistent with a persistently exciting and sufficiently long input sequence u_d. More specifically, for deterministic DPC, which we consider here, consistency means that there exists a model (1) with initial state x_0 such that

$$\mathrm{y}_d = \mathcal{O}_{N_d} x_0 + \mathcal{T}_{N_d} \mathrm{u}_d. \tag{8}$$

Further, according to Willems et al. (2005), u_d is persistently exciting of order $N_e \in \mathbb{N}$ if the Hankel matrix

$$\mathcal{H}_{N_e}(\mathrm{u}_d) := \begin{pmatrix} u(0) & u(1) & \dots & u(N_d - N_e) \\ u(1) & u(2) & \dots & u(N_d - N_e + 1) \\ \vdots & & \ddots & \vdots \\ u(N_e - 1) & u(N_e) & \dots & u(N_d - 1) \end{pmatrix}$$

has full row rank, i.e., $\operatorname{rank}(\mathcal{H}_{N_e}(\mathrm{u}_d)) = mN_e$. Note that this requires $\mathcal{H}_{N_e}(\mathrm{u}_d)$ to have as least as many columns as rows, i.e.,

$$N_d - N_e + 1 \ge mN_e \quad \Longleftrightarrow \quad N_d \ge (m+1)N_e - 1. \tag{9}$$

Finally, the fundamental lemma by Willems et al. (2005) allows associating the given sequences u_d and y_d with other input-output sequences of the same system. In fact, under the assumption that the underlying system is linear, controllable, and u_d is persistently exciting of order $N_e := N_c + n$, with n being the state dimension, candidate sequences $(\mathrm{u}_c, \mathrm{y}_c)$ of length $N_c \in \mathbb{N}$ belong to the same system as $(\mathrm{u}_d, \mathrm{y}_d)$ if and only if

$$\begin{pmatrix} \mathrm{u}_c \\ \mathrm{y}_c \end{pmatrix} \in \operatorname{im} \begin{pmatrix} \mathcal{H}_{N_c}(\mathrm{u}_d) \\ \mathcal{H}_{N_c}(\mathrm{y}_d) \end{pmatrix}.$$

At this point, we briefly note that recent extensions of the fundamental lemma by van Waarde et al. (2020) and Markovsky and Dörfler (2020) allow alleviating some of the restrictions above. Now, in order to utilize the previous results for DPC, we proceed similarly to Coulson et al. (2019). We choose an integer $N_p \le n$ equal to or larger than the observability index, i.e., such that the corresponding matrix $\mathcal{O}_{N_p}$ has full column rank, which clearly requires observability. Next, we assume that u_d is persistently exciting of order

$$N_e := N_p + N_f + n. \tag{10}$$

According to the fundamental lemma, we then find that the concatenated sequences $(\mathrm{u}_p^\top \;\; \mathrm{u}_f^\top)^\top$ and $(\mathrm{y}_p^\top \;\; \mathrm{y}_f^\top)^\top$ with

$$\mathrm{u}_p := \begin{pmatrix} u(-N_p) \\ \vdots \\ u(-1) \end{pmatrix} \quad \text{and} \quad \mathrm{y}_p := \begin{pmatrix} y(-N_p) \\ \vdots \\ y(-1) \end{pmatrix}$$

and with $(\mathrm{u}_f, \mathrm{y}_f)$ as in (3), belong to the same system as $(\mathrm{u}_d, \mathrm{y}_d)$ if and only if

$$\begin{pmatrix} \mathrm{u}_p \\ \mathrm{u}_f \\ \mathrm{y}_p \\ \mathrm{y}_f \end{pmatrix} = \begin{pmatrix} \mathcal{H}_{N_p+N_f}(\mathrm{u}_d) \\ \mathcal{H}_{N_p+N_f}(\mathrm{y}_d) \end{pmatrix} a. \tag{11}$$

for some $a \in \mathbb{R}^l$ with $l := N_d - N_f - N_p + 1$. Based on reordering and partitioning, (11) can be rewritten as

$$\xi := \begin{pmatrix} \mathrm{u}_p \\ \mathrm{y}_p \end{pmatrix} = W_p a, \quad \mathrm{u}_f = U_f a, \quad \text{and} \quad \mathrm{y}_f = Y_f a \tag{12}$$

with the matrices W_p, U_f, and Y_f representing blocks of the concatenated Hankel matrices. We are now ready to formulate the OCP associated with DPC. In fact, the combination of (4) and (12) allow expressing the costs

$$\|\mathrm{y}_f\|_{\mathcal{Q}}^2 + \|\mathrm{u}_f\|_{\mathcal{R}}^2 = \|a\|_{Y_f^\top \mathcal{Q} Y_f + U_f^\top \mathcal{R} U_f}^2$$

as a function of a. Taking into account the constraints $\mathcal{M}_u \mathrm{u}_f \le \mathcal{V}_u$ and $\mathcal{M}_y \mathrm{u}_f \le \mathcal{V}_y$ and the remaining condition $\xi = W_p a$ then leads to the QP

$$\begin{aligned} a^*(\xi) := \arg\min_{a} \; & \frac{1}{2} a^\top \tilde{H} a \\ \text{s.t.} \quad & \tilde{G} a \le d, \\ & W_p a = \xi \end{aligned} \tag{13}$$

with the parameter ξ, the vector d as in (6), and

$$\tilde{H} := 2Y_f^\top \mathcal{Q} Y_f + 2U_f^\top \mathcal{R} U_f, \qquad \tilde{G} := \begin{pmatrix} \mathcal{M}_u U_f \\ \mathcal{M}_y Y_f \end{pmatrix}.$$

Remarkably, the role of the initial state x_0 in (6) is replaced by ξ, i.e., the N_p previous inputs and outputs, in (13). Furthermore, $a^*(\xi)$ only reflects an intermediate result that is used to compute optimal inputs via $\mathrm{u}_f^*(\xi) := U_f a^*(\xi)$.

3. FROM EXPLICIT MPC TO EXPLICIT DPC

The QPs (6) or (13) are typically solved for the current state x_0 or the most recent sequences ξ, respectively, to

obtain the optimal input for the current time-step. Subsequently, the procedure is repeated at the next sampling instance. Alternatively, in order to avoid numerical optimization during runtime, (6) can also be solved explicitly using parametric optimization. As a result, we then find the continuous and piecewise affine (PWA) solution

$$\mathrm{u}_f^*(x_0) = \begin{cases} L_1 x_0 + c_1 \text{ if } & x_0 \in \mathcal{X}_1, \\ \vdots & \vdots \\ L_s x_0 + c_s \text{ if } & x_0 \in \mathcal{X}_s, \end{cases} \tag{14}$$

which is defined on a polyhedral partition $\{\mathcal{X}_i\}_{i=1}^s$ of the state space (Bemporad et al., 2002). Computing this solution offline and evaluating it online is referred to as explicit MPC. While conceptually attractive, explicit MPC can usually only be applied for moderate "sizes" of the underlying QP since it is well-known that the number of regions $s \in \mathbb{N}$ typically grows exponentially with the number of decisions variables and constraints. As a consequence, solving (13) parametrically seems unattractive at first sight, since especially the number of decision variables is significantly larger than in (6). In fact, while u_f is of dimension mN_f, the dimension l of a is lower-bounded by

$$\begin{aligned} l &\geq (m+1)(N_p + N_f + n) - N_f - N_p \\ &= mN_p + mN_f + (m+1)n \end{aligned}$$

according to (9) and (10). Now, while the difference of at least $mN_p + (m+1)n$ decisions variables is significant especially for $m > 1$, we claim that this increase does not result in a more complex explicit solution for the special case of deterministic DPC. In fact, we claim that the increase in decision variables only leads to ambiguous solutions and that this ambiguity can be reduced (or even removed) by systematically eliminating variables.

3.1 Eliminating equality constraints for DPC

Following this claim, we initially eliminate the equality constraints in (13). To this end, we assume that a generalized inverse W_p^+ of W_p (satisfying the Penrose conditions) and a matrix V_p characterizing the null-space of W_p (i.e., $\mathrm{im}(V_p) = \ker(W_p)$) are known. Then, we can substitute a in (13) with

$$a := W_p^+ \xi + V_p \alpha,$$

where α is of dimension $\nu := \mathrm{nullity}(W_p) = l - \mathrm{rank}(W_p)$. Clearly, the equality constraints in (13) are satisfied for every $\alpha \in \mathbb{R}^\nu$. Hence, we obtain the transformed QP

$$\begin{aligned} \alpha^*(\xi) = \arg\min_{\alpha} \ & \frac{1}{2}\alpha^\top \hat{H} \alpha + \xi^\top \hat{F}^\top \alpha \\ \text{s.t.} \quad & \hat{G}\alpha \leq \hat{E}\xi + d \end{aligned} \tag{15}$$

with

$$\hat{H} := V_p^\top \tilde{H} V_p,\ \hat{G} := \tilde{G} V_p,\ \hat{F} := V_p^\top \tilde{H} W_p^+,\ \hat{E} := -\tilde{G} W_p^+.$$

Now, taking into account that W_p contains mN_p rows of the full rank matrix $\mathcal{H}_{N_p+N_f}(\mathrm{u}_d)$, we obviously have $\mathrm{rank}(W_p) \geq mN_p$ (and tighter bounds can be obtained with moderate effort). Hence, the number of decision variables in (15) is significantly smaller than in (13). Apart from this benefit, the two OCPs are almost equivalent. However, the transition from (13) to (15) involves a subtle modification. In fact, while (13) is infeasible for ξ not belonging to the system, (15) may be feasible for such ξ. This is due to to the fact that $W_p W_p^+ \xi$ (implicitly) maps such ξ to belonging ones as specified in Corollary 1 below.

3.2 The "common denominator"

The QP (15) not only provides a reduced number of decision variables but it also allows establishing a closer relation between MPC and DPC. To see this, we simply need to specify the (trivial) relation between x_0 and ξ. To this end, we recognize that ξ and the assumed observability allow reconstructing $x(-N_p)$. Using u_p, it is then easy to derive x_0. More formally, the procedure is captured by the relation $x_0 = \Gamma \xi$, where

$$\Gamma := \begin{pmatrix} \mathcal{B} - A^{N_p} \mathcal{O}_{N_p}^+ \mathcal{T}_{N_p} & A^{N_p} \mathcal{O}_{N_p}^+ \end{pmatrix}$$

with $\mathcal{B} := \begin{pmatrix} A^{N_p-1}B & \dots & B \end{pmatrix}$ and $\mathcal{O}_{N_p}^+ := (\mathcal{O}_{N_p}^\top \mathcal{O}_{N_p})^{-1} \mathcal{O}_{N_p}^\top$. Using this relation, we obtain the following relationship between the QPs (6) and (15).

Corollary 1. The cost and constraint specifications of (6) and (15) satisfy

$$\begin{aligned} \hat{H} &= V_p^\top U_f^\top H U_f V_p, \\ \hat{F} &= V_p^\top U_f^\top F \Gamma W_p W_p^+ + V_p^\top U_f^\top H U_f W_p^+, \\ \hat{G} &= G U_f V_p, \quad \hat{E} = E\Gamma W_p W_p^+ - G U_f W_p^+. \end{aligned}$$

A formal proof is omitted due to space restrictions. We note, however, that the key ingredient is the equation

$$Y_f = \mathcal{O}_{N_f} \Gamma W_p + \mathcal{T}_{N_f} U_f, \tag{16}$$

which can be considered as a variant of (5) for multiple sequences represented by Hankel matrices and which similarly appears in Persis and Tesi (2020). In fact, given (16), the relations in Corollary 1 follow from simple rearrangements and facts like $W_p V_p = 0$.

By further exploiting the novel relation between (6), (13), and (15), one can derive even stricter connections between MPC and DPC. In fact, we show in Klädtke et al. (2022) that there is actually a one-to-one relation between the (explicit) solutions of (6) and (15). While a formal specification of this relation, which is based on an additional parametrization and analysis of the involved subspaces, is beyond the scope of this note, we illustrate some of our findings with a numerical example next.

4. CASE STUDY

For our case study, we consider system (1) with

$$A = 1.2 \quad \text{and} \quad B = C = D = 1.$$

and the constraints $\mathcal{U} = [-1, 1]$ and $\mathcal{Y} = [-4, 4]$. Further, we choose $Q = R = 0.5$ and $N_f = 2$, which already determines the MPC problems (2) and (6). Explicitly solving (6) then leads to (14), where the $s = 5$ segments are specified by

$$L_1 = L_5 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \quad L_2 = L_4 = \begin{pmatrix} 0 \\ -0.6 \end{pmatrix}, \quad L_3 = \begin{pmatrix} -0.64 \\ -0.28 \end{pmatrix},$$

$$c_1 = -c_5 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad c_2 = -c_4 = \begin{pmatrix} 1 \\ -0.5 \end{pmatrix}, \quad c_3 = \begin{pmatrix} 0 \\ 0 \end{pmatrix},$$

as well as $\mathcal{X}_1 = [-5, -2.5]$, $\mathcal{X}_2 = [-2.5, -1.5625]$, $\mathcal{X}_3 = [-1.5625, 1.5625]$, $\mathcal{X}_4 = [1.5625, 2.5]$, and $\mathcal{X}_5 = [2.5, 5]$. The corresponding PWA solution is illustrated in Figure 1.

Now, to setup and investigate the DPC, we first note that $N_p = 1$ guarantees full rank of $\mathcal{O}_{N_p} = C = 1$. Hence, we choose an input sequence u_d, which is persistently exciting

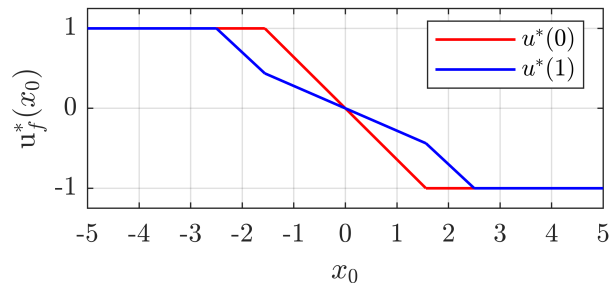

Fig. 1. Explicit solution $\mathrm{u}_f^*(x_0)$ for MPC.

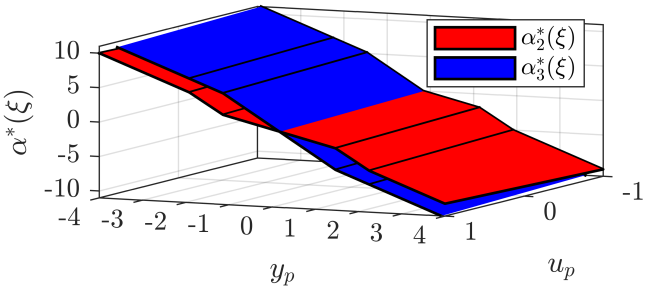

Fig. 2. Explicit solution $\alpha^*(\xi)$ for (modified) DPC. Note that (y_p, u_p) is artificially restricted to $\mathcal{Y} \times \mathcal{U}$ for visualization.

of order $N_e = 4$. According to (9), this requires at least $N_d = 7$ elements. It can be easily verified that

$$\mathrm{u}_d := (-0.6 \;\; 0 \;\; 0 \;\; 0 \;\; 0.5 \;\; 0.5 \;\; 1)^\top$$

satisfies all conditions. Furthermore,

$$\mathrm{y}_d := (-0.1 \;\; 0 \;\; 0 \;\; 0 \;\; 0.5 \;\; 1 \;\; 2.1)^\top$$

is a consistent output sequence since (8) is satisfied for $x_0 = 0.5$. According to (12), u_d and y_d specify

$$W_p = \begin{pmatrix} -0.6 & 0 & 0 & 0 & 0.5 \\ -0.1 & 0 & 0 & 0 & 0.5 \end{pmatrix}, \quad U_f = \begin{pmatrix} 0 & 0 & 0 & 0.5 & 0.5 \\ 0 & 0 & 0.5 & 0.5 & 1 \end{pmatrix},$$

and Y_f with $l = 5$. In the following, we mainly focus on the transformation to (15) and its explicit solution. To this end, we require the generalized inverse W_p^+ and the null-space description via V_p. Taking $\operatorname{rank}(W_p) = 2$ and, consequently, $\nu = 3$ into account, suitable choices are

$$W_p^+ = \begin{pmatrix} -2 & 2 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ -0.4 & 2.4 \end{pmatrix} \quad \text{and} \quad V_p = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

Obviously, the transformation from (13) to (15) allows to reduce the number of decision variables from $l = 5$ to $\nu = 3$. Still, (6) involves only $mN_f = 2$ variables. Hence, following our original claim, the transformed DPC problem should still offer some ambiguity. This can be confirmed by investigating the matrices

$$\hat{H} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0.50 & 0.75 \\ 0 & 0.75 & 1.75 \end{pmatrix}, \quad \hat{G} = \begin{pmatrix} 0 & 0 & 0.5 \\ 0 & 0.5 & 0.5 \\ 0 & 0 & -0.5 \\ 0 & -0.5 & -0.5 \\ 0 & 0 & 0.5 \\ 0 & 0.5 & 1 \\ 0 & 0 & -0.5 \\ 0 & -0.5 & -1 \end{pmatrix},$$

$$\hat{F} = \begin{pmatrix} 0 & 0 \\ -0.62 & 3.72 \\ -1.34 & 8.04 \end{pmatrix},$$

In fact, as apparent from the zero rows and columns, the choice of α_1 neither affects the cost function nor the constraint satisfaction. Without giving details, this is not surprising since $(1 \;\; 0 \;\; 0)^\top$ spans the null-space of $U_f V_p$. Now, eliminating this variable from (13) results in a strictly convex QP (whereas (13) is only convex as apparent from $\hat{H}$). Solving the reduced QP explicitly leads to the PWA functions in Figure 2. Clearly, while the domain is different, $\alpha^*(\xi)$ likewise consists of $s = 5$ affine segments.

5. CONCLUSIONS AND OUTLOOK

By establishing a stricter relation to its explicit MPC counterpart, we have shown that explicit DPC for deterministic LTI systems may not be as intractable as the parameter dimensions of the corresponding OCP suggest. While the analyzed example is kept simple to allow visualization, similar results can be obtained for more complex systems.

Future work will, among other things, thoroughly establish the connection between both formulations in terms of the (number of) partitions and (strongly) active constraints as well as further classify and reduce the amount of redundancies. Furthermore, it must be examined how (well) the results can be extended to systems or data with uncertainty.

Abstract: We are interested in determining the worst performance exhibited by a given first-order optimization method on the class of quadratic functions. Since its introduction, the *Performance Estimation Problem* (PEP) methodology has allowed the computation of the exact worst-case performance of first-order optimization methods on several functions classes, including smooth convex, strongly convex or nonconvex functions.
In this work, we extend the PEP framework to the class of quadratic functions, and apply it to analyze the difference of performance of the gradient method between convex quadratic and general smooth convex functions.

Keywords: Performance estimation, First-order methods, Quadratic functions, Linear matrix inequalities

1. INTRODUCTION

The *Performance Estimation Problem* (PEP) methodology (introduced by Drori and Teboulle (2014)) allows to compute the exact worst-case performance of a first-order optimization method on a given class of functions. More precisely, given a method and a performance criterion (lower is better), a PEP is an optimization problem that maximizes this criterion among all possible functions belonging to some class. Thus, it provides the worst possible behavior of the method on the class of functions.

It has been shown in Taylor et al. (2017) that a PEP can be reformulated as a convex semidefinite program for a wide range of function classes $\mathcal{C}$. This provided several tight results on the performance of first-order methods. In particular, the worst-case behavior of the *Gradient Method* (GM) on the class $\mathcal{F}_{\mu,L}$ of L-smooth μ-strongly convex functions was exhaustively covered.

In this work, we extend the PEP framework to function classes defined by matrices. This typically allows to study the worst-case performance of first-order methods on the class $\mathcal{Q}_{\mu,L}$ of homogeneous quadratic functions of the form $f(x) = \frac{1}{2}x^TQx$ with $\mu I \preceq Q \preceq LI$ for given parameters μ and L ($0 \leq \mu \leq L$). Another type of classes newly analyzable through our extension of the PEP are function classes $\mathcal{C}_1$ and $\mathcal{C}_2$ of the form $g(Ax)$ and $h(x) + g(Ax)$. These three classes turn out to be included in $\mathcal{F}_{\mu,L}$ if we define the smoothness and strong convexity parameters of A, g and h in a proper way. Since the worst-case functions of $\mathcal{F}_{\mu,L}$ for (GM), found in Taylor et al. (2017), are sometimes but not always quadratic or of the form $g(Ax)$, we will quantify the performance gap between the general class $\mathcal{F}_{\mu,L}$ and the classes $\mathcal{Q}_{\mu,L}$, $\mathcal{C}_1$, $\mathcal{C}_2$ or other function classes involving matrices that we can now analyze through the PEP framework.

Theorems are stated without proofs in this extended abstract, they will be appear in a forthcoming paper.

2. PEP FORMULATION

Typically, a PEP can be formulated as follows. Given the class of functions $\mathcal{C}$, the optimization method $\mathcal{M}$ performing N iterations, the initial distance R and the classical performance criterion $f(x_N) - f^*$ (objective function accuracy after N iterations), the PEP is

$$\begin{aligned} \max_{x_0,\dots,x_N,f} \quad & f(x_N) - f^* \\ \text{s.t.} \quad & f \in \mathcal{C}, \\ & x_k \text{ generated by applying } \mathcal{M} \text{ to } f \text{ from } x_0, \\ & ||x_0 - x^*|| \leq R. \end{aligned} \tag{PEP}$$

We can study any method $\mathcal{M}$ that computes each iterate as a linear combination of the initial point x_0 and the gradients of the previous iterations, i.e.

$$x_k = x_0 - \sum_{i=0}^{k-1} h_{k,i}\nabla f(x_i).$$

Coefficients $h_{k,i}$ entirely describe the method $\mathcal{M}$. For example, the gradient method with constant step size $\frac{1}{L}$ started from x_0:

For $i = 0 : N-1$

$$\begin{aligned} x_{i+1} &= x_i - \frac{1}{L}\nabla f(x_i) \\ &= x_0 - \frac{1}{L}\sum_{i=0}^{k-1}\nabla f(x_i). \end{aligned} \tag{GM}$$

is described with

$$\begin{cases} h_{k,i} = \dfrac{1}{L} & \text{if } i < k, \\ h_{k,i} = 0 & \text{otherwise.} \end{cases}$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

The constraint $f \in \mathcal{C}$ must be expressed in an explicit way with *interpolation conditions* in order to have a tractable problem.

Definition 1. Given a set of triplet $\{(x_i, g_i, f_i)\}_{i\in I}$ with I some set of indices, *interpolation conditions* for the class of functions $\mathcal{C}$ are such that there exists a function $f \in \mathcal{C}$ with

$$\begin{aligned} f(x_i) &= f_i \quad \forall i \in I, \\ \nabla f(x_i) &= g_i \quad \forall i \in I, \end{aligned}$$

if and only if the *interpolation conditions* are satisfied.

When those conditions are available, the PEP can be rewritten as the following finite-dimensional problem

$$\begin{aligned} \max_{x_0,\dots,x_N,x_*,g_0,\dots,g_N,g_*,f_0,\dots,f_N,f_*} \quad & f_N - f_* \\ \text{s.t.} \quad & x_k = x_0 - \sum_{i=0}^{k-1} h_{k,i}\nabla g_i, \\ & ||x_0 - x_*||^2 \leq R^2, \\ & \|g_*\|^2 = 0, \\ & \{(x_i, g_i, f_i)\}_{i\in I=\{0,1,\dots,N,*\}} \text{ are interpolable} \\ & \text{by some function } f \in \mathcal{C}. \end{aligned} \tag{PEP}$$

Finally, it was shown in Taylor et al. (2017) that this problem becomes a convex semidefinite problem provided that the iterates x_i and their gradients g_i are represented as elements of the Gram matrix $G = P^T P$, with

$$P = \begin{pmatrix} x_1 & \cdots & x_N & g_1 & \cdots & g_N \end{pmatrix} \in \mathbb{R}^{d\times 2N}.$$

3. PROBLEM STATEMENT

The key step and our main contribution is to obtain interpolation conditions for the class $\mathcal{Q}_{\mu,L}$ of quadratic functions. Indeed, we want to solve the following PEP on the class $\mathcal{Q}_{\mu,L}$,

$$\begin{aligned} \max_{x_0,\dots,x_N,f} \quad & f(x_N) - f^* \\ \text{s.t.} \quad & f \in \mathcal{Q}_{\mu,L}, \\ & x_k \text{ generated by applying } \mathcal{M} \text{ to } f \text{ from } x_0, \\ & ||x_0 - x^*|| \leq R. \end{aligned} \tag{PEP-Q}$$

where we need an explicit equivalent reformulation of the condition $f \in \mathcal{Q}_{\mu,L}$ in order to solve (PEP-Q).

As mentioned above, (PEP) can be formulated under the form of a semidefinite program (see Taylor et al. (2017)) involving only the Gram matrix G of the iterates x_i and their gradients g_i and the values f_i of the function at these iterates.

In order to work in the class $\mathcal{Q}_{\mu,L}$, we must consider the set of Gram matrices associated to a quadratic function. Note that in that case we have

$$\nabla f(x) = Qx \quad \forall x \tag{1}$$

Definition 2. A symmetric matrix $G \in \mathbb{S}^{2N}$ is a (μ, L, N)-*quadratic-Gram matrix* if and only if there exist a dimension $d \in \mathbb{N}$, a symmetric matrix $Q \in \mathbb{S}^d$ with $\mu I \preceq Q \preceq LI$ and a sequence $x_i \in \mathbb{R}^d$ for $i = 1, \dots, N$ such that $G = P^T P$ with

$$P = \begin{pmatrix} x_1 & \cdots & x_N & \overbrace{Qx_1}^{g_1} & \cdots & \overbrace{Qx_N}^{g_N} \end{pmatrix} \in \mathbb{R}^{d\times 2N}.$$

The set of all (μ, L, N)-quadratic-Gram matrices is denoted $\mathcal{G}_{\mu,L,N}$. It can be shown that any conic combination of (μ, L, N)-quadratic-Gram matrices is also a (μ, L, N)-quadratic-Gram matrix, hence the set $\mathcal{G}_{\mu,L,N}$ is a convex cone.

In the following, we provide an explicit convex description of this set in order to be able to include those constraints to (PEP-Q). In other words, we show a convex formulation of the condition $f \in \mathcal{Q}_{\mu,L}$.

4. INTERPOLATION CONDITIONS

Several observations can be made about the form of the (μ, L, N)-quadratic-Gram matrices. Indeed, if a matrix G belongs to $\mathcal{G}_{\mu,L,N}$, then, by diagonalization of Q, it can be written under the form

$$\begin{aligned} G &= \begin{pmatrix} X^TX & X^TQX \\ X^TQX & X^TQ^2X \end{pmatrix} \\ &= \begin{pmatrix} Y^TY & Y^TDY \\ Y^TDY & Y^TD^2Y \end{pmatrix} \\ &= \sum_{k=1}^{d} \begin{pmatrix} u_k u_k^T & \lambda_k u_k u_k^T \\ \lambda_k u_k u_k^T & \lambda_k^2 u_k u_k^T \end{pmatrix} \end{aligned} \tag{2}$$

where $X = (x_1 \cdots x_N) \in \mathbb{R}^{d\times N}$, $Q = VDV^T$ is the eigenvalue decomposition of Q, $Y = V^TX \in \mathbb{R}^{d\times N}$, $D = \operatorname{diag}(\lambda_1, \dots, \lambda_d)$, $\lambda_k \in [\mu, L]$ and $u_k = \begin{pmatrix} y_{1,k} \\ \vdots \\ y_{N,k} \end{pmatrix}$.

Vector u_k contains the k-th component of all vectors y_i. Expression (2) informs us that each block X^TX, X^TQX, X^TQ^2X can be expressed as the sum of d positive definite rank-1 matrices $u_k u_k^T$, $\lambda_k u_k u_k^T$ and $\lambda_k^2 u_k u_k^T$.

By characterizing the Gram matrices exhibiting this structure, we are able to obtain the following explicit description of (μ, L, N)-quadratic-Gram matrices.

Theorem 2. Given a symmetric matrix

$$G = \begin{pmatrix} A & B \\ B^T & C \end{pmatrix} \in \mathbb{S}^{2N}$$

with $A, C \in \mathbb{S}^N$ and $B \in \mathbb{R}^{N\times N}$, the conditions

$$G \succeq 0 \tag{C1}$$

$$B = B^T \tag{C2}$$

$$B \succeq \frac{\mu L}{\mu + L} A + \frac{1}{\mu + L} C \tag{C3}$$

are necessary and sufficient for

$$G \in \mathcal{G}_{\mu,L,N}.$$

Observe that the quadratic interpolation conditions (C1), (C2) and (C3) of Theorem 2 do not involve the function values f_i. Actually, the variables f_i are directly encoded in the diagonal of the block matrix $B = X^TQX$. Indeed, thanks to (1), we have

$$f(x) = \frac{1}{2} x^T Q x = \frac{1}{2} x^T \nabla f(x)$$

and the iterates x_i, g_i and f_i are linked through

$$f_i = \frac{1}{2} x_i^T g_i.$$

Since B contains the scalar products $x_i^T g_j$, whenever we need the value of f_i, we just use

$$f_i = \frac{1}{2} B_{ii}.$$

It is now possible to replace the condition $f \in \mathcal{Q}_{\mu,L}$ in (PEP-Q) by the interpolation conditions obtained in Theorem 2, which allows to reformulate the whole problem as a tractable optimization problem. This problem is a convex semidefinite program involving linear matrix constraint and can be comfortably written and solved with the *Python* library `PEPit` (see Goujaud et al. (2022)).
Note that as we only consider homogeneous quadratic functions in the class $\mathcal{Q}_{\mu,L}$, we can assume implicitly that $x^* = 0$ and $f^* = f(x^*) = 0$, which simplifies the formulation.

Finally, as mentioned in the introduction, we actually obtained more general interpolation conditions that the ones of the class of quadratic functions. Indeed, Definition 2 and Theorem 2 provide interpolation conditions for any two sequences x_i and y_i linked by a matrix, i.e. $y_i = Qx_i \quad \forall i$. For example, if we apply a first-order method to the class of functions of the form $f(x) = g(Qx)$, then we will need to compute the gradient of f, i.e.

$$\nabla f(x) = Q \nabla g(Qx). \tag{3}$$

In order to describe this class with interpolation conditions, we need to force x_i and $y_i = Qx_i$ to be linked by a matrix as well as the $u_i = \nabla g(Qx_i)$ and $v_i = Q\nabla g(Qx_i)$. Thanks to Theorem 2, we are able to do it and, thus, to analyze the worst-case performance of this class through PEP.

5. RELATION BETWEEN INTERPOLATION CONDITIONS OF $\mathcal{F}_{\mu,L}$ AND $\mathcal{Q}_{\mu,L}$

The class of quadratic functions $\mathcal{Q}_{\mu,L}$ is included in $\mathcal{F}_{\mu,L}$, therefore, from the interpolation conditions of $\mathcal{Q}_{\mu,L}$, it must be possible to obtain the interpolation conditions of $\mathcal{F}_{\mu,L}$.

In Taylor et al. (2017), the following interpolation conditions for the class $\mathcal{F}_{\mu,L}$ have been obtained $\forall i, j = 0, 1, \dots, N$

$$\begin{aligned} f_i - f_j - g_j^T(x_i - x_j) \geq \frac{1}{2(1-\mu/L)} & \\ \left(\frac{1}{L}(g_i^T g_i + g_j^T g_j - 2 g_i^T g_j) \right. & \\ + \mu(x_i^T x_i + x_j^T x_j - 2 x_i^T x_j) & \\ \left. - 2\frac{\mu}{L}(g_j^T x_j - g_j^T x_i - g_i^T x_j + g_i^T x_i) \right). & \end{aligned} \tag{4}$$

In the quadratic case, if we define a matrix $M = -\frac{\mu L}{\mu+L} A + B - \frac{1}{\mu+L} C$, the condition (C3) can be written as the positive semidefiniteness of matrix M which is equivalent to

$$\begin{aligned} M \succeq 0 \Leftrightarrow z^T M z \geq 0 \quad \forall z \in \mathbb{R}^N & \\ \Leftrightarrow \sum_{k=1}^{N} \sum_{l=1}^{N} z_k z_l M_{kl} \geq 0 \quad \forall z \in \mathbb{R}^N. & \end{aligned} \tag{5}$$

Choosing $z_i = 1$, $z_j = -1$ and all the other components of z equal to zero in (5) and then using $f_i = \frac{1}{2} x_i^T g_i$ yields the interpolation conditions (4) of the class $\mathcal{F}_{\mu,L}$.

Therefore, the finite set of interpolation conditions of $\mathcal{F}_{\mu,L}$ is explicitly seen as a consequence of the set of interpolation conditions of $\mathcal{Q}_{\mu,L}$.

6. ANALYSIS OF THE GRADIENT METHOD

In Taylor et al. (2017), the worst-case performance and the functions reaching it for the class $\mathcal{F}_{\mu,L}$ have been completely analyzed thanks to the PEP methodology. We would like to compare these results with the behavior of (GM) on the class $\mathcal{Q}_{\mu,L}$ and other classes involving matrices.

In the convex case $\mu = 0$, the worst-case performance on the class $\mathcal{F}_{0,L}$ is (from Taylor et al. (2017))

$$f(x_N) - f^* \leq \frac{LR^2}{4N+2}. \tag{6}$$

Note that this worst-case performance is reached by a Huber function, which is not quadratic and does not belong to $\mathcal{Q}_{0,L}$.

Thanks to our extension of PEP for the class $\mathcal{Q}_{\mu,L}$, we can solve (PEP) for the class $\mathcal{Q}_{0,L}$. It yields the following numerical results. Fig. 1 is the worst-case performance of (GM) on $\mathcal{F}_{0,L}$ (red) and $\mathcal{Q}_{0,L}$ (blue) for each number of iterations N.

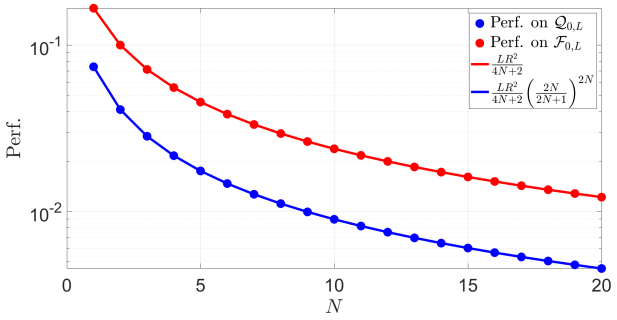

Fig. 1. Worst-case performance of (GM) on $\mathcal{Q}_{\mu,L}$ (blue dots) obtained by PEP and on $\mathcal{F}_{\mu,L}$ (red dots).

It turns out that it is possible to identify the worst-case rate of performance of (GM) on $\mathcal{Q}_{0,L}$, which is equal to the following analytical expression

$$f(x_N) - f^* \leq \frac{LR^2}{4N+2} \left(\frac{2N}{2N+1} \right)^{2N} \tag{7}$$

and this worst performance is achieved by the quadratic function

$$f(x) = \frac{Lx^2}{4N+2}.$$

We observe that the numerical results of PEP (blue dots) in Fig. 1 exactly matches the rate (7) (blue line).

Interestingly, the difference between the worst-case performance of (GM) on $\mathcal{F}_{0,L}$ and $\mathcal{Q}_{0,L}$ is the factor $\left(\frac{2N}{2N+1}\right)^{2N}$. Moreover, this factor exhibits two particular properties

$$\lim_{N\to\infty}\left(\frac{2N}{2N+1}\right)^{2N} = \frac{1}{e},$$
$$\left(\frac{2N}{2N+1}\right)^{2N} \geq \frac{1}{e} \quad \forall N \in \mathbb{N}.$$

Therefore, we can say that, for any number N of iterations, the worst-case performance of (GM) with constant step size $\frac{1}{L}$ on $\mathcal{F}_{0,L}$ is always lower than the performance on $\mathcal{Q}_{0,L}$ multiplied by a factor e.

To be complete, we must now mention that the literature already provides a methodology to analyze the worst-case performance of a first-order method on the class of quadratic functions with eigenvalues between μ and L (see for example Flanders and Shortley (1950); Nemirovsky and Polyak (1984); d'Aspremont et al. (2021)) and, thus, to obtain the rate (7). Indeed, given a quadratic function $\frac{1}{2}x^TQx$, an initial point x_0 and a method $\mathcal{M}$, the maximization of the last iterate x_N can be expressed as the maximization of a polynomial evaluated at the elements of the spectrum of Q, where the coefficients of the polynomial only depend on the method $\mathcal{M}$. Therefore this leads to the maximization of some explicit polynomial whose degree grows with the number of iterations. It can be shown that such a reasoning will provide the same rate (7).

However, as explained earlier, we are now also able to analyze the class of functions of the form $g(Ax)$, which cannot be tackled by the simple polynomial approach described in the previous paragraph. We observe a difference of worst-case performance of (GM) between the general class $\mathcal{F}_{0,L}$ and the class $\mathcal{C}_1$ of functions of the form $f(x) = g(Ax)$ where f is still L-smooth convex. Fig. 2 is the worst-case performance of (GM) on $\mathcal{F}_{0,L}$ (red) and $\mathcal{C}_1$ (blue) for each number of iterations N. Note again that such

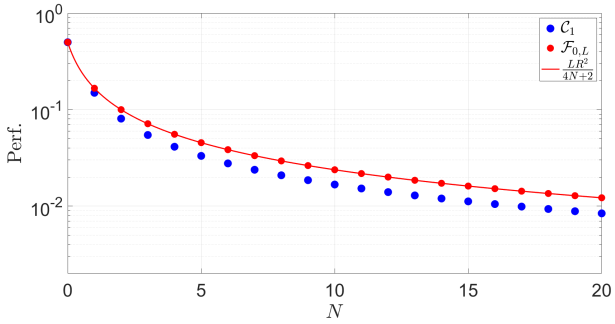

Fig. 2. Worst-case performance of (GM) on C_1 (blue dots) obtained by PEP.

results cannot be obtained by the abovementioned spectral analysis, and that it is possible with PEP to study even more complex functions classes such as $h(x) + g(Ax)$.

7. CONCLUSION

PEP has been shown to be a powerful tool for the analysis of the worst-case behavior of first-order optimization methods on a given class of functions. We showed how to extend PEP to the class of quadratic functions, thanks to Theorem 2, using a list of explicit convex constraints on the Gram matrix G. Moreover, we are able to implement and solve the PEP thanks to the *Python* library `PEPit`.

Our numerical experiments exactly match the analytical expression of the worst-case performance of the gradient method on convex quadratic functions $\mathcal{Q}_{0,L}$ and we compared it to the worst-case performance on smooth strongly convex functions $\mathcal{F}_{0,L}$. An interesting direction for future research would be to obtain a bound on the performance gap of any method between the general class $\mathcal{F}_{\mu,L}$ and the class $\mathcal{Q}_{\mu,L}$.

Moreover, in addition to the class of quadratic functions, we are now able to formulate explicit interpolation conditions for any class of functions involving matrices and to analyze them through PEP. This include for example the simple class of functions $f(x) = g(Ax)$ but also more complicated classes of functions as $f(x) = h(x) + g(Ax)$. Although the worst-case performance on the class of quadratic methods could already be obtained via the spectrum analysis approach, our extension of PEP appears to the best of our knowledge to be the first tool able to analyze classes of function of the forms $f(x) = g(Ax)$ or $f(x) = h(x) + g(Ax)$.

Abstract: It is well known that noncommutative (nc) rational functions regular at the origin admit a good realization (or linearization) theory. This is very useful both conceptually and for a variety of applications since it often essentially reduces the study of these rational functions to a study of linear pencils. By translation the method can be applied to nc rational functions that are regular at some scalar point, but not beyond. In this talk we discuss the realization problem for nc rational functions regular at an arbitrary given matrix point using the nc difference–differential calculus and the general Taylor–Taylor series of nc function theory Kaliuzhnyi-Verbovetskyi and Vinnikov (2014) and provide a solution which is the analogue of the classical Hankel realization.

Keywords: Noncommutative Rational Functions, Free Noncommutative Function Theory, Taylor–Taylor Series, Noncommutative Multidimensional Systems

NC RATIONAL FUNCTIONS

We consider the ring of nc polynomials (the free ring) $\mathbb{K}\langle x_1, \dots, x_d\rangle$ over a field $\mathbb{K}$. Here $x_1, \dots, x_d$ are nc indeterminates, and $p \in \mathbb{K}\langle x_1, \dots, x_d\rangle$ is of the form

$$p = \sum_{w \in \boldsymbol{\mathcal{G}}_d} p_w x^w, \tag{1}$$

where $\boldsymbol{\mathcal{G}}_d$ denotes the free monoid on d generators (letters) $g_1, \dots, g_d$ with identity $\emptyset$ (the empty word), $p_w \in \mathbb{K}$, x^w are nc monomials in $x_1, \dots, x_d$ ($x^w = x_{j_1} \cdots x_{j_l}$ for $w = g_{j_1} \cdots g_{j_l} \in \boldsymbol{\mathcal{G}}_d$ and $x^\emptyset = 1$), and the sum is finite. p can be evaluated in an obvious way on d-tuples of square matrices of all sizes over $\mathbb{K}$: for $X = (X_1, \dots, X_d) \in (\mathbb{K}^{n\times n})^d$,

$$p(X) = \sum_{w \in \boldsymbol{\mathcal{G}}_d} p_w X^w = \sum_{w \in \boldsymbol{\mathcal{G}}_d} X^w p_w \in \mathbb{K}^{n\times n}. \tag{2}$$

Notice that nonzero p can vanish on $(\mathbb{K}^{n\times n})^d$ for some n: $p = x_1x_2 - x_2x_1$ vanishes on $\left(\mathbb{K}^{1\times 1}\right)^d$, and $p = \sum_{\pi \in \mathcal{S}_{n+1}} \operatorname{sign}(\pi)\, x_1^{\pi(1)-1} x_2 \cdots x_1^{\pi(n+1)-1} x_2$ (where $\mathcal{S}_{n+1}$ is the symmetric group on $n+1$ elements) vanishes on $(\mathbb{K}^{n\times n})^d$. However if $p(X) = 0$ for all $X \in \coprod_{n=1}^\infty (\mathbb{K}^{n\times n})^d$ then $p = 0$.

The skew field of nc rational functions $\mathbb{K}\langle\langle x_1, \dots, x_d\rangle\rangle$ over a field $\mathbb{K}$ (the free skew field) is the universal skew field of fractions of the ring of nc polynomials over $\mathbb{K}$. This involves some non-trivial details since unlike the commutative case, a nc rational function does not admit a canonical coprime fraction representation; see Amitsur (1966); Bergman (1970); Cohn (1971a, 1972) for some of the original constructions, and Rowen (1980) (Chapter 8) and Cohn (1971b, 2006) for good expositions and background. The following is most natural from the point of view of nc function theory and is a version of Amitsur's original construction except that we use evaluation on d-tuples of square matrices of all sizes over $\mathbb{K}$ instead of evaluation on a "large" auxilliary skew field; see Kaliuzhnyi-Verbovetskyi and Vinnikov (2009, 2012) for details and further references. We first define (scalar) nc rational expressions by starting with nc polynomials and then applying successive arithmetic operations — addition, multiplication, and inversion. A nc rational expression r can be evaluated on a d-tuple X of $n\times n$ matrices in its *domain of regularity*, $\operatorname{dom} r$, which is defined as the set of all d-tuples of square matrices of all sizes such that all the inverses involved in the calculation of $r(X)$ exist. (We assume that $\operatorname{dom} r \neq \emptyset$, in other words, when forming nc rational expressions we never invert an expression that is nowhere invertible.) Two nc rational expressions r_1 and r_2 are called *equivalent* if $\operatorname{dom} r_1 \cap \operatorname{dom} r_2 \neq \emptyset$ and $r_1(Z) = r_2(Z)$ for all d-tuples $Z \in \operatorname{dom} r_1 \cap \operatorname{dom} r_2$. We define a *nc rational function* $\mathfrak{r}$ to be an equivalence class of nc rational expressions; notice that it has a well-defined evaluation on $\operatorname{dom} \mathfrak{r} = \bigcup_{R\in\mathfrak{r}} \operatorname{dom} R$ (here R denotes a 1×1 matrix-valued rather than scalar nc rational expression, i.e., some of the intermediate expressions may involve matrices of scalar nc rational expressions, cf. below). We set $(\operatorname{dom}\mathfrak{r})_n = \operatorname{dom}\mathfrak{r} \cap (\mathbb{K}^{n\times n})^d$.

It is clear that the evaluation of a nc rational function respects direct sums and simultaneous similarities, so that a nc rational function $\mathfrak{r}$ defines a nc function (Kaliuzhnyi-Verbovetskyi and Vinnikov (2014)) on $\operatorname{dom}\mathfrak{r}$ (technically, on an apriori somewhat larger set called the extended domain of regularity of $\mathfrak{r}$ obtained by evaluating $\mathfrak{r}$ on d-tuples of generic matrices). In particular, nc rational functions admit a difference-differential calculus. The partial nc difference-differential operators

$$\Delta_j \colon \mathbb{K}\langle\langle x_1, \dots, x_d\rangle\rangle \to \mathbb{K}\langle\langle x_1, \dots, x_d\rangle\rangle \otimes \mathbb{K}\langle\langle x_1, \dots, x_d\rangle\rangle,$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$j = 1, \dots, d$, can be defined recursively (on the level of nc rational expressions) starting with $\Delta_j(x_i) = \delta_{ij}(1 \otimes 1)$ and using the nc calculus rules, see Kaliuzhnyi-Verbovetskyi and Vinnikov (2012).

POWER SERIES EXPANSION AROUND A SCALAR POINT

A nc rational expression which is regular at 0 determines a nc formal power series. This correspondence is defined recursively using addition and multiplication of nc formal power series and inversion of a nc formal power series with an invertible constant term (the coefficient of $z^{\emptyset}$). Furthermore, r_1 and r_2 are equivalent if and only if the corresponding nc formal power series coincide. By translation, if $\lambda = (\lambda_1, \dots, \lambda_d) \in (\operatorname{dom} \mathfrak{r})_1 \subseteq \mathbb{K}^d$ we obtain, for $X = (X_1, \dots, X_d) \in \mathbb{K}^{n \times n}$,

$$\mathfrak{r}(X) \sim \sum_{w \in \boldsymbol{\mathcal{G}}_d} (X - I_n \lambda)^w \mathfrak{r}_w. \tag{3}$$

Here $\mathfrak{r}_w \in \mathbb{K}$ are the coefficients, and $X - I_n\lambda$ stands for $(X_1 - I_n\lambda_1, \dots, X_d - I_n\lambda_d)$.

From the point of view of nc function theory, (3) is the Taylor–Taylor (TT) power series expansion of $\mathfrak{r}$ around λ. In particular, the coefficients $\mathfrak{r}_w$ can be calculated by means of the nc difference-differential calculus: $\mathfrak{r}_w = \Delta^w \mathfrak{r}(\lambda, \dots, \lambda)$, Also, the series (3) actually converges to $\mathfrak{r}(X)$ in the following cases: (a) if $X - I_n\lambda$ is a jointly nilpotent d tuple of matrices so that the sum is finite; (b) in the case $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$, the series converges normally on any open nc ball $\coprod_{n=1}^{\infty} \left\{ X \in (\mathbb{K}^{n \times n})^d : \|X - I_n\lambda\| < r \right\}$ (with respect to any operator space norm on $\mathbb{K}^d$, e.g., $\|Z\| = \|Z_1^* Z_1 + \cdots + Z_d^* Z_d\|$ for $Z = (Z_1, \dots, Z_d)$) contained in the (extended) domain of regularity of $\mathfrak{r}$.

REALIZATION THEORY AROUND THE ORIGIN

We have the following basic facts of life (Kleene (1956), Schützenberger (1961, 1963), Fliess (1970, 1974a,b), see Berstel and Reutenauer (1988) for a good survey, Ball, Groenewald, and Malakorn (2005, 2006a,b), Kaliuzhnyi-Verbovetskyi and Vinnikov (2009, 2012)):

(1) A nc power series $\sum_{w \in \boldsymbol{\mathcal{G}}_d} \mathfrak{r}_w x^w \in \mathbb{K}\langle\langle x_1, \dots, x_d \rangle\rangle$ is the power series expansion of a nc rational function at a scalar point iff the corresponding infinite $\boldsymbol{\mathcal{G}}_d \times \boldsymbol{\mathcal{G}}_d$ *Hankel matrix* $\mathbb{H} = [\mathfrak{r}_{uv}]_{u,v \in \boldsymbol{\mathcal{G}}_d}$ has finite rank.

(2) If a nc rational function $\mathfrak{r}$ is regular at 0 it admits a unique (up to unique similarity) minimal (controllable and observable) state space realization:

$$\mathfrak{r}(x) = D + C(I - A_1 x_1 - \cdots - A_d x_d)^{-1} (B_1 x_1 + \cdots + B_d x_d), \tag{4}$$

where $A_1, \dots, A_d \in \mathbb{K}^{L \times L}$ for some integer L, $B_1, \dots, B_d \in \mathbb{K}^{L \times 1}$, $C \in \mathbb{K}^{1 \times L}$, and $D = \mathfrak{r}(0)$. Furthermore,

$$\operatorname{dom} \mathfrak{r} = \coprod_{n=1}^{\infty} \left\{ X = (X_1, \dots, X_d) \in \left(\mathbb{K}^{n \times n}\right)^d : \det(I_{Ln} - X_1 \otimes A_1 - \cdots - X_d \otimes A_d) \neq 0 \right\}.$$

Here a realization is called *minimal* if the state space dimension L is as small as possible, *controllable* if

$$\operatorname{span}_{i=1,\dots,d,\, w \in \boldsymbol{\mathcal{G}}_d} \operatorname{im} A^w B_i = \mathbb{C}^L,$$

and *observable* if

$$\cap_{w \in \boldsymbol{\mathcal{G}}_d} \ker C A^w = \{0\}.$$

The items (1) and (2) are closely related: the realization (4) implies immediately that the column rank of the Hankel matrix $\mathbb{H}$ is at most L, and whereas a realization can be constructed recursively by synthesis, starting with polynomuals (or even just the basic monomials $x_1, \dots, x_d$) and using sum, product, and inversion formulae, it can also be constructed in one step using the columns space of $\mathbb{H}$. We refer to Ball, Groenewald, and Malakorn (2005) and Kaliuzhnyi-Verbovetskyi and Vinnikov (2012) for details and further references.

POWER SERIES EXPANSION AROUND A MATRIX POINT

Some notation: for $P = [P_{ij}]_{i,j=1,\dots,m}, Q = [Q_{ij}]_{i,j=1,\dots,m} \in \mathbb{K}^{sm \times sm} \cong \left(\mathbb{K}^{s \times s}\right)^{m \times m}$, we let $P \odot_s Q$ denote the product of P and Q viewed as $m \times m$ matrices over the tensor algebra of $\mathbb{K}^{s \times s}$:

$$P \odot_s Q = \left[\sum_{j=1}^{m} P_{ij} \otimes Q_{jk} \right]_{i,k=1,\dots,m} \in \left(\mathbb{K}^{s \times s} \otimes \mathbb{K}^{s \times s}\right)^{m \times m}.$$

For $Z = (Z_1, \dots, Z_d) \in \left(\mathbb{K}^{sm \times sm}\right)^d$ and $w = g_{j_1} \cdots g_{j_l} \in \boldsymbol{\mathcal{G}}_d$, we let $Z^{\odot_s w} = Z_{i_1} \odot_s \cdots \odot_s Z_{i_l} \in \left(\left(\mathbb{K}^{s \times s}\right)^{\otimes l}\right)^{m \times m}$.

The power series expansion around $Y \in (\operatorname{dom} \mathfrak{r})_s$ is now given by, for $X \in \left(\mathbb{K}^{sm \times sm}\right)^d$,

$$\mathfrak{r}(X) \sim \sum_{w \in \boldsymbol{\mathcal{G}}_d} (X - I_m \otimes Y)^{\odot_s w}\, \mathfrak{r}_w. \tag{5}$$

Here, the coefficient $\mathfrak{r}_w$ is a l-linear mapping $\left(\mathbb{K}^{s \times s}\right)^l \longrightarrow \mathbb{K}^{s \times s}$, where l is the length of the word w, or alternatively a linear mapping $\left(\mathbb{K}^{s \times s}\right)^{\otimes l} \longrightarrow \mathbb{K}^{s \times s}$. Notice that

$$\left(X - \bigoplus_{\alpha=1}^{m} Y \right)^{\odot_s w} \in \left(\left(\mathbb{K}^{s \times s}\right)^{\otimes l}\right)^{m \times m},$$

hence we can apply $\mathfrak{r}_w$ to every entry of this matrix yielding a matrix in $\left(\mathbb{K}^{s \times s}\right)^{m \times m} \cong \mathbb{K}^{sm \times sm}$ — which is where the value $\mathfrak{r}(X)$ lies.

NC formal power series with a matrix centre Y, of the form (5), form a ring with an obvious convolution product. It is clear that any nc polynomial can be written as a (finite) nc power series with centre Y, and the power series expansion of a nc rational expression r regular at Y can be obtained recursively using addition and multiplication of nc formal power series with centre Y and inversion of a nc formal power series with an invertible constant term. From the point of view of nc function theory, (3) is the TT power series expansion of $\mathfrak{r}$ around a matrix centre Y. One important difference with the case of a scalar centre is that the coefficients $\mathfrak{r}_w$ are not arbitrary multilinear mappings; they have to satisfy certain compatibility conditions with respect to Y, see Kaliuzhnyi-Verbovetskyi and Vinnikov (2014) ((4.14)–(4.17)).

REALIZATION THEORY AROUND A MATRIX POINT

We have shown in Porat and Vinnikov (2021, 2020) that if a nc rational function $\mathfrak{r}$ is regular at $Y \in (\mathbb{K}^{s\times s})^d$, it admits a unique (up to unique similarity) minimal (controllable and observable) state space realization with centre Y: for $X \in (\mathbb{K}^{sm\times sm})^d$,

$$\mathfrak{r}(X) = I_m \otimes D + (I_m\otimes C)\big(I_{Lsm} - (X_1 - I_m\otimes Y_1)\mathbf{A}_1 - \cdots - (X_d - I_m\otimes Y_d)\mathbf{A}_d\big)^{-1} \big((X_1 - I_m\otimes Y_1)\mathbf{B}_1 + \cdots + (X_d - I_m\otimes Y_d)\mathbf{B}_d\big). \quad (6)$$

Here $\mathbf{A}_1, \ldots, \mathbf{A}_d \colon \mathbb{K}^{s\times s} \to \mathbb{K}^{Ls\times Ls}$ for some integer L and $\mathbf{B}_1, \ldots, \mathbf{B}_d \colon \mathbb{K}^{s\times s} \to \mathbb{K}^{Ls\times s}$ are linear mappings, $C \in \mathbb{K}^{s\times Ls}$, and $D = \mathfrak{r}(Y) \in \mathbb{K}^{s\times s}$. Furthermore,

$$(\operatorname{dom}\mathfrak{r})_{sm} = \big\{X = (X_1, \ldots, X_d) \in \big(\mathbb{K}^{sm\times sm}\big)^d : \det\big(I_{Lsm} - (X_1 - I_m\otimes Y_1)\mathbf{A}_1 - \cdots - (X_d - I_m\otimes Y_d)\mathbf{A}_d\big) \neq 0\big\}.$$

In contrast to the case of realizations around the origin (or around a scalar centre), there are necessary and sufficient compatibility conditions with respect to Y on the coefficients $\mathbf{A}_1, \ldots, \mathbf{A}_d$, $\mathbf{B}_1, \ldots, \mathbf{B}_d$, C, D for the corresponding sequence of coefficients $\mathfrak{r}_w$ to satisfy the compatibility conditions of Kaliuzhnyi-Verbovetskyi and Vinnikov (2014) ((4.14)–(4.17)) and for (6) to define a nc rational function.

HANKEL REALIZATIONS AND A GENERALIZED FLIESS–KRONECKER THEOREM

The construction of the realisation (6) in Porat and Vinnikov (2021, 2020) involves synthesis using sum, production, and inversion formulae. In this talk we will use the nc difference–differential calculus to associate to the realisation (6) a functional model that is obtained directly from the function $\mathfrak{r}$ and the $s \times s$ matrix centre Y. This leads to a generalization of the Fliess–Kronecker theorem. Let $\mathbb{I} = \bigcup_{\ell=0}^{\infty} \mathbb{I}_\ell$, $\mathbb{I}_\ell = \{\omega \in \boldsymbol{\mathcal{G}}_d \colon |\omega| = \ell\} \times (\{1, \ldots, s\}\times\{1, \ldots, s\})^\ell$. Then the nc power series (5) with centre Y, with the coefficients satisfying the corresponding compatibility conditions of Kaliuzhnyi-Verbovetskyi and Vinnikov (2014) ((4.14)–(4.17)) with respect to Y, is the power series expansion at Y of a nc rational function iff the infinite Hankel matrix

$$\mathbb{H} = \Big[\mathfrak{r}_{uu'}\Big(E_{i_1,j_1}, \ldots, E_{i_{|u|},j_{|u|}}, E_{i'_1,j'_1}, E_{i'_{|u'|},j'_{|u'|}}\Big)\Big]$$

where $(u, (i_1, j_1), \ldots, (i_{|u|}, j_{|u|}))$, $(u', (i'_1, j'_1), \ldots, (i'_{|u'|}, j'_{|u'|})) \in \mathbb{I}$ has finite rank.

The power series expansions and realizations around an arbitrary matrix point provide a direct construction of the free skew field as the limit of the corresponding local rings.

Abstract: We consider overdetermined multidimensional discrete-time systems where the evolution of the whole state vector is given by several update equations in several linearly independent directions. Such systems are overdetermined and we assume that they come equipped with compatibility difference equations for the input and output signals. As a consequence of these compatibility equations frequency domain analysis leads to function theory on a certain algebraic curve rather than to function theory in several complex variables. More precisely, the transfer function of the system is (under certain assumptions) a meromorphic bundle map on a compact Riemann surface. In this talk we will discuss the corresponding realization problem and provide a solution which is the higher genus analogue of the classical Hankel realization.

Keywords: Multidimensional Systems, Algebraic Curves, Vector Bundles on a Compact Riemann Surface

OVERDETERMINED SYSTEMS AND COMPATIBILITY DIFFERENCE EQUATIONS

We consider a 2D (linear, time-invariant) discrete-time input/state/output (i/s/o) system given by

$$\Sigma: \quad \begin{cases} x(t+\mathbf{e}_1) &= A_1 x(t) + B_1 u(t) \\ x(t+\mathbf{e}_2) &= A_2 x(t) + B_2 u(t) \\ y(t) &= Cx(t) + Du(t) \end{cases} \tag{1}$$

where $t \in \mathbb{Z}^2$, $u(t)$ takes values in the *input space* $\mathcal{E}$, $x(t)$ takes values in the *state space* $\mathcal{X}$, and $y(t)$ takes values in the *output space* $\mathcal{E}_*$ and $\mathbf{e}_1$, $\mathbf{e}_2$ denote the two standard basis vectors

$$\mathbf{e}_1 = (1,0), \quad \mathbf{e}_2 = (0,1)$$

for $\mathbb{R}^2$, here used to indicated increments in the horizontal and vertical directions, respectively, on the integer lattice $\mathbb{Z}$. The system is *overdetermined* since there are two ways to compute $x(t+\mathbf{e}_1+\mathbf{e}_2)$ from $x(t)$:

$$x(t) \mapsto x(t+\mathbf{e}_1) \mapsto x(t+\mathbf{e}_1+\mathbf{e}_2),$$
$$x(t) \mapsto x(t+\mathbf{e}_2) \mapsto x(t+\mathbf{e}_2+\mathbf{e}_1).$$

This leads to the necessity of consideration of *compatibility conditions* to be satisfied in order that the system equations have solutions.

Requiring the system equations to be compatible for the free evolution (zero input) and arbitrary initial state leads to the commutativity condition:

$$A_1 A_2 = A_2 A_1. \tag{V1}$$

Analysis of non-free evolution leads us to assume that we have factorizations

$$B_1 = \widetilde{B}\sigma_1, \quad B_2 = \widetilde{B}\sigma_2,$$
$$A_2 B_1 - A_1 B_2 = A_2\widetilde{B}\sigma_1 - A_1\widetilde{B}\sigma_2 = \widetilde{B}\gamma \tag{V2}$$

for operators σ_1, σ_2 and γ mapping the input space $\mathcal{E}$ into some auxiliary input space $\widetilde{\mathcal{E}}$ and an input operator $\widetilde{B}\colon \widetilde{\mathcal{E}} \to \mathcal{X}$; then a sufficient condition for the input signal to be compatible is given by the input difference equation:

$$\sigma_2 u(t+\mathbf{e}_1) - \sigma_1 u(t+\mathbf{e}_2) + \gamma u(t) = 0. \tag{2}$$

We seek a similar output difference equation for the corresponding output signal

$$\sigma_{2*} y(t+\mathbf{e}_1) - \sigma_{1*} y(t+\mathbf{e}_2) + \gamma_* y(t) = 0 \tag{3}$$

for some σ_{1*}, σ_{2*} and γ_* in $\mathcal{L}(\mathcal{E}_*\widetilde{\mathcal{E}}_*)$. Using the system equations, this leads us naturally to assume that there is an operator $\widetilde{D} \in \mathcal{L}(\widetilde{\mathcal{E}}, \widetilde{\mathcal{E}}_*)$ so that

$$\sigma_{1*} C A_2 - \sigma_{2*} C A_1 = \gamma_* C, \tag{V3}$$

$$\sigma_{2*} D = \widetilde{D}\sigma_2, \quad \sigma_{1*} D = \widetilde{D}\sigma_1,$$
$$\sigma_{2*} C\widetilde{B}\sigma_1 - \sigma_{1*} C\widetilde{B}\sigma_2 + \gamma_* D = \widetilde{D}\gamma. \tag{V4}$$

A collection of spaces and operators satisfying (V1)–(V4) is called a (commutative two-operator) vessel. It corresponds to the overdetermined system (1) with the compatibility difference equations (2) & (3), as well as to the dual system

$$\Sigma_*: \quad \begin{cases} x_*(t-\mathbf{e}_1) &= A_1^* x_*(t) + C^*\sigma_{1*}^* u_*(t) \\ x_*(t-\mathbf{e}_2) &= A_2^* x_*(t) + C^*\sigma_{1*}^* u_*(t) \\ y_*(t) &= \widetilde{B}^* x_*(t) + \widetilde{D}^* u_*(t) \end{cases} \tag{4}$$

with state space $\mathcal{X}$, input space $\widetilde{\mathcal{E}}_*$ and output space $\widetilde{\mathcal{E}}$, and compatibility difference equations

$$\sigma_{2*}^* u_*(t-\mathbf{e}_1) - \sigma_{1*}^* u_* t - \mathbf{e}_2) + \gamma_*^* u_*(t) = 0 \tag{5}$$

and

$$\sigma_2^* y_*(t-\mathbf{e}_1) - \sigma_1^* y_*(t-\mathbf{e}_2) + \gamma^* y_*(t) = 0. \tag{6}$$

These systems are the discrete-time analogues of overdetermined 2D continuous-time systems that were discovered

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

by Livšic (1978, 1979a,b). They were extensively studied, see Livšic–Kravitsky–Markus–Vinnikov (1995); Vinnikov (1998); Livšic (2001); Ball and Vinnikov (2003), primarily as a system-theoretic tool for spectral analysis of pairs of commuting nonselfadjoint (primarily dissipative) operators [1], and for applying the state-space method to function theory on algebraic curves and compact Riemann surfaces. Assorted applications were considered in Livšic (1997, 2002).

FREQUENCY DOMAIN ANALYSIS

We consider a discrete wave trajectory

$$u(t) = \lambda_1^{t_1}\lambda_2^{t_2}u_0,\ x(t) = \lambda_1^{t_1}\lambda_2^{t_2}x_0,\ y(t) = \lambda_1^{t_1}\lambda_2^{t_2}y_0,$$

$t = (t_1, t_2) \in \mathbb{Z}^2$, where $\lambda = (\lambda_1, \lambda_2) \in \mathbb{C}^2$ (double frequency), $u_0 \in \mathcal{E}$, $x_0 \in \mathcal{X}$, $y_0 \in \mathcal{E}_*$ (amplitudes). We assume that the four input and output spaces are all finite dimensional and that (non-degeneracy assumption) $\exists \xi_1, \xi_2$ s.t. $\xi_1\sigma_1 + \xi_2\sigma_2$, $\xi_1\sigma_{1*} + \xi_2\sigma_{2*}$ are invertible. It follows that $\dim \mathcal{E} = \dim \widetilde{\mathcal{E}}$, $\dim \mathcal{E}_* = \dim \widetilde{\mathcal{E}}_*$, and we define the input discriminant polynomial, the input discriminant curve, and the input family of subspaces threreupon:

$$\begin{aligned}
&\mathbf{p}(\lambda) = \det(\lambda_1\sigma_2 - \lambda_2\sigma_1 + \gamma),\\
&\mathbf{C}_0 = \left\{\lambda \in \mathbb{C}^2 \colon \mathbf{p}(\lambda) = 0\right\},\\
&\boldsymbol{\mathcal{E}}(\lambda) = \ker(\lambda_1\sigma_2 - \lambda_2\sigma_1 + \gamma) \text{ for } \lambda \in \mathbf{C}_0,
\end{aligned}$$

and similarly on the output side:

$$\begin{aligned}
&\mathbf{p}_*(\lambda) = \det(\lambda_1\sigma_{2*} - \lambda_2\sigma_{1*} + \gamma_*),\\
&\mathbf{C}_{0*} = \left\{\lambda \in \mathbb{C}^2 \colon \mathbf{p}_*(\lambda) = 0\right\},\\
&\boldsymbol{\mathcal{E}}_*(\lambda) = \ker(\lambda_1\sigma_{2*} - \lambda_2\sigma_{1*} + \gamma_*) \text{ for } \lambda \in \mathbf{C}_{0*}.
\end{aligned}$$

We conclude that if we are given a wave trajectory as above with $u_0 \neq 0$, then $\lambda \in \mathbf{C}_0$, $u_0 \in \boldsymbol{\mathcal{E}}(\lambda)$, and $y_0 = S(\lambda)u_0 \in \boldsymbol{\mathcal{E}}_*(\lambda)$, where

$$\begin{aligned}
S(\lambda) = D + C\,&\left((\xi_1\lambda_1 + \xi_2\lambda_2)I - (\xi_1A_1 + \xi_2A_2)\right)^{-1}\\
&\widetilde{B}\xi_1\sigma_1 + \xi_2\sigma_2)\,\big|_{\boldsymbol{\mathcal{E}}(\lambda)} : \boldsymbol{\mathcal{E}}(\lambda) \to \boldsymbol{\mathcal{E}}_*(\lambda)
\end{aligned}$$

is the joint transfer function of the vessel (independent of the choice of $\xi_1, \xi_2 \in \mathbb{C}$ as long as the rsolvent exists).

Allowing for zero multiplicities, we may assume that the input and the output discriminant polynomials share the same irreducible factors with possibly different multiplicities r_i and r_{i*}. Under additional assumptions (maximality of determinantal representations), $\boldsymbol{\mathcal{E}}$ and $\boldsymbol{\mathcal{E}}_*$ lift to vector bundles of ranks r_i and r_{i*} respectively on the corresponding desingularizing Riemann surfaces. If we assume now that the system is finite-dimensional, i.e., $\dim \mathcal{X} < \infty$, then it follows that the joint transfer functions lifts, for each irredicible component of the discriminant curve, to a meromorphic budle map between kernel bundles (if the vessel is minimal $\Longleftrightarrow$ controllable and observable then the poles of the joint transfer function coincide exactly with the joint spectrum of A_1 and A_2).

The theory of determinantal representations identifies exactly, up to isomorphism, kernel bundles of determinantal representations: up to a certain twist they are isomorphic to vector bundles of the form $\mathbf{V}_\chi \otimes \Delta$, where $\mathbf{V}_\chi$ is a flat vector bundle corresponding to some representation χ of the fundamental group and Δ is a line bundle of differentials of order 1/2 (a square root of the canonical bundle), so that $h^0(\mathbf{V}_\chi \otimes \Delta) = 0$. The corresponding collection, one for veach irreducible component of the discriminant curve, of meromorphic bundle maps $\mathbf{V}_\chi \otimes \Delta \to \mathbf{V}_{\chi_*} \otimes \Delta$, is called the normalized joint transfer function of the vessel.

[1] So the discrete-time version yields a tool for spectral analysis of pairs of commuting nonunitary operators (primarily, commuting contractions).

THE REALIZATION PROBLEM

Assume for simplicity that we have only one irreducible component. The realization problem is then as follows: we are given a compact Riemann surface X together with a pair of meromorphic functions y_1 and y_2 on X that generate the whole field of meromorphic functions and determine therefore a birational embedding of X into $\mathbb{P}^2$ as an irreducible projective curve $\mathbf{C}$. We are also given a pair of vector bundles $\mathbf{V}_\chi \otimes \Delta$ and $\mathbf{V}_{\chi_*} \otimes \Delta$ on X as above, and a meromorphic bundle map $T\colon \mathbf{V}_\chi \otimes \Delta \to \mathbf{V}_{\chi_*} \otimes \Delta$ which is holomorphic at the poles of y_1 and y_2. We want to construct a vessel with discriminant curve $\mathbf{C}$, input and output determinantal representations with kernel bundles isomorphic to $\mathbf{V}_\chi \otimes \Delta$ and $\mathbf{V}_{\chi_*} \otimes \Delta$ respectively, and normalized joint transfer function T.

One approach to this problem, worked out essentially in Livšic–Kravitsky–Markus–Vinnikov (1995) in the infinite dimensional conservative setting, proceeds by first constructing the two determinantal representations and using the so called restoration formula to recover from T the characteristic function of a 1D colligation. One then applies the usual realization theorem. Another approach, worked out in Ball and Vinnikov (1996) in case T has only simple poles, is the analogue of the so called Gilbert realization — it constructs the vessel explicitly by factoring the residues.

Our approach will be very different: we will construct both the state space and the input/output spaces of the vessel as spaces of meromorphic sections of the bundle $\mathbf{V}_{\chi_*} \otimes \Delta$ using the meromorphic bundle map T and the functions y_1, y_2, analogously to the usual construction of the Hankel realization.

Abstract: The relationship between the cone of positive semidefinite (psd) real forms and its subcone of sums of squares (sos) of forms is of fundamental importance in real algebraic geometry and optimization, and has been studied extensively (see for instance Marshall (2008)). The study of this relationship goes back to the 1888 seminal paper of Hilbert, where he gave a complete characterisation of the pairs $(n, 2d)$ for which a psd n-ary $2d$-ic form can be written as sos. In this talk we discuss how this relationship changes under the additional assumptions of invariance on the given forms, i.e. when we consider the induced action of a real finite reflection group on the ring of polynomials. We will see that in equivariant situations Hilbert's classification does not remain true in general and depends on the group action, the degree and the number of variables.

Keywords: Positive semidefinite forms, Sums of squares, Symmetric forms, Test sets, Extremal rays

1. INTRODUCTION

Hilbert (1888) studied the inclusion $\mathcal{P}_{n,2d} \supseteq \Sigma_{n,2d}$, where $\mathcal{P}_{n,2d}$ and $\Sigma_{n,2d}$ are respectively the cones of psd and sos forms of degree $2d$ in n variables. He proved that:

$$\mathcal{P}_{n,2d} = \Sigma_{n,2d} \text{ if and only if } n = 2, d = 1, \text{ or } (n, 2d) = (3, 4).$$

In order to establish that $\Sigma_{n,2d} \subsetneq \mathcal{P}_{n,2d}$, he demonstrated that $\Sigma_{3,6} \subsetneq \mathcal{P}_{3,6}$, $\Sigma_{4,4} \subsetneq \mathcal{P}_{4,4}$, thus reducing the problem to these two basic cases using an argument to increase the number of variables and degree of a given psd not sos form while simultaneously preserving the psd not sos property. In these two cases Hilbert described a method to produce examples of psd not sos forms, which was "elaborate and unpractical" (see Choi et al (1977)), so no explicit examples appeared in literature for next 80 years. The first explicit examples of psd not sos forms in these two cases were found by Motzkin (1967) and Robinson (1969), in the late 1970's. Subsequently more examples were given by Choi-Lam (see Choi (1975), Choi et al (1976), Choi et al (1977)), Reznick (see Reznick (1989)) and Schmüdgen (see Schmüedgen (1979)).

In 1976, Choi and Lam (see Choi et al. (1977)) considered the same inclusion for *symmetric forms*, i.e forms invariant under the action of the symmetric group S_n. As an analogue of Hilbert's approach, they demonstrated that establishing the strict inclusion for all $n \geq 3, 2d \geq 4$ and $(n, 2d) \neq (3, 4)$ reduces to show it just for the pairs $(n, 2d) = (3, 6), (n, 4)_{n\geq 4}$, by using a trick that increases the degree – however not the number of variables – of a given psd not sos symmetric form by simultaneously preserving the psd not sos symmetric property. Assuming the existence of psd not sos symmetric n-ary quartics for $n \geq 5$, they showed that Hilbert's characterisation above remains unchanged. Recently, we (see Goel et al (2016)) constructed explicitly these quartic forms, thus completing their proof. For this we used test set for (positivity of) symmetric quartics, that was originally given by Choi-Lam-Reznick (see Choi et al (1980)) and later generalized by Timofte (see Timofte (2003)) for symmetric polynomials of degree $2d$ in n variables.

Recently, we studied systematically the above inclusion of cones for *even symmetric forms*, i.e. forms invariant under the action of the group $S_n \times \mathbb{Z}_2^n$. The idea was to develop an analogue of reduction to basic cases, in the same spirit as Hilbert and Choi-Lam. Choi-Lam-Reznick (see Choi et al (1987)) and Harris (see Harris (1999)) established that Hilbert's characterisation is no longer true for even symmetric forms; indeed equality of these cones holds also for the pairs $(n, 4)_{n\geq 4}$ and $(3, 8)$. Moreover, they gave psd not sos even symmetric examples for the pairs $(n, 6)_{n\geq 3}, (3, 10)$ and $(4, 8)$. Building up on their work, we (see Goel et al (2017)) established strict inclusion for the pairs $(3, 2d)_{d\geq 6}, (n, 8)_{n\geq 5}, (n, 2d)_{n\geq 4, d\geq 5}$, and proved that it suffices for all the remaining cases [i.e. for all $n \geq 3, 2d \geq 6$ and $(n, 2d) \neq (3, 8)$]. For this we introduced as our leading tool a "Degree Jumping Principle"(that increases the degree of a given psd not sos even symmetric form while simultaneously preserving the psd not sos even symmetric property) and constructed explicit counterexamples for the pairs $(n, 8)_{n\geq 5}, (n, 10)_{n\geq 4}, (n, 12)_{n\geq 4}$. This let us to a complete resolution of all remaining open cases, thus providing a complete analogue of Hilbert's theorem for even symmetric forms (see Goel et al (2017)), namely,

"*an even symmetric n-ary 2d-ic psd form is sos if and only if* $n = 2$ *or* $d = 1$ *or* $(n, 2d) = (n, 4)_{n\geq 3}$ *or* $(n, 2d) = (3, 8)$".

Recently, Blekherman-Riener (2020) studied the asymptotic behaviour of symmetric psd forms and symmetric sos forms when the degree $2d$ is fixed and the number of variables n grows. For degree 4 they showed that the difference between symmetric psd forms and sos forms asymptotically goes to zero. For $n \geq 4$, they gave *symmetric n-ary quartic forms which lies on the boundary of the symmetric sos cone but not on the boundary of the symmetric psd cone*. They used representation theory of the symmetric group and examined possible kernels of an extreme ray of the dual cone of symmetric n-ary sos quartics which does not come from a point evaluation. They developed this method for the symmetric situation from the work in Blekherman (2012) for the non-symmetric situation [where for $(3, 6)$ and $(4, 4)$ cases, the author constructed quadratic forms that span extremal rays of the dual cone of $\Sigma_{n,2d}$ but are not point evaluations]. Recently, Debus (2019) used methods similar to the ones in Blekherman et al. (2020), and *proved equality of psd and sos quaternary quartics invariant under the diagonal action of $D_{2.4} \times D_{2.4}$*, where the Dihedral group $D_{2.m}$ is the symmetry group of a regular m-gon.

2. PSD VS SOS IN EQUIVARIANT SITUATIONS

The problem of finding sos decompositions of a polynomial invariant under the action of a finite group was studied by Gatermann-Parrilo (2003) and by Cimpric et al. (2009) (for reductive groups). Further, it is interesting as well as important to find the explicit description of the cone of invariant sos forms; this is done for invariance under a finite group generated by pseudo reflections and octahedral group by Vallentin et al. (2017).

As discussed in section 1 above, taking invariance under a bigger group results in equality of the cones of invariant psd and invariant sos forms for more number of pairs. This naturally opens up an idea to *investigate a wider generalization of analogues of Hilbert's theorem for forms invariant under other group actions.*

One possible approach tries to *develop more sophisticated arguments and tools for the invariant forms under consideration*, along the same lines as Hilbert (1888), Choi-Lam (1977) and Goel-Kuhlmann-Reznick (2017), in particular

- reduction to basic cases
- indefinite irreducible multipliers invariant under the considered group G (like Degree jumping principle)
- counterexamples in basic cases
- generalization of Timofte's degree principle (see Timofte (2003)) to invariant forms

This is very important since all these tools (in particular test sets for positivity of symmetric polynomials) played an important role in establishing the analogues of Hilbert's theorem for symmetric and even symmetric forms. An adaptation of Riener's algebraic proof (see Riener (2012)) of Timofte's theorem would be necessary, depending on the invariants of the group action. In this spirit we are investigating the inclusion of cones for forms invariant under the action of finite reflection groups and Lie groups, using a recent generalization of Timofte's degree principle for these groups given by Acevedo-Velasco (2015) and Friedl-Riener-Sanyal (see Friedl et al. (2016)).

Another possible approach is to see how the representation theory of these groups allows to use the symmetry inherent in these cones to give more efficient descriptions, in particular using the methods similar to the ones in Blekherman-Riener (2012) and Debus (2019).

Any real reflection group can be identified with a direct product of essential reflection groups G. According to Coxeter classification (see Humphreys (1992)), these G includes four infinite families of irreducible reflection groups $A_{n-1}, B_n, D_n, I_2(m)$, and the six exceptional reflection groups $E_6, E_7, E_8, F_4, H_3, H_4$. In a joint work with Sebastian Debus and Cordian Riener, we are investigating inclusion of cones for forms invariant under the action of finite reflection groups, using the second approach.

For the first approach we needed "test sets" a la Timofte. On the other hand with the second approach that we suggested above, it would circumvent the need of a currently non existing general Timofte result for reductive groups (although such a general result would be interesting of course in its own right).

In this talk we will focus especially on the results for forms invariant under the action of A_{n-1}, B_n and D_n (based on joint work with Sebastian Debus and Cordian Riener). The case of forms invariant under the action of $I_2(m)$ is trivial, since the $I_2(m)$-invariant forms are bivariate and thus by Hilbert's characterisation these forms are psd if and only if they are sos.

3. CONCLUSION

It is noteworthy that the first counterexamples (i.e. psd not sos ternary sextics and quaternary quartics) substantiating Hilbert's 1888 theorem were given almost 80 years later in 1967. Moreover, the results on equality and strict inclusions of the cones of psd and sos forms (respectively symmetric, even symmetric forms) by Hilbert (respectively Choi-Lam-Reznick, Harris and Goel-Kuhlmann-Reznick) were building stones in establishing Hilbert's theorem (respectively its analogue for symmetric and even symmetric forms). Thus, given a finite group G, establishing equality or strict inclusion of cones of invariant psd and invariant sos forms for any (n, 2d) will be a novel contribution in this research area and would have a strong impact on the applications of sums of squares.

Abstract: The best low rank tensor approximation problem occurs in a wide variety of applications; however, this problem is strictly speaking not well posed. Indeed, best low rank tensor approximations can fail to exist. In the case that a best low rank approximation fails to exist, computing a near optimal low rank approximation is highly numerically ill-conditioned. In this talk we will consider the best low rank approximation problem for the special class of tensors which are positive definite. We will show that the set of low rank tensors that are positive definite is relatively closed as a subset of the set of tensors that are positive definite. Using this fact, we will provide a deterministic bound for the existence of a best low rank approximation of a positive definite tensor. We will illustrate through numerical experiments that our bound is highly predictive of numerical errors when attempting to compute a best low rank approximation of a measured tensor.

Keywords: Tensors, Canonical polyadic decomposition, Best low rank approximation, Positive definite

1. INTRODUCTION

Tensors, or multiindexed arrays, play an important role in fields such as machine learning and signal processing. These higher-order generalizations of matrices allow for preservation of higher-order structure present in data, and low rank decompositions of tensors allow for recovery of underlying information. One of the most popular decompositions for tensors is the canonical polyadic decomposition (CPD) which expresses a tensor as a sum of rank one tensors.

Tensor decompositions are widely used applications as they many desirable qualities which are distinct from matrix decompositions. For example, a decomposition of a low rank tensor is generically unique. This essential uniqueness allows for extraction of component information from a measured tensor of interest and makes tensor decomposition a valuable tool in applications such as blind source separation.

A common setting in practice is to have access to a noisy measurement of some low rank signal tensor of interest. This measurement itself does not have low rank, so one must compute a best low rank CPD approximation of the measured tensor. However, this approximation problem is ill-posed as the set of tensors of rank less than or equal to R is in general not closed when $R > 1$.

In the case a tensor does not have a best rank R approximation, then as one's rank R approximation improves, the norm of rank-1 tensors in the rank R approximation must approach infinity. This phenomena known as "diverging components". These diverging components present a serious numerical issue when one wishes to obtain component information from a tensor which does not have a best low rank approximation.

One particularly important setting is where the tensor of interest is positive (semi)definite. For example, positive definite tensors in the form of higher-order statistics play a key role in blind source separation. In addition, there are many applications in which a tensor models a nonlinear function which has positive evaluation on any input. The tensor used to model such a function will be positive definite.

In this talk, we show that the set of "low rank" positive definite tensors is relatively closed as a subset of the set of positive definite tensors. Using this result, we produce present a deterministic guarantee for the existence of a best low rank approximation in the form of a spectral norm bound on measurement error. Furthermore we show that this bound is computable via semidefinite programming and sharp in certain settings.

2. POSITIVE DEFINITE TENSORS

In this talk, a tensor is a multiinedexed array $\mathcal{T}$ of size $R \times \ldots \times R$. Here the integer R occurs a total of N times where N is even. We denote this space by $(\mathbb{R}^R)^{\otimes N}$. We say a tensor $\mathcal{T} \in (\mathbb{R}^R)^{\otimes N}$ is symmetric if $\mathcal{T}$ if the entries of $\mathcal{T}$ are invariant under a permutation of indices. That is, $\mathcal{T} \in (\mathbb{R}^R)^{\otimes N}$ is symmetric if for all permutations π acting on the set $\{1, \ldots, N\}$, one has

$$\mathcal{T}(i_1, i_2, \ldots, i_N) = \mathcal{T}(i_{\pi(1)}, i_{\pi(2)}, \ldots, i_{\pi(N)}).$$

for all $i_1, i_2, \ldots, i_N$.

Given a symmetric tensor $\mathcal{T} \in (\mathbb{R}^R)^{\otimes N}$, a common goal is to compute the (symmetric) canonical polyadic decomposition (CPD) of $\mathcal{T}$. That is, one wishes to decompose

$$\mathcal{T} = \sum_{r=1}^{R} \delta_r (\mathbf{u}_r \otimes \ldots \otimes \mathbf{u}_r) \tag{1}$$

where R is as small as possible. Here $\mathbf{u}_r \in \mathbb{R}^R$ and $\delta_r = \pm 1$ for each $r = 1, \ldots, R$. The product $\otimes$ denotes the outer product of vectors. In particular, the tensor $\mathbf{u}_r \otimes \ldots \otimes \mathbf{u}_r$ has $i_1, i_2, \ldots, i_{N+1}$ entry equal to

$$\mathbf{u}_r(i_1) \ldots \mathbf{u}_r(i_N),$$

where $\mathbf{u}_r(i_n)$ denotes the i_nth entry of $\mathbf{u}_r$. When R is as small as possible in equation (1), we say the tensor $\mathcal{T}$ has rank R. From here on, will use $(\mathbf{u_r})^{\otimes N}$ to denote the symmetric rank one tensor $\mathbf{u}_r \otimes \ldots \otimes \mathbf{u}_r$.

We let $\langle \cdot, \cdot \rangle$ denote the usual Frobenius inner product on $(\mathbb{R}^R)^{\otimes N}$. That is, given tensors $\mathcal{T}, \mathcal{S} \in (\mathbb{R}^R)^{\otimes N}$, one has

$$\langle \mathcal{T}, \mathcal{S} \rangle = \sum \mathcal{T}(i_1, i_2, \ldots, i_N) \mathcal{S}(i_1, i_2, \ldots, i_N).$$

Define quantities $\lambda_{\min}(\mathcal{T})$ and $\lambda_{\max}$ by

$$\lambda_{\min}(\mathcal{T}) = \min_{\|\mathbf{u}\|_2 = 1} \langle \mathcal{T}, (\mathbf{u})^{\otimes N} \rangle \qquad \lambda_{\max}(\mathcal{T}) = \max_{\|\mathbf{u}\|_2 = 1} \langle \mathcal{T}, (\mathbf{u})^{\otimes N} \rangle.$$

We say a tensor $\mathcal{T}$ is positive definite if $\mathcal{T}$ is symmetric and if $\lambda_{\min}(\mathcal{T}) > 0$.

The first main result of the talk will be to show that the set of rank R positive definite tensors in $(\mathbb{R}^R)^{\otimes N}$ is relatively closed as a subset of the set of positive definite tensors in $(\mathbb{R}^R)^{\otimes N}$. Intuitively this is accomplished by showing that a rank R positive definite tensor in $(\mathbb{R}^R)^{\otimes N}$ must be expressed as a positive coefficient sum of positive semidefinite rank one tensors. This prevents the occurrence of diverging components for tensors in a neighborhood of $\mathcal{T}$ which in turn leads to the relative closedness of the set of rank R positive definite tensors.

We use this result to provide a deterministic guarantee for the existence of a best low rank approximation of a perturbation of a rank R positive definite tensor $\mathcal{T}$. In particular, we show that if $\mathcal{E} \in (\mathbb{R}^R)^{\otimes N}$ is a symmetric tensor which satisfies

$$\lambda_{\max}(\mathcal{E})/2 < \lambda_{\min}(\mathcal{T}),$$

then $\mathcal{T} + \mathcal{E}$ has a best rank R approximation among the set of symmetric tensors.

For tensors arising in applications where the tensor of interest is expected to be positive definite, this existence result can be interpreted as saying that the measured tensor $\mathcal{T} + \mathcal{E}$ has a best low rank approximation so long as the conditioning of $\mathcal{T}$ and the signal to noise ratio of $\mathcal{T}$ to $\mathcal{E}$ is good enough so that near optimal low rank approximations to $\mathcal{T} + \mathcal{E}$ are positive definite. Thus, a best low rank approximation exists so long as it exhibits the properties that are expected for the setting.

A Mayer Form for Finite Horizon Hybrid Optimal Control Problems

Ricardo G. Sanfelice and Berk Altin

***Abstract*— We consider finite horizon optimal control problems for hybrid plants that are modeled as hybrid equations. To determine key properties of the problem, such as existence and regularity of the optimal cost, we formulate a Mayer form that is tailored to hybrid systems. Within the setting of nominally outer well-posed hybrid plants, and under mild (and standard) regularity conditions, establishing existence of optimal solutions and nice (upper semicontinuous and continuous) dependence of the optimal cost is enabled by the proposed Mayer form. The advantage of the proposed approach is that it does not require additional properties that are typically required in the literature, such as assumptions on the continuous dynamics or that the terminal cost is a control Lyapunov function on the terminal constraint set. The proposed new form is illustrated in examples.**

I. Introduction

Models and algorithms characterized by the interplay of continuous-time dynamics and instantaneous changes have become prevalent due to their capabilities of leading to solutions to control problems that classical techniques cannot solve, or simply do not apply. These advances have been enabled by the modeling, analysis, and design techniques for *hybrid dynamical systems*. A hybrid dynamical system, or just a *hybrid system*, is a dynamical system that exhibits characteristics of both continuous-time and discrete-time dynamical systems.

Numerous tools are available in the literature for the study of hybrid systems [1]–[6]. The literature is rich in tools for the analysis of reachability [7]–[9], asymptotic stability [1], [3], [5], forward invariance [10], [11], and control design [6]. On the other hand, optimality for hybrid systems is much less mature.

Initial results on optimality of trajectories over finite horizons were developed in [12], including a maximum principle for optimality, for a class of switched systems. This result was extended in [13], [14] to a broader class of systems, one allowing for state resets – the models considered are in the spirit of hybrid automata. More recently, linear-quadratic control for a class of hybrid systems with a sample-and-hold structure was considered in [15], [16]. In particular, the development in [15] is within the hybrid inclusions framework of [5], [6], for the special case when the continuous dynamics are modeled by a differential equation that is linear and the discrete dynamics are governed by a linear difference equation. The problem of guaranteeing existence of optimal control inputs for a class of hybrid systems was studied in [17]. The hybrid inclusions framework is employed in [17] and the conditions for existence of optimal control inputs require the continuous dynamics of the system to be governed by a differential equation whose right-hand side is affine in the control input. Optimality of static state-feedback laws for hybrid inclusions with continuous and discrete dynamics modeled by (single-valued) nonlinear maps was studied in [18]. Infinitesimal conditions involving a Lyapunov-like function are presented in [18] to guarantee optimality over the infinite (hybrid) horizon. The finite horizon optimization problem for the same broad class of hybrid systems was formulated and developed in a sequence of papers leading to a model predictive control framework; see [19]–[22].

Though the advances cited above have contributed to optimal control for hybrid systems, some of the key properties of the optimal control problem associated to general hybrid systems, wherein trajectories are constrained to evolve continuously (*flow*) in certain regions of the state space and to exhibit instantaneous changes (*jump*) under certain conditions, have not been yet revealed in the literature. Specifically, the regularity properties of the optimal cost, in particular, (semi) continuous dependence of the optimal cost and optimal trajectories on the constraints on where the trajectories can flow or jump have not yet been investigated. Very importantly, conditions enabling the approximations of the optimal cost in a continuous manner are not available in the literature. Indeed, results that permit relating the effect of varying parameters and initial conditions when they approach nominal values, the expectation being that the optimal cost also approaches its nominal value, are missing. Understanding such a dependency is critical due to the fact that it is unavoidable to numerically compute trajectories (hence the optimal trajectories) without error [23], [24].

II. Overview of the Presentation

We consider concrete finite horizon optimization problems for hybrid plants given by

$$\mathcal{H}_P \begin{cases} \dot{x}_P \in F_P(x_P, u) & (x_P, u) \in C_P \\ x_P^+ \in G_P(x_P, u) & (x_P, u) \in D_P \end{cases} \tag{1}$$

where C_P is the flow set, F_P is the flow map, D_P is the jump set, and G_P is the jump map. A solution of $\mathcal{H}_P$ is defined by a pair (called a *solution pair*) $(t, j) \mapsto (x_P(t, j), u(t, j))$ on a hybrid time domain $\mathrm{dom}(x_P, u)$ satisfying the dynamics of $\mathcal{H}_P$, in a similar manner as the way a solution of the (closed-loop) hybrid system $\mathcal{H}$ is defined in [5]. Given a solution pair (x_P, u) with compact domain, the associated

R. G. Sanfelice is with the Department of Electrical and Computer Engineering, University of California, Santa Cruz, CA 95064. Email: ricardo@ucsc.edu. Research partially supported by NSF Grants no. ECS-1710621, CNS-2039054, and CNS-2111688, by AFOSR Grants no. FA9550-19-1-0053, FA9550-19-1-0169, and FA9550-20-1-0238, and by ARO Grant no. W911NF-20-1-0253.

cost is defined by

$$\left(\sum_{j=0}^{J}\int_{t_j}^{t_{j+1}} L_{C_P}(x_P(t,j),u(t,j))\,dt\right)+\left(\sum_{j=0}^{J-1} L_{D_P}(x_P(t_{j+1},j),u(t_{j+1},j))\right)+V(x_P(T,J)) \tag{2}$$

where t_j is the j-th jump time and $(T,J)\in \mathrm{dom}(x_P,u)$ is the terminal time, i.e.,

$$\mathrm{dom}(x_P,u)=\bigcup_{j=0}^{J}([t_j,t_{j+1}]\times\{j\})$$

and $T=T_{J+1}$. In (2), the first term L_{C_P} is the stage cost capturing the cost over intervals of flows, L_{D_P} is the stage cost capturing the cost to jump, and V is the terminal cost.

The constructions presented above lead to the following finite horizon hybrid optimization problem.

Problem: Given a hybrid system $\mathcal{H}_P$ as in (1), a stage cost for flows L_{C_P}, a stage cost for jumps L_{D_P}, a terminal cost V, a closed set X_P, a hybrid time $(T,J)\in\mathbb{R}_{\geq 0}\times\mathbb{N}:=[0,\infty)\times\{0,1,\ldots\}$, and an initial condition ξ, find a solution pair (x_P,u) minimizing (2) subject to

- The initial condition constraint $x_P(0,0)=\xi$.
- The terminal constraint $x_P(T,J)\in X_P$.

Note that the flow and jump sets of $\mathcal{H}_P$ impose constraints that the solution pair needs to satisfy during flows and jumps, respectively. In fact, for the solution pair to exist up to hybrid time (T,J) it has to belong to C_P and D_P: as [6, Definition 2.29] indicates, (x_P,u) is a solution of $\mathcal{H}_P$ if

- $(x_P(0,0),u(0,0))\in\overline{C_P}\cup D_P$;
- For each $j\in\mathbb{N}$,

  $$(x_P(t,j),u(t,j))\in C_P$$

  for all $t\in \mathrm{int}I^j$ and

  $$\frac{dx_P}{dt}(t,j)\in F_P(x_P(t,j),u(t,j))$$

  for almost all $t\in I^j$, where $I^j:=\{t:(t,j)\in\mathrm{dom}(x_P,u)\}$;
- For each $(t,j)\in\mathrm{dom}(x_P,u)$ such that $(t,j+1)\in\mathrm{dom}(x_P,u)$,

  $$(x_P(t,j),u(t,j))\in D_P$$

  and

  $$x_P(t,j+1)\in G_P(x_P(t,j),u(t,j))$$

In this presentation, we determine key properties of the problem, such as existence and regularity of the optimal cost, by formulating a Mayer form that is tailored to hybrid systems. Under mild – and standard – regularity conditions, we show that when the hybrid system is well-posed, existence of optimal solutions and nice (upper semicontinuous and continuous) dependence of the optimal cost can be established using the proposed Mayer form. The results will be illustrated in examples.

Realization of matrix monotone and matrix convex functions ⋆

Ryan Tully-Doyle *

* *California Polytechnic State University, San Luis Obispo, CA USA (e-mail: rtullydo@calpoly.edu).*

Keywords: matrix monotone functions, matrix convex functions, matrix valued functions, realization theory

A fundamental result of Löwner gives that a real-valued function is matrix monotone if and only if it extends to an analytic function with a rather rigid structure. Löwner's student Kraus essentially showed that functions that are matrix convex are analytic functions with a similarly rigid form.

Recall that Hermitian matrices have a partial ordering where $A \leq B$ if $0 \leq B - A$ (that is, $B - A$ is positive semidefinite). Suppose that $f : (a, b) \to \mathbb{R}$. A function is called **matrix monotone** if $f(A) \leq f(B)$ whenever $A \leq B$ and the spectrum of A, B is in (a, b). The classical Löwner theorem gives the following connection between monotonicity and analyticity. Let $\mathbb{H}$ denote the complex upper half plane.

Theorem 1. (K. Löwner (1934)). A function $f(a, b) \to \mathbb{R}$ is matrix monotone if and only if f extends to a continuous function $f : \mathbb{H} \cup (a, b) \to \overline{\mathbb{H}}$ that is analytic on $\mathbb{H}$.

Functions that map $\mathbb{H}$ into itself are called **Pick functions**. Nevalinna showed that Pick functions are characterized by a straightforward integral representation in terms of a positive Borel measure μ:

Theorem 2. (Nevanlinna (1929)). Let $f : \mathbb{H} \to \mathbb{C}$. The function f is analytic and maps $\mathbb{H}$ to $\overline{\mathbb{H}}$ if and only if there exist $a \in \mathbb{R}$, $b \geq 0$ and a positive Borel measure μ on $\mathbb{R}$ where $\frac{1}{1+t^2}$ is μ-integrable such that

$$f(z) = a + bz + \int_{\mathbb{R}} \frac{1}{t - z} - \frac{t}{1 + t^2} \, d\mu(t)$$

for all $z \in \mathbb{H}$.

Now let $f : (a, b) \to \mathbb{R}$ be a function. We say that f is **matrix convex** if

$$f\left(\frac{A + B}{2}\right) \leq \frac{f(A) + f(B)}{2}$$

for all A, B self-adjoint with spectrum in (a, b). Matrix convex functions demonstrate the same essential rigidity as matrix monotone functions.

Theorem 3. (Kraus (1936)). Let $f : (-1, 1) \to \mathbb{R}$. f is matrix convex if and only if

$$f(x) = a + bx + \int_{[-1,1]} \frac{x^2}{1 + tx} \, d\mu(t)$$

where $a, b \in \mathbb{R}$ and μ is a finite measure supported on $[-1, 1]$. Note that all such functions analytically continue to the upper half plane - that is, matrix convex functions also continue as to a subset of Pick functions.

We are concerned with how to generalize these results to functions of several variables. A natural setting for the study of such functions turns out to be the rapidly developing area of noncommutative function theory, which concerns functions several noncommuting variables acting on domains of matrix tuples.

Define the **matrix universe** to be tuples of same sized matrices

$$M^d = \bigcup M_n(\mathbb{C})^d.$$

A **free set** $D \subseteq M^d$ satisfies

(1) $X, Y \in D \Rightarrow X \oplus Y \in D$
(2) X implies $U^*XU \in D$ whenever U is unitary.

A **(real) free function** $f : D \to M^1$ satisfies:

(1) $f(X \oplus Y) = f(X) \oplus f(Y)$
(2) $f(U^*XU) = U^*f(X)U$ whenever U is unitary.

In the context of functions of several noncommuting variables, we have a direct generalization of this single-variable connection between monotonicity/convexity, analytic extension, and structured representation. We first consider the case of matrix monotone functions (a selection of relevant work in commutative and noncommutative variables can be found in Agler et al. (2012); Pascoe (2019, 2018); Palfia (2020); Pascoe and Tully-Doyle (2017, 2022, 2021)).

We restrict our attention to the noncommutative case. As in the single-variable setting, a noncommutative function f is said to be matrix monotone if $f(A) \leq f(B)$ whenever $A \leq B$.

Theorem 4. (Pascoe and Tully-Doyle (2022)). Let f be a locally bounded matrix monotone function defined on a convex free set of self-adjoints containing 0. Then there exist a scalar a_0, a vector Q, projections P_i, and a bounded self-adjoint contraction A such that

$$f(X) = a_0 + Q^*(A - \sum P_i X_i^{-1})^{-1} Q. \tag{1}$$

As in the classical case, the form of this "Nevanlinna representation" gives analytic continuation to a matrix upper half plane - that is, matrix monotone functions in

⋆ Partially supported by National Science Foundation DMS Analysis Grant 2055098

the noncommutative setting are those that analytically continue as Pick functions.

The idea of the proof goes through power series. The assumptions on f allow the application of the "royal road" idea, which uses a complex analytic approach to show that matrix monotone functions must be real analytic. Then a matrix monotone function f has a power series $f(X) = \sum c_\alpha X^\alpha$. Taking the derivative of f gives

$$Df(X)[H] = \sum c_{\beta^* x_i \alpha} X^{\beta^*} H_i X^\alpha$$

The monotonicity of f leads to the positivity of the x_i-localizing matrices $C_i = [c_{\beta^* x_i \alpha}]_{\alpha,\beta}$, which in turn allow the construction of the ambient Hilbert spaces $\mathcal{H}_i$ from which the projections P_i and the operator A are derived in the representation (1) .

The royal road approach to realization runs through a argument involving an application of the classical theorem and presupposes the form of the realization formula to be established. Another line of argument uses a Hilbert space approach (for example, in Agler et al. (2012) in the case of several commuting variables) to derive the representations. For a thorough treatment of the Hilbert space methods, (so-called operator analysis) see Agler et al. (2020). Löwner's theorem has recently received attention even in the classical case (see Simon (2019)).

We now consider the analogue of Kraus's theorem on matrix convex functions. As in the classical case, say that a noncommutative function f is matrix convex if

$$f\left(\frac{A+B}{2}\right) \leq \frac{f(A)+f(B)}{2}.$$

Matrix convex functions arise as an important object of study in the body of work surrounding linear matrix inequalities. In Helton et al. (2006), Helton, McCullough, and Vinnikov constructed a Kraus-like "butterfly realization" for noncommutative rational matrix convex functions. A similar argument to the proof of Theorem 4 gives that the result holds for general functions.

Theorem 5. (Pascoe and Tully-Doyle (2022)). Let f be a locally bounded matrix convex function defined on a convex free set of self-adjoints containing 0. Then there exist self-adjoint T_i, a vector Q, a scalar a_0, and a linear function L such that

$$f(X) = a_0 + L(X) + (\sum Q_i X_i)^*(I - \sum T_i X_i)^{-1}(\sum Q_i X_i).$$

As in the case of monotone functions, this representation also has an analytic continuation result, but in this case to a subset of a matrix upper half plane.

The study of noncommutative realizations for structured families of functions has developed to include, for example, partially matrix convex functions (see Jury et al. (2021)) and plurisubharmonic functions (see Dym et al. (2020); Pascoe (2021)). A noncommutative function is **partially matrix convex** if it is convex in one class of variables - that is

$$f\left(A, \frac{X+Y}{2}\right) \leq \frac{f(A,X)+f(A,Y)}{2}.$$

Combining the complex analytic "royal road" viewpoint of Pascoe and Tully-Doyle (2022) with the study of partially matrix convex rational functions in Dym et al. (2020) leads to the following realization theorem.

Theorem 6. (Jury et al. (2021)). A noncommutative rational function r in two variables a and x is partially matrix convex in x on self-adjoints near 0 if and only if there exists a vector rational function $\ell(a,x)$ that is linear in x and a matrix rational function $w(a)$ such that

$$r(a,x) = \ell(a,x)^* \sqrt{w(a)}(I - \sum \sqrt{w(a)} T_i x_i \sqrt{w(a)})^{-1} \sqrt{w(a)} \ell(a,x) + f(a,x)$$

where $f(a,x)$ is affine linear in x and the T_i are matrices.

Ultimately, the perspective underlying this line of work leads to a striking monodromy result (Pascoe (2021)) in the noncommutative setting.

Constrained Multiagent Dynamical systems and Hamilton-Jacobi-Bellman inequalities on the Wasserstein space

Marc Quincampoix *

* *Laboratoire de Mathématiques de Bretagne Atlantique, UMR CNRS 6205, Univ Brest 6 , avenue Victor Le Gorgeu, 29200 Brest, France. (e-mail: marc.quincampoix@univ-brest.fr)*

Abstract: Several optimal control problems in R^d, like systems with uncertainty, control of flock dynamics, or control of multiagent systems, can be naturally formulated in the space of probability measures in R^d. The compatibility of such control systems with a state constraint can be studied by an Hamilton-Jacobi-Bellman equation stated in the Wasserstein space of probability measure. We show that the dynamic is compatible with the constraint when the distance function satisfies the Hamilton Jacobi inequality in a suitable viscosity sense.

Keywords: Optimal control, optimal transport, Hamilton-Jacobi-Bellman equation, multi-agent.

1. INTRODUCTION

The studied multiagent system concerns a control systems with a so huge amount of agent that they are indistiguishable and only a statistical description of the position of the agents is available : at every time for every subset $A \subset R^d$, the fraction $\nu(A)$ of the total amount of agents that are present in A is known. So the state variable of the system is a Borel probabily measure on R^d (the set of such probability measure is denoted by $\mathcal{P}(R^d)$. Hence, the evolution of the controlled multi-agent system can be represented by the following two-scale dynamics

- *microscopic dynamics:* each agent's position at time t is given by $x(t)$, which evolves according to the dynamical system
$$\dot{x}(t) \in F(\mu_t, x(t)), \text{ for a.e. } t > 0\,, \tag{1}$$
where F is a set-valued map.Here each agent's dynamics is nonlocal since it depends also on the instantaneous configuration μ_t of the crowd of agents at time t, described by the probability measure $\mu_t \mathcal{P}(R^d)$.
- *macroscopic dynamics:* the evolution of the crowd of agents at time t is given by a time-depending measure $\mu_t \in \mathcal{P}(R^d)$ whose evolution satisfies the following *continuity equation*(cf Amb (2008))
$$\partial_t \mu_t + \text{div}(v_t \mu_t) = 0,\ t > 0, \tag{2}$$
coupled with the control constraint
$$v_t(x) \in F(\mu_t, x) \text{ for } \mu_t\text{-a.e. } x \in R^d \text{ for a.e. } t \geq 0. \tag{3}$$
which represents the possible velocity $v_t(x)$ for an agent at time t and at the position x.

Similar models have been studied in Ave (2018, 2021); Bard (2022); Bon (2021); Cav (2021); Jim (2020, 2021); Mar (2018).

⋆ The research of the third author has been partially supported by the Air Force Office of Scientific Research under award number FA9550-18-1-0254.

Here we investigate the existence of solution of the above multiagent system under a closed constraint $K \subset \mathcal{P}(R^d)$. This constraint could be satisfied in the both folool=wing meaning:

- The multiagent system is *viable* if and only if for any initial condition $\mu \in K$ *there exists* a solution $t \mapsto \mu_t$ of the controlled continuity equation (2)-(3) with $\mu_0 = \mu$ such that $\mu_t \in rK$ for all $t \geq 0$;
- The multiagent system is *invariant* if and only if for any μK and *for any* solution $t \mapsto \mu_t$ of the controlled continuity equation (2)-(3) with $\mu_0 = \mu$ we have $\mu_t \in K$ for all $t \geq 0$.

Following an idea firstly used in Buck (1998) in the framework of stochastic control systems we give an equivalent characterization of the viability and invariance in terms of of a suitable Hamilton Jacobi Bellman inequalities understood in the viscosity sense. This short note uses result obtained in collaboration with Cavagnari, Jimenez and Marigonda.

2. ASSUMPTIONS ON THE DYNAMICS

We denote by $\mathcal{P}_2(R^d)$ the subset of the elements $\mathcal{P}(R^d)$ with finite second moment, endowed with the 2-Wasserstein distance (cf e.g. Amb (2008)).

We make the following supposition on the set-valued map F

- (F_1) $F : \mathcal{P}_2(R^d) \times R^d \mapsto R^d$ is continuous with convex, compact and nonempty images, where on $\mathcal{P}_2(R^d) \times R^d$ we consider the metric $W_2(\mu_1, \mu_2) + |x_1 - x_2|$.
- (F_2) there exists $L > 0$, a compact metric space U and a continuous map $f : \mathcal{P}_2(R^d) \times R^d \times U \to R^d$ satisfying
$$|f(\mu_1, x_1, u) - f(\mu_2, x_2, u)| \leq L(W_2(\mu_1, \mu_2) + |x_1 - x_2|),$$

for all μ_1, μ_2 in $\mathcal{P}_2(R^d)$ and x_1, x_2 in R^d such that

$$F(\mu, x) = \{f(\mu, x, u) : u \in U\}.$$

Under these assumptions we know that the set of solution of (2)-(3) with $\mu_0 = \mu$ is nonempty and compact (cf Jim (2020, 2021); Mar (2018)).

Given a closed subset $K \subset \mathcal{P}_2(R^d)$, we define its distance function $d_K : \mathcal{P}_2(R^d) \mapsto R^+$ by

$$d_K(\mu) := \inf\{\, W_2(\mu, \nu),\ \ \nu \in K\,\}.$$

3. HAMILTON JACOBI INEQUALITIES

Under the above assumptions are now ready to state the main result

***Theorem** 3.1.* Let K be a closed subset of $\mathcal{P}_2(R^d)$

The constraint K is *viable* iff the function $\mu \mapsto d_K(\mu)$ is a viscosity supersolution of

$$(L+2)u(\mu) + H_F^{viab}(\mu, D_\mu u(\mu)) = 0,$$

where, for all $\mu \in \mathcal{P}_2(R^d)$, $p \in L^2_\mu(R^d; R^d)$,

$$H_F^{viab}(\mu, p) := -d_K(\mu) - \inf_{\substack{v(\cdot) \in L^2_\mu(R^d) \\ v(x) \in F(\mu, x)}} \int_{R^d} v(x).p(x)\, d\mu(x).$$

K is *invariant* iff the function $\mu \mapsto d_K(\mu)$ is a viscosity supersolution of

$$(L+2)u(\mu) + H_F^{inv}(\mu, D_\mu u(\mu)) = 0,$$

where, for all $\mu \in \mathcal{P}_2(R^d)$, $p \in L^2_\mu(R^d; R^d)$,

$$H_F^{inv}(\mu, p) := -d_K(\mu) - \sup_{\substack{v(\cdot) \in L^2_\mu(R^d) \\ v(x) \in F(\mu, x)}} \int_{R^d} v(x).p(x)\, d\mu(x).$$

where the relations $v(x) \in F(\mu, x)$ appaearring under the supremum and infimum means that for μ almost every $x \in R^d$ we have $v(x) \in F(\mu, x)$.

The notion of super solution has to be understood in viscosity sense namely : The functioon $u : \mathcal{P}_2(R^d) \mapsto \mathcal{P}_2(R^d)$ is a viscosity supersolution to

$$(L+2)u(\mu) + H(\mu, D_\mu u(\mu)) = 0,$$

if and only if for every $\bar{\mu} \in \mathcal{P}_2(R^d)$ and $\varepsilon > 0$ and any continuous differentiable [1] function $v : \mathcal{P}_2(R^d) \mapsto \mathcal{P}_2(R^d)$ such there exists $r > 0$ such that: $v(\bar{\mu}) = u(\bar{\mu})$ and

$$u(\nu) \le v(\nu) - \varepsilon W_2(\bar{\mu}, \nu) \quad \forall \nu \in \mathcal{P}_2(R^d) \text{ s.t. } W_2(\bar{\mu}, \nu) < r$$

we have

$$(L+2)v(\mu) + H(\mu, D_\mu v(\mu)) \le C\varepsilon,$$

for a constant which depends only on F.

The proof of the theorems is based on a comparison result for the Hamilton Jacobi equation that satisfy the following value functions defined on : $[0, T] \times \mathcal{P}_2(R^d)$

$$V^{viab}(t_0, \mu) := \inf_{(\mu_t)_{t \in [t_0, T]}} \int_{t_0}^{T} d_K(\mu_t)\, dt, \tag{4}$$

[1] For the definition of continouly differentiable function with Lions derivatives we refer te reader to Car (2018, 2013)

$$V^{inv}(t_0, \mu) := \sup_{(\mu_t)_{t \in [t_0, T]}} \int_{t_0}^{T} d_K(\mu_t)\, dt, \tag{5}$$

where the infimum and supremum are taken on the set of solutions of (2)-(3) with $\mu_{t_0} = \mu$.

Abstract: We investigate in this work a fully-discrete semi-Lagrangian approximation of second order possibly degenerate Hamilton-Jacobi-Bellman (HJB) equations on a bounded domain $\mathcal{O} \subset \mathbb{R}^N$ $(N = 1, 2, 3)$ with oblique derivatives boundary conditions. These equations appear naturally in the study of optimal control of diffusion processes with oblique reflection at the boundary of the domain.
The proposed scheme is shown to satisfy a consistency type property, it is monotone and stable. Our main result is the convergence of the numerical solution towards the unique viscosity solution of the HJB equation. The convergence result holds under the same asymptotic relation between the time and space discretization steps as in the classical setting for semi-Lagrangian schemes on $\mathcal{O} = \mathbb{R}^N$. We present some numerical results, in dimensions $N = 1$, 2, on unstructured meshes, that confirm the numerical convergence of the scheme.

Keywords: HJB equations oblique boundary conditions numerical approximation convergence analysis

1. INTRODUCTION

In this work we deal with the numerical approximation of the following parabolic Hamilton-Jacobi-Bellman (HJB) equation

$$\begin{aligned} \partial_t u + H\left(t, x, Du, D^2u\right) &= 0 \quad \text{in } (0,T] \times \mathcal{O}, \\ L(t, x, Du) &= 0 \quad \text{on } (0,T] \times \partial\mathcal{O}, \\ u(0, x) &= \Psi(x) \quad \text{in } \overline{\mathcal{O}}. \end{aligned} \tag{1}$$

In the system above, $T > 0$, $\mathcal{O} \subset \mathbb{R}^N$ is a nonempty smooth bounded open set and H and L are nonlinear functions having the form

$$\begin{aligned} H(t, x, p, M) = \sup_{a \in A} \Big\{ &-\frac{1}{2} \operatorname{trace}\left(\sigma(t, x, a)\sigma(t, x, a)^\top M\right) \\ &- \langle \mu(t, x, a), p\rangle - f(t, x, a)\Big\}, \\ L(t, x, p) = \sup_{b \in B} &\left\{\langle \gamma(x, b), p\rangle - g(t, x, b)\right\}, \end{aligned}$$

where $A \subset \mathbb{R}^{N_A}$ and $B \subset \mathbb{R}^{N_B}$ are nonempty compact sets, $\sigma : [0,T] \times \overline{\mathcal{O}} \times A \to \mathbb{R}^{N \times N_\sigma}$, with $1 \le N_\sigma \le N$, $\mu : [0,T] \times \overline{\mathcal{O}} \times A \to \mathbb{R}^N$, $f : [0,T] \times \overline{\mathcal{O}} \times A \to \mathbb{R}$, $\gamma : \partial\mathcal{O} \times \mathcal{V} \to \mathbb{R}^N$, with $\mathcal{V} \subseteq \mathbb{R}^{N_B}$ being an open set containing B, $g : [0,T] \times \partial\mathcal{O} \times B \to \mathbb{R}$, and $\Psi : \overline{\mathcal{O}} \to \mathbb{R}$.

If $A = \{a\}$ and $B = \{b\}$, for some $a \in \mathbb{R}^{N_A}$ and $b \in \mathbb{R}^{N_B}$, and $\gamma(x, b) = n(x)$, with $n(x)$ being the unit outward normal vector to $\overline{\mathcal{O}}$ at $x \in \partial\mathcal{O}$, then (1) reduces to a standard linear parabolic equation with Neumann boundary conditions. In the general case, and after a simple change of the time variable in order to write (1) in backward form, the HJB equation (1) appears in the study of optimal control of diffusion processes with controlled reflection on the boundary $\partial\mathcal{O}$ (see e.g. Lions (1985) for the first order case, i.e. $\sigma \equiv 0$, and Lions (1983); Bouchard (2008) for the general case). Since the HJB equation (1) is possibly degenerate parabolic, one cannot expect the existence of classical solutions and we have to rely on the notion of viscosity solution (see e.g. Crandall et al. (1992)). Moreover, as it has been noticed in Lions (1982, 1985), in general the boundary condition in (1) does not hold in the pointwise sense and we have to consider a suitable weak formulation of it. We refer the reader to Lions (1985); Barles and Lions (1991) and Crandall et al. (1992); Barles (1993, 1999); Ishii and Sato (2004); Bourgoing (2008), respectively, for well-posedness results for HJB equations with oblique boundary condition in the first and second order cases.
The main purpose of this work is to provide a consistent,

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

stable, monotone and convergent SL scheme to approximate the unique viscosity solution to (1). By the results in Barles (1993), the latter is well-posed in $C([0,T]\times\overline{\mathcal{O}})$. Semi-Lagrangian schemes to approximate the solution to (1) when $\mathcal{O}=\mathbb{R}^N$ (see e.g. Camilli and Falcone (1995); Debrabant and Jakobsen (2013)) can be derived from the optimal control interpretation of (1) and a suitable discretization of the underlying controlled trajectories. These schemes enjoy the feature that they are explicit and stable under an inverse Courant-Friedrichs-Lewy (CFL) condition and, consequentely, they allow large time steps. A second important feature is that they permit a simple treatement of the possibly degenerate second order term in H. The scheme that we propose for $\mathcal{O}\neq\mathbb{R}^N$ preserves these two properties and seems to be the first convergent scheme to approximate (1) with the rather general assumptions. In particular, our results cover the stochastic and degenerate case. Consequently, from the stochastic control point of view, our scheme allows to approximate the so-called value function of the optimal control of a controlled diffusion process with possibly oblique reflection on the boundary $\partial\mathcal{O}$ (see Bouchard (2008)). The main difficulty in devising such a scheme is to be able to obtain a consistency type property at points in the space grid which are near the boundary $\partial\mathcal{O}$ while maintaining the stability. This is achieved by considering a discretization of the underlying controlled diffusion which suitably emulates its reflection at the boundary in the continuous case. We refer the reader to Milstein (1996) for a related construction of a semi-discrete in time approximation of a second order non-degenerate linear parabolic equation.

2. A SEMI-LAGRANGIAN SCHEME

Let $\Delta t>0$, set $N_{\Delta t}:=\lfloor T/\Delta t\rfloor$, $\mathcal{I}_{\Delta t}:=\{0,\dots,N_{\Delta t}\}$ and $\mathcal{I}^*_{\Delta t}:=\mathcal{I}_{\Delta t}\setminus\{N_T\}$. We define the time grid $\mathcal{G}_{\Delta t}:=\{t_k\,|\,t_k=k\Delta t,\ k\in\mathcal{I}_{\Delta t}\}$. Given $(k,i)\in\mathcal{I}^*_{\Delta t}\times\mathcal{I}_{\Delta x}$, $a\in A$, and $\ell=1,\dots,N_\sigma$, we define the discrete characteristics

$$y^{\pm,\ell}_{k,i}(a)=x_i+\Delta t\mu\left(t_k,x_i,a\right)\pm\sqrt{N_\sigma\Delta t}\sigma^\ell(t_k,x_i,a).$$

Let $\mathcal{I}=\{+,-\}\times\{1,\dots,N_\sigma\}$ and let $\bar c>0$ be a fixed constant. For any $\delta>0$ we set

$$(\partial\mathcal{O})_\delta:=\{x\in\mathbb{R}^N\,|\,d(x,\partial\mathcal{O})<\delta\}.$$

Tthere exist $R>0$ and two C^1 functions $(\partial\mathcal{O})_R\times B\ni(x,b)\mapsto p^{\gamma_b}(x)\in\partial\mathcal{O}$ and $(\partial\mathcal{O})_R\times B\ni(x,b)\mapsto d^{\gamma_b}(x)\in\mathbb{R}$, uniquely determined, such that

$$x=p^{\gamma_b}(x)+d^{\gamma_b}(x)\gamma_b(p^{\gamma_b}(x)),\quad\text{for all }(x,b)\in(\partial\mathcal{O})_R\times B.$$

Therefore, there exists $\overline{\Delta t}>0$ such that for all $\Delta t\in[0,\overline{\Delta t}]$, $(k,i)\in\mathcal{I}^*_{\Delta t}\times\mathcal{I}_{\Delta x}$, $a\in A$, $b\in B$, and $s\in\mathcal{I}$, the *reflected characteristic*

$$\tilde y^s_{k,i}(a,b):=\begin{cases}y^s_{k,i}(a) & \text{if } y^s_{k,i}(a)\in\overline{\mathcal{O}},\\ p^{\gamma_b}(y^s_{k,i}(a))-\bar c\sqrt{\Delta t}\gamma_b(p^{\gamma_b}(y^s_{k,i}(a))) & \text{else}\end{cases}$$

is well-defined. Let us also set

$$\tilde d^s_{k,i}(a,b):=\begin{cases}0 & \text{if } y^s_{i,k}(a)\in\overline{\mathcal{O}},\\ d^{\gamma_b}(y^s_{k,i}(a))+\bar c\sqrt{\Delta t} & \text{otherwise,}\end{cases}$$

$$\tilde g^s_{k,i}(a,b):=\begin{cases}0 & \text{if } y^s_{k,i}(a)\in\overline{\mathcal{O}},\\ g\left(t_k,p^{\gamma_b}\left(y^s_{k,i}(a)\right),b\right) & \text{otherwise.}\end{cases}$$

Notice that if $y^s_{k,i}(a)\notin\overline{\mathcal{O}}$, then

$$\tilde y^s_{k,i}(a,b)=y^s_{k,i}(a)-\tilde d^s_{k,i}(a,b)\gamma_b\left(p^{\gamma_b}(y^s_{k,i}(a))\right).$$

For $(k,i)\in\mathcal{I}^*_{\Delta t}\times\mathcal{I}_{\Delta x}$ and $\Phi:\mathcal{G}_{\Delta x}\to\mathbb{R}$, let us define $\mathcal{S}_{k,i}[\Phi]:A\times B\to\mathbb{R}$ by

$$\begin{aligned}\mathcal{S}_{k,i}[\Phi](a,b)\quad&:=\frac{1}{2N_\sigma}\sum_{s\in\mathcal{I}}\big[I[\Phi](\tilde y^s_{k,i}(a,b))\\&\qquad+\tilde d^s_{k,i}(a,b)\tilde g^s_{k,i}(a,b)\big]+\Delta t f(t_k,x_i,a)\end{aligned}$$

and set

$$S_{k,i}[\Phi]:=\inf_{a\in A,\,b\in B}\mathcal{S}_{k,i}[\Phi](a,b).$$

We consider the following fully discrete SL scheme to approximate the solution to (HJB).

$$\begin{aligned}U_{k,i}&=S_{k,i}\big[U_{k+1,(\cdot)}\big],\quad\text{for }(k,i)\in\mathcal{I}^*_{\Delta t}\times\mathcal{I}_{\Delta x},\\U_{N_{\Delta t},i}&=\Psi(x_i),\qquad\text{for } i\in\mathcal{I}_{\Delta x}.\end{aligned}$$

Abstract: A learning approach for optimal feedback gains for nonlinear continuous time control systems is proposed and analysed. Numerical results demonstrate the feasibilty of the approach, which allows to obtain suboptimal feedback gains, without focusing on directly solving the underlying Hamilton Jacobi Belman equation.

Keywords: Asymptotic stabilization, tracking, feedback control, learning techniques, neural networks.

1. INTRODUCTION

In this talk we focus on minimization problems associated to controlled dynamical systems of the form

$$\dot{y} = f(y) + g(y)u, \quad y(0) = y_0,$$

on the state space $\mathbb{R}^n$ and a time interval $I = [0, T]$ for $T \leq +\infty$. Here, $f\colon I \times \mathbb{R}^n \to \mathbb{R}^n$ describes the nonlinear dynamics of the system and y_0 denotes its initial state which is contained in a given compact set $Y_0 \subset \mathbb{R}^n$. We assume that the associated state trajectory y can be influenced by a control input $u(t) \in \mathbb{R}^m$ which enters the system via the, possibly state-dependent, control operator g. Our interest lies in choosing a control u^* such that the associated control-state pair (u^*, y^*) minimizes an energy $\mathcal{J}$,

$$\begin{cases} \inf\limits_{y,u} \ \mathcal{J}(y,u) := \displaystyle\int_0^T J(t, y(t), u(t)) \ \mathrm{d}t + \Psi_T(y(T)) \\ \quad s.t. \quad \dot{y} = f(y) + Bu, \quad y(0) = y_0, \end{cases} \tag{$P(y_0)$}$$

which is given in terms of a running cost functional $J\colon \mathbb{R}^n \times \mathbb{R}^m$ and a final time penalty $\Psi_T(y(T))$, in case $T < \infty$. Note that this general setting allows to consider stabilization problems on infinite time horizons, of the form

$$J(t, y, u) = \frac{1}{2}|Q_1 y|^2 + \frac{\beta}{2}|u|^2, \ \Psi_T(y) = 0, \ \text{if } T = +\infty,$$

as well as tracking-type optimal control problems with

$$J(t, y, u) = \frac{1}{2}|Q_1(y - y_d(t))|^2 + \frac{\beta}{2}|u|^2,$$

and

$$\Psi_T(y) = \frac{1}{2}|Q_2(y - y_d^T)|^2, \ \text{if } T < +\infty,$$

where $Q_1 \geq 0, Q_2 \geq 0, \beta > 0$, in a unified way.

2. OPTIMAL FEEDBACK CONTROL

Computing optimal controls by solving the *open loop* minimization problem comes with several drawbacks. First, such controls are only constructed as a function of time and thus cannot take into account possible perturbations of the dynamical system. Second, changing the initial condition y_0 the control action for a new initial condition requires to solve $P(y_0)$ all over.

For these reasons, we turn to optimal controls in feedback form, i.e. control inputs that are constructed as a function of the state variable at every time point t. In more detail we aim for a *feedback law* $F^*\colon \mathbb{R}^n \to \mathbb{R}^m$ such that:

- For every $y_0 \in Y_0$ there is a solution y^* to
$$\dot{y} = f(y) + g(y)F^*(y), \ y(0) = y_0.$$
- For every $y_0 \in Y_0$, the pair $(y^*, F^*(y^*))$ is a minimizer to $(P(y_0))$.

Constructing an optimal feedback F^* is closely related to the computation of the optimal value function

$$V^*(t, y_0) = \inf_{u,y} \int_t^T J(t, y(t), u(t)) \ \mathrm{d}t + \Psi_T(y(T))$$

which satisfies a *Hamilton-Jacobi-Bellman equation* (HJB), a partial differential equation on the state space. Once available, the optimal control to $(P(y_0))$ can be expressed in feedback form as $u^*(t) = -\frac{1}{\beta} g(t, y^*(t))^\top \nabla V^*(t, y^*(t))$. Following the HJB approach one is inevitably faced with the *curse of dimensionality*: If M degrees of freedom are used to discretize the HJB equation in each of the spatial directions, then this results in a discrete system with M^n degrees of freedom. Except for small dimensions n of the state equation this is unfeasible and alternatives must be sought.

2.1 A learning approach to feedback control

To circumvent the solution of the HJB-equation, in this talk we propose to replace the control u in $(P(y_0))$ by the closed loop expression $F_\theta^\varepsilon(y)$ where $\{F_\cdot^\varepsilon\}_{\varepsilon>0}$ denotes a family of parametrized models, each described by a parameter $\theta \in \mathcal{N}_\varepsilon \simeq \mathbb{R}^{N_\varepsilon}$, $N_\varepsilon \in \mathbb{N}$. We assume that $\{F_\cdot^\varepsilon\}_{\varepsilon>0}$ satisfies a $\mathcal{C}^1$-universal approximation property regarding the optimal feedback F^*:

Assumption 1. Suppose that there exists a compact set $N(Y_0)$ such that $y^*(t) \in N(Y_0)$ for every $t \in I$ and $y_0 \in Y_0$. The family $\{F^\varepsilon_\cdot\}_{\varepsilon>0}$ is said to be a universal approximator of F^* if there are parameters

$$\sup_{t\in I, y\in N(Y_0)} [|F^*(t,y) - F^\varepsilon_{\theta_\varepsilon}| + \|D_y F^*(t,y) - D_y F^\varepsilon_{\theta_\varepsilon}\|] \leq C\epsilon$$

for all $\varepsilon > 0$.

Under suitable assumptions on F^*, this requirement holds, for example for certain deep neural networks of varying width/depth or for piecewise polynomials of increasing total degree. Subsequently, an approximate optimal feedback law is determined from solving

$$\begin{cases} \inf\limits_{\theta} \int_0^T J(t, y(t), F^\varepsilon_\theta(t, y(t)))\ \mathrm{d}t + \Psi_T(y(T)) \\ \quad s.t. \quad \dot{y} = f(y) + g(y)F^\varepsilon_\theta(y), \quad y(0) = y_0, \end{cases} \tag{P_{Y_0}}$$

While it may be appealing to use a blackbox model for the approximation of the feedback law, we will show the merit of incorporating a priori knowledge on the structure of V^* (and its gradient) in the construction of the approximate feedback. For example, in the case of stabilizing a non-autonomous system with $f(0) = 0$ and $g(y) = B$, it is well known that the associated optimal feedback law is independent of time and satisfies $F^*(0) = 0$. Similarly, in the context of tracking-type optimal control problems, we can directly imprint the transversality condition

$$F^*(T, y) = -\frac{1}{\beta} g(y)^\top Q_2^\top Q_2 (y - y_d^T),$$

which follows from the necessary optimality conditions, onto the model. Finally, we could also exploit the connection between F^* and the gradient of the optimal value function V^*. This leads to an ansatz of the form

$$F^\varepsilon_\theta = -\frac{1}{\beta} g(\cdot)^\top \nabla V^\varepsilon_\theta(\cdot)$$

where V^ε_θ denotes a parametrized model for the scalar value function.

Of course, it can be expected that the effectiveness of this procedure depends on the location of the orbit $\mathcal{O} = \{y(t; y_0) : t \in (0, \infty)\}$ within the state space $\mathbb{R}^n$. To accommodate the case that $\mathcal{O}$ does not 'cover' the state-space sufficiently well, we propose to look at the ensemble of orbits departing from the compact set Y_0 of initial conditions and reformulate the problem accordingly. For this purpose we introduce a probability measure μ on Y_0 describing a "training set" of initial conditions and replace (P_{Y_0}) by

$$\left\{ \inf_{\theta} \int_{Y_0} \int_0^T J(t, \mathbf{y}(t), F_\theta(t, \mathbf{y}(t)))\ \mathrm{d}t + \Psi_T(\mathbf{y}(T)) d\mu(y_0) \right. \tag{$\mathcal{P}_\varepsilon$}$$

Here $\mathbf{y}$ is to be understood as an *ensemble* of state variables which assigns to every y_0 in the support of μ the solution of the closed loop state equation

$$\dot{y} = f(y) + g(y)F_\theta(y), \quad y(0) = y_0.$$

Our work gives mathematical rigor to this formulation including e.g. a discussion of its well-posedness.

Theorem 2. Under suitable conditions on f, g, Ψ, and appropriate constraints on the ensemble state $\mathbf{y}$ and the parameters θ, Problem $(\mathcal{P})$ admits at least one minimizing pair $(\mathbf{y}^*_\varepsilon, \theta^*_\varepsilon)$.

This requires a careful perturbation analysis of the underlying equation which is e.g. aggravated by the, potential, instability of the uncontrolled system as well as infinite time-horizons. For the practical realization of the approach we rely on first-order type methods. In this context, we provide a characterization of the gradient of the objective functional in the learning problem by means of adjoint calculus.

We also address the convergence of feedback laws obtained as the parametrized model gets more complex i.e. once $\varepsilon \to 0$. This leads to a variety of different convergence results depending on the particular type of problem under consideration (e.g. tracking-type vs. stabilization problems) as well as the training measure μ. In the aforementioned stabilization example and for an arbitrary training measure μ, we can show that the optimal objective functional values satisfy

$$\min(\mathcal{P}_\varepsilon) \to \int_{Y_0} V^*(y_0)\ \mathrm{d}\mu(y_0)$$

and thus approximate V^* in a suitable sense. Additionally, the optimal approximate ensemble states $\mathbf{y}^*_\varepsilon$ and the associated *approximate control actions* $BF^\varepsilon_{\theta^*_\varepsilon}(\mathbf{y}^*_\varepsilon)$ converge to the respective optimal quantities as $\varepsilon \to 0$. This is expressed in the following two theorems, for which the complete set of conditions on the problem data can be found in Walter (2021-1), Walter (2021-2), and Walter (2021-3).

Theorem 3. Assume that $\mathcal{P}(y_0)$ admits a unique optimal solution for every y_0 in the support of μ. Then there holds

$$(\mathbf{y}^*_\varepsilon, BF^\varepsilon_{\theta^*_\varepsilon}(\mathbf{y}^*_\varepsilon)) \to (\mathbf{y}^*, BF^*(\mathbf{y}^*))$$

where $\mathbf{y}^*$ is the optimal ensemble i.e. $\mathbf{y}^*(y_0) = y^*$ and convergence is obtained w.r.t a suitable topology on the space of ensemble functions.

In the important case of finite training data, the uniqueness assumption can be dropped and still convergence of the feedback controls can be obtained:

Theorem 4. Assume that $\mu = \sum_{j=1}^N \lambda_j \delta_{y_0^j}$, $y_0^j \in Y_0$. Then $\mathbf{y}^*_\varepsilon$ is of the form

$$\mathbf{y}^*_\varepsilon = (y^*_{\varepsilon,1}, y^*_{\varepsilon,2}, \ldots, y^*_{\varepsilon,N})$$

and every accumulation point of $\{(y^*_{\varepsilon,j}, F^\varepsilon_{\theta^*_\varepsilon}(y^*_{\varepsilon,j}))\}_{\varepsilon>0}$ is a minimizing pair of $(P(y_0^j))$.

Similar results can also be derived in the context of tracking-type problems with more general control operators. The cited papers Walter (2021-1), Walter (2021-2), and Walter (2021-3) contain numerical examples which illustrate the practical relevance of our learning approach. They range from highly unstable low dimensional systems to high dimensional examples stemming from the discretization of PDE systems. For related work with detailed numerical investigations we refer to Onken et al. (2021).

3. CONCLUSION

In summary, on the one hand, the results presented in this talk will show the great potential and success of learning feedback laws for optimal control problems. On the other hand, they also reveal open questions which stimulates further research. These include the development of fast and

reliable solution methods as well as the extension of our approach to PDE systems. Moreover, the approach itself is highly flexible in the sense that it directly allows to include control and/or state constraints into the problem as well as constraints on the feedback function itself.

Abstract: The goal of this note is to present a rigorous derivation of a macroscopic traffic flow model with a bifurcation or a local perturbation from a microscopic one. The microscopic model is a simple follow-the-leader with random parameters. The random parameters are used as a statistical description of the road taken by a vehicle and its law of motion. The limit model is a deterministic and scalar Hamilton-Jacobi equation on a network with a flux limiter, the flux-limiter describing how much the bifurcation or the local perturbation slows down the vehicles. The proof of the existence of this flux limiter relies on a concentration inequality and on a delicate derivation of a super-additive inequality.

Keywords: traffic flow, stochastic homogenization, Hamilton-Jacobi equations on networks.

1. INTRODUCTION

In this note, we present the results of Cardaliaguet et al. (2022) concerning the study of traffic flows models with a bifurcation consisting in a single incoming road which is divided after a junction into several outgoing ones. There are two main classes of models to describe these situations: microscopic models, which explain how each vehicle behaves in function of the vehicles in front; and macroscopic ones, taking the form of a conservation law in which the main unknown is the density of vehicles on the roads. Our aim is to start from simple microscopic models on a bifurcation and derive from these models continuous ones after scaling. The point is to get a better understanding of the continuous traffic flow models arising as the limit of discrete ones. Indeed there exists many different continuous models of traffic flow on a junction or with a local perturbation in the literature (see Garavello et al. (2006) and references therein) and the relation between these models is not completely clear. If the basic continuous model on a single straight road (the so-called LWR model, from Lighthill et al. (1955) and Richards (1956)) is well understood and justified by micro-macro limits in several contexts (see for example Di Francesco et al. (2015)), there is no consensus for problems with a junction or a bifurcation: the models are only obtained so far by heuristic arguments, with the exception of Forcadel et al. (2020) discussed below. Our goal is to show that the continuous model suggested in Imbert et al. (2017) pops up as the natural limit of follow-the-leader models. The continuous model in Imbert et al. (2017) takes the form of a flux limited Hamilton-Jacobi equation: it is a kind of integrated form of the basic LWR model outside the junction combined with a "flux limiting condition" on the junction. Our micro-macro derivation holds for a large class of follow-the-leader models, allowing for a possible heterogeneous behavior of the vehicles.

Our starting point is a microscopic model. Before describing it, let us recall that few discrete traffic flow models with a junction or a local perturbation exist in the literature (see for example Colombo et al. (2020); Andreianov et al (2018)). The only model proving micro-macro derivation in the case of a bifurcation is Forcadel et al. (2020) in which there are two outgoing roads and it is assumed (no too realistically) that every second vehicle takes a given road. In this setting the authors show that the convergence of the discrete problem to a flux limited solution of a Hamilton-Jacobi equation on a junction. One of the goals of the paper is to introduce a more realistic model in which one replaces the deterministic rule of Forcadel et al. (2020) by a random one (e.g., every second vehicle *in average* takes a given outgoing road). The introduction of randomness in traffic flow problems is natural and can be traced back to Chiabaut et al. (2010). The micro-macro derivation of the LWR model from a random one on a single road was established in Cardaliaguet et al. (2021). Here we present the corresponding result for a bifurcation.

2. MAIN RESULT

2.1 Short description of the microscopic model.

In our discrete model there is one incoming road and K outgoing ones, where $K \in \mathbb{N}$, $K \geq 1$. A position on the road is given by a pair (x, k) where x is a real number and k is a label in $\{0, \dots, K\}$. If x is nonpositive, then by convention $k = 0$ and the vehicle is on the incoming road. If x is positive then $k \in \{1, \dots, K\}$ and the vehicle is on the outgoing road k. The junction is an interval around $x = 0$, say, to fix the ideas, $[-R_0, 0]$. The vehicles are

labelled by $i \in \mathbb{Z}$. The position of the vehicle labelled i at time t is denoted by $U_i(t)$. The outgoing road the vehicle chooses is fixed from the beginning (independent of time) and denoted by $T_i \in \{1, \dots, K\}$. The motion of the vehicles is given by a leader-follower model: it satisfies the system of ordinary differential equations

$$\frac{d}{dt}U_i(t) = V_{Z_i}(U_{i+1}(t) - U_i(t), U_{\ell_i}(t) - U_i(t), U_i(t)), \qquad t \geq 0,\ i \in \mathbb{Z}, \quad (1)$$

where $V : \mathcal{Z} \times \mathbb{R}^3 \to \mathbb{R}_+$ is Lipschitz continuous in the three last variables (uniformly in the $z-$variable), nondecreasing with respect to the two middle ones and bounded by $\|V\|_\infty$. The type of the vehicle $i \in \mathbb{Z}$ is the random variable Z_i in $\mathcal{Z}$. We assume that $\mathcal{Z}$ is a finite set. Throughout the paper, $\Omega := \mathcal{Z}^{\mathbb{Z}}$ is endowed with the product $\sigma-$field $\mathcal{F}$ and with the product probability measure $\mathbb{P}$. We denote by $\tau : \mathbb{Z} \times \Omega \to \Omega$ the shift map defined by

$$(\tau_n \omega)_i = \omega_{i+n}, \qquad \forall \omega = (\omega_i)_{i \in \mathbb{Z}} \in \Omega,\ \forall n \in \mathbb{Z}.$$

We set $Z_i^\omega = \omega_i$ for $\omega = (\omega_i) \in \Omega$ and $i \in \mathbb{Z}$. As $\mathbb{P}$ is the product measure on Ω, this means that the $(Z_i)_i \in \mathbb{Z}$ are i.i.d.

The junction $\mathcal{R}$ is given by

$$\mathcal{R} = \bigcup_{k=0}^{K} \mathcal{R}^k$$

where

$\mathcal{R}^0 = (-\infty, 0] \times \{0\},\ \mathcal{R}^k = [0, +\infty) \times \{k\}$ for $k \in \{1, \dots, K\}$.

We also denote by $\overset{o}{\mathcal{R}}$ the interior of the roads:

$$\overset{o}{\mathcal{R}} = \bigcup_{k=0}^{K} \overset{o}{\mathcal{R}}{}^k,$$

where

$\overset{o}{\mathcal{R}}{}^0 = (-\infty, 0) \times \{0\},\ \overset{o}{\mathcal{R}}{}^k = (0, +\infty) \times \{k\}$ for $k \in \{1, \dots, K\}$.

We assume that all the vehicle are going or have gone through the junction and were ordered before going through the junction: $i+1$ is the label of the vehicle right in front of the vehicle i before this vehicle has gone through the junction. We denote by ℓ_i the label of the first vehicle in front of vehicle i taking the same outgoing road as i (in other words, $\ell_i = \inf\{j > i, T_i = T_j\}$). Each vehicle has a type Z_i encoding, on the one hand, the outgoing road the vehicle is taking or is going to take (namely, $T_i = T(Z_i)$ for a deterministic map $T : \mathcal{Z} \to \{1, \dots, K\}$) and, on the other hand, the "behavior" of the vehicle (for instance, if it is a truck or a race car). The velocity law $V = V_z(e_1, e_2, x)$ depends on the type $z \in \mathcal{Z}$ of the vehicle, the distances e_1 or e_2 to the next vehicle and the position x of the vehicle.

In order to obtain a limit model with a few unknowns and as simple as possible, we do not keep track of all the vehicles of a given type (in contrast with Colombo et al. (2018)). Instead we prefer a statistical description and assume that the types (Z_i) of the vehicles are random, independent and with the same law (i.i.d.); as a consequence the (T_i) are also i.i.d. In addition, we also suppose that the traffic is homogeneous outside the junction (see Assumption (H_3) below).

For later use we denote by $\pi^k := \mathbb{P}[T_i = k]$ the proportion of vehicle taking (or planning to take) road k.

2.2 The continuous macroscopic model.

The goal of the paper is to understand the behavior of the solution on large scale of time and space: namely, the behavior of $(x,t) \to \epsilon U_{[x/\epsilon]}(t/\epsilon)$, (where $[y]$ is the integer part of the real number y).

For $\epsilon > 0$, we look at the (scaled) traffic density of vehicles on each road:

$$m^\epsilon(dx, k, t) = \begin{cases} \epsilon \displaystyle\sum_{i \in \mathbb{Z},\ T_i = k} \delta_{\epsilon U_i(t/\epsilon)}(dx) \\ \qquad\qquad \text{if } x > 0,\ k \in \{1, \dots, K\} \\ \epsilon \displaystyle\sum_{i \in \mathbb{Z}} \delta_{\epsilon U_i(t/\epsilon)}(dx) \\ \qquad\qquad \text{if } x \leq 0,\ k = 0 \end{cases}$$

and want to understand the limit, as $\epsilon \to 0$, of m^ϵ. For this it is convenient to integrate in space m^ϵ and look instead at:

$$\nu^\epsilon(x, k, t) = \begin{cases} \epsilon(\pi^k)^{-1} \Big(\displaystyle\sum_{i \in \mathbb{Z},\ i \leq 0,\ T_i = k} \delta_{\epsilon U_i(t/\epsilon)}((x, +\infty)) \\ \qquad - \displaystyle\sum_{i \in \mathbb{Z},\ i > 0,\ T_i = k} \delta_{\epsilon U_i(t/\epsilon)}((-\infty, x]) \Big) \\ \qquad\qquad \text{if } x > 0,\ k \in \{1, \dots, K\} \\ \epsilon \Big(\displaystyle\sum_{i \in \mathbb{Z},\ i \leq 0} \delta_{U_i(t)}((x, +\infty)) \\ \qquad - \displaystyle\sum_{i \in \mathbb{Z},\ i > 0} \delta_{U_i(t)}((-\infty, x]) \Big) \\ \qquad\qquad \text{if } x \leq 0,\ k = 0. \end{cases} \quad (2)$$

Note that $\partial_x \nu^\epsilon = -m^\epsilon$ if $x \leq 0$ while $\partial_x \nu^\epsilon = -(\pi^k)^{-1} m^\epsilon$ if $x \geq 0$ and $k \in \{1, \dots, K\}$. This choice ensures the map ν^ϵ to be "almost continuous" at 0 since the vehicles are split between the K roads after the junction in proportion π^k for the road k. Our main result (Theorem 1) roughly states that, under suitable assumptions on V and if $\nu^\epsilon(\cdot, \cdot, 0)$ has a locally uniform (deterministic) limit $\nu_0(\cdot, \cdot)$ at time $t = 0$, then ν^ϵ has a.s. a locally uniform (deterministic) limit ν which is the unique viscosity solution to

$$\begin{cases} \partial_t \nu(x, k, t) + H^k(\partial_x \nu(x, k, t)) = 0 \quad \text{if } x \neq 0,\ t > 0 \\ \partial_t \nu + \\ \max\{\bar{A}, H^{0,+}(\partial_0 \nu), H^{1,-}(\partial_1 \nu), \dots, H^{K,-}(\partial_K \nu))\} = 0 \\ \qquad\qquad \text{at } x = 0 \\ \nu(x, k, 0) = \nu_0(x, k) \quad \text{for any } x, k, \end{cases} \quad (3)$$

where for $k \in \{0, \dots, K\}$, we denote by $H^{k,+}$ (resp. $H^{k,-}$) the largest nondecreasing (resp. nonincreasing) map below H^k.

The first equation is a Hamilton-Jacobi (HJ) equation in which the homogenized Hamiltonians $H^k(p)$ can be explicitly computed from the $\tilde{V}^k$. It corresponds to an integrated form of the LWR equation. The second equation describes the behavior of the vehicles at the junction (reduced after scaling to $x = 0$): we explain below the different terms. It roughly says that $\partial_t \nu + \bar{A} = 0$ at $x = 0$ (unless the HJ equation is satisfied at $x = 0$). The real number $\bar{A}$ is the so-called flux limiter. This is the main unknown of the paper. It quantifies how the traffic is slowed down by the junction. We show that

$$A_0 \le \bar{A} \le 0, \text{ where } A_0 := \max_{k\in\{0,\dots,K\}} \min_{p\in\mathbb{R}} H^k(p).$$

When $\bar{A} = A_0$, the flux is not limited at all. If $\bar{A} = 0$, then the traffic is completely stopped by the junction (this does not happen under our assumptions). The existence of $\bar{A}$ is the main point of the paper, which presents the first existence result of a flux limiter in the context of a stochastic homogenization problem. We show that $\bar{A}$ can be computed as follows:

$$\bar{A} = -\lim_{t\to+\infty} \frac{1}{t} \sharp\big\{i \in \mathbb{Z},\ \exists s \in [0,t],\ U_{e,i}(s) = 0\big\},$$

where $\sharp E$ denotes the number of elements of a set E, $e = (e^k)_{k=0,\dots,K}$ is such that $H^k(-1/e^k) = \min_p H^k(p)$ for any $k \in \{0,\dots,K\}$ and $(U_{e,i})$ is the solution to (1) with the "flat" initial condition $U_{e,i}(0) = e^k i$ (where $k = 0$ if $i \le 0$ and $k = T_i$ if $i \ge 0$). The quantity $\bar{A}$ can be interpreted as the maximal fraction of vehicles the junction can let pass given an amount of time. The introduction of Hamilton-Jacobi equations on a junction or stratified domains can be traced back to Achdou et al. (2013, 2015); Barles et al. (2013); Bressan et al. (2007); Imbert et al. (2013); Schieborn (2013); a general theory of flux limited solutions was developed in Imbert et al. (2017) (see also Barles et al. (2018)) with, as fundamental result, a comparison theorem; Lions et al. (2016, 2017) present different arguments for the comparison while Barles et al. (2018) proposes a general survey on the topic.

2.3 Assumptions

Let us state our standing assumptions on V_z:

- (H_1) For any $z \in \mathcal{Z}$, the map $(e_1, e_2, x) \to V_z(e_1, e_2, x)$ is Lipschitz continuous from $\mathbb{R}^2_+ \times \mathbb{R}$ to $\mathbb{R}_+$ and nondecreasing with respect to the first two variables;
- (H_2) There exists $e_{\max} > \Delta_{\min} > 0$ and $0 < R_2 < R_1 < R_0$, with $R_0 > e_{\max}$, such that for any $z \in \mathcal{Z}$, for any $(e_1, e_2, x) \in \mathbb{R}^2_+ \times \mathbb{R}$,
  - (i) $V_z(e_1, e_2, x) = 0$ if ($e_1 \le \Delta_{\min}$ and $x \le -R_2$) or if ($e_2 \le \Delta_{\min}$ and $x \ge -R_1$),
  - (ii) $V_z(e, e_2, x) = V_z(e_{\max}, e_2, x)$ and $V_z(e_1, e, x) = V_z(e_1, e_{\max}, x)$ if $e \ge e_{\max}$;
- (H_3) There exists $\tilde{V}^0, \dots, \tilde{V}^K : [0, +\infty) \to [0, +\infty)$ such that
$$V_z(e_1, e_2, x) = \begin{cases} \tilde{V}^0_z(e_1) \text{ if } x \le -R_0 \\ \tilde{V}^k_z(e_2) \text{ if } x \ge 0 \text{ and } T(z) = k. \end{cases}$$
- (H_4) For any $z \in \mathcal{Z}$ and any $k \in \{0,\dots,K\}$, there exists $h^k_{\max,z} \in (\Delta_{\min}, e_{\max}]$ such that $p \to \tilde{V}^k_z(p)$ is increasing and concave in $[\Delta_{\min}, h^k_{\max,z}]$ and constant on $[h^k_{\max,z}, +\infty)$;
- (H_5) There exists $\kappa > 0$ such that, for any $z \in \mathcal{Z}$,
  - (i) $V_z(e_1, e_2, x) = \tilde{V}^0_z(e_1)$ if $e_1 \le e_2$, $x \le -R_2$ and $V_z(e_1, e_2, x) \le \kappa$,
  - (ii) $\partial_x V_z(e_1, e_2, x) \ge 0$ if $x \in [-R_1, 0]$ and $V_z(e_1, e_2, x) \le \kappa$,
  - (iii) $V_z(e_1, e_2, x) > 0$ if $e_1 \wedge e_2 > \Delta_{\min}$.

Note that, by assumption (H_2), we have $\tilde{V}^k_z(e) = 0$ if $e \le \Delta_{\min}$ and $\tilde{V}^k_z(e) = \tilde{V}^k_z(e_{\max})$ if $e \ge e_{\max}$.

Some comment on the assumption are now in order. Assumption (H_2) is standard in the analysis of leader-follower models. The existence of $\Delta_{\min}$ prevents vehicles to collide (and could correspond to the size of the smallest vehicle for instance). The existence of $e_{\max}$ just says that the vehicles do not take into account the vehicles too far ahead. Assumption $R_0 > e_{\max}$ can be made without loss of generality. Assumption (H_3) means that the roads are homogeneous outside the bifurcation. This formalizes the fact that we concentrate here on a single bifurcation. Assumption (H_4) is also standard in the analysis of leader-follower models. There is one restriction though: the minimal distance such that the velocity has to be positive (i.e., here $\Delta_{\min}$) has to be the same for all vehicle and is not allowed to depend on the type of the vehicle; this restriction is related to the last (and technical) assumption (H_5). Assumption (H_5) has to do with the behavior of vehicles with slow velocity on the junction and ensures that the vehicles starting with a flat initial condition ($U_i(0) := e^k i)_{i\in\mathbb{Z}}$ (where $k = 0$ if $i \le 0$ and $k = T_i$ if $i \ge 0$ and e^k is such that $H^k(-1/e^k) = \min_p H^k(p)$) have a velocity bounded below by a positive constant independent of time and position. This last property is instrumental throughout the proofs. Assumption (H_5), without being unrealistic, is a little restrictive, but we do not know if it is possible to relax it.

2.4 The homogenized velocities and Hamiltonians.

Let $V^k_{\max,z} := \tilde{V}^k_z(h^k_{\max,z})$. Under assumptions (H1)—(H4), the map $\tilde{V}^k_z : [\Delta_{\min}, h^k_{\max,z}] \to [0, V^k_{\max,z}]$ is increasing and continuous for any $z \in \mathcal{Z}$ and any $k \in \{0,\dots,K\}$. We denote by $(\tilde{V}^k_z)^{-1}$ its inverse.

Let

$$\bar{v}^0 := \inf_{z\in\mathcal{Z}} \tilde{V}^0_z(e_{\max}), \qquad \bar{v}^k := \inf_{z\in\mathcal{Z},\ T(z)=k} \tilde{V}^k_z(e_{\max}). \quad (4)$$

We recall from Cardaliaguet et al. (2021) the definition of the homogenized velocities $\bar{V}^k$ and homogenized Hamiltonians: $\bar{V}^0$ is the inverse of the continuous increasing map defined on $(0, \bar{v}^0)$ by $v \to \mathbb{E}\left[(\tilde{V}^0_{Z_0})^{-1}(v)\right]$. We note that $\bar{V}^0$ is defined on $(\Delta_{\min}, \mathbb{E}\left[(\tilde{V}^0_{Z_0})^{-1}(\bar{v}^0)\right])$. We extend it for any $e \in [0, \Delta_{\min}]$ by $\bar{V}^0(e) = 0$ and for $e \ge \mathbb{E}\left[(\tilde{V}^0_{Z_0})^{-1}(\bar{v}^0)\right]$ by $\bar{V}^0(e) = \bar{v}^0$. In the same way we define $\bar{V}^k$ as the inverse of the continuous increasing map defined on $(0, \bar{v}^k)$ by $v \to \mathbb{E}\left[(\tilde{V}^k_{Z_0})^{-1}(v) \mid T_0 = k\right]$. It defines $\bar{V}^k$ on $(\Delta_{\min}, \mathbb{E}\left[(\tilde{V}^k_{Z_0})^{-1}(\bar{v}^0) \mid T_0 = k\right])$. We extend it for any $e \in [0, \Delta_{\min}]$ by $\bar{V}^k(e) = 0$ and for any $e \ge \mathbb{E}\left[(\tilde{V}^k_{Z_0})^{-1}(\bar{v}^0) \mid T_0 = k\right]$ by $\bar{V}^k(e) = \bar{v}^k$. The maps $\bar{V}^k$ (for $k \in \{0,\dots,K\}$) are continuous and bounded on $[0, +\infty)$.

We set, for any $k \in \{1,\dots K\}$,

$$\begin{cases} H^0(p) = p\bar{V}^0(-1/p), \\ H^k(p) = p\bar{V}^k(-1/(\pi^k p)), \end{cases} \quad p \in (-\infty, 0),$$
$$H^0(p) = H^k(p) = 0,\ \forall p \ge 0$$

and

$$A_0 = \max_{k\in\{0,\dots,K\}} \min_{p\in\mathbb{R}} H^k(p). \quad (5)$$

By Assumption $(H4)$, for $i \in \{0, \dots, K\}$, H^k is convex in $(-1/(\pi^k \Delta_{\min}), 0)$.

2.5 The main result

The main result of this note states that the system homogenizes: let $(U_i^{0,\epsilon})_{i\in\mathbb{Z}}$ be a deterministic family of initial conditions satisfying the compatibility condition: for any $i \in \mathbb{Z}$,

$$U_{i+1}^{0,\epsilon} \geq U_i^{0,\epsilon} + \Delta_{\min} \text{ if } U_{i+1}^{0,\epsilon} \leq -R_2$$

and

$$U_{\ell_i}^{0,\epsilon} \geq U_i^{0,\epsilon} + \Delta_{\min} \text{ for any } i \in \mathbb{Z}. \tag{6}$$

Up to relabel the indices, we also assume that $U_{i,0}^{\epsilon} \leq 0$ iff $i \leq 0$. Let U^ϵ be the solution of (1) with initial condition $(U_i^{0,\epsilon})_{i\in\mathbb{Z}}$.

Theorem 1. There is a set Ω_0 of full probability and a constant $\bar{A} < 0$ (the flux limiter) such that, if $(U_i^{0,\epsilon})_{i\in\mathbb{Z}}$ is a family of initial conditions such that the associated scaled function $\nu^\epsilon(\cdot,\cdot,0)$ defined by (2) (with $t = 0$) converges locally uniformly in $\mathcal{R}$ to a Lipschitz continuous map $\nu_0 : \mathcal{R} \to \mathbb{R}$, then, for any $\omega \in \Omega_0$, ν^ϵ converges locally uniformly in $\mathcal{R} \times [0, +\infty)$ to the unique continuous viscosity solution of the Hamilton-Jacobi equation (3) with flux limiter $\bar{A}$.

Time–dependent Hamilton–Jacobi equations on networks

Antonio Siconolfi

Dipartimento di Matematica, Sapienza Università di Roma, Piazzale A. Moro 5 Italy (e-mail: siconolf@mat.uniroma1.it).

Keywords: time–dependent Hamilton-Jacobi equations, Embedded networks, Viscosity solutions, Comparison principle, semidiscrete equations on graphs.

The purpose of this presentation is to study the well posedness of a time–dependent Hamilton–Jacobi equation, coupled with suitable additional conditions, posed on a network.

We consider a connected network Γ embedded in $\mathbb{R}^N$ with a finite number of arcs γ, which are regular simple curves parametrized in $[0,1]$, linking points of $\mathbb{R}^N$ called vertices, which make up a set we denote by $\mathbf{V}$. We define a Hamiltonian on Γ as a collection of Hamiltonians $H_\gamma : [0,1] \times \mathbb{R} \to \mathbb{R}$, indexed by arcs, with the crucial feature that Hamiltonians associated to arcs possessing different support, are totally unrelated.

The equations we deal with are accordingly of the form

$$u_t + H_\gamma(s, u') = 0 \qquad \text{in } (0,1) \times (0, +\infty)$$

on each arc γ, the aim being to uniquely select distinguished viscosity type solutions of each equation which can be assembled together continuously, making up a continuous function $u : \Gamma \times (0, +\infty) \longrightarrow \mathbb{R}$ with $u(\gamma(s), t)$ solution of the above equation for each γ. To accomplish it, one has to appropriately exploit the network geometry, via the adjacency condition between arcs and vertices, and the decisive issue for that is the right definition of supersolution. The subtle point in fact is that the conditions for supersolutions are not the same at all vertices, but are given taking into account the network structure.

The problem becomes discontinuous across all the one–dimensional interfaces of the form

$$\{(x,t), t \in [0, +\infty)\} \qquad \text{with } x \in \mathbf{V},$$

in contradiction to what happens for the stationary version of this kind of equations, where the discontinuities are located at the vertices, that is to say: they are finite and of zero dimension. This dimensional change explains why the analysis of evolutive equations on networks is by far more challenging than the stationary ones.

There are consequently few results available in the literature. A basic reference is (3) by Imbert and Monneau, where the topic is treated through PDE techniques, adapting tools from viscosity solutions theory, under the assumptions that the Hamiltonians in play are continuous, semiconvex and coercive. In (1), (2) applications of this theory are given.

We prove existence, uniqueness and stability of solutions on the network assuming convexity of the Hamiltonians, but without the growth conditions which allow applying Fenchel transform, so that an action functional cannot be defined. We do not have consequently representation formulae for solutions at hand, and our techniques employ purely PDE methods.

One of the main discoveries in (3) is that to get well posedness of the evolutive problem, the assignment of an initial datum at $t = 0$ is not enough. It must actually be coupled with a condition regarding the time derivative of solutions on the discontinuity interfaces. They qualify as *flux–limited* the corresponding solutions. We adopt here the same point of view, and the terminology of *flux limiter* as well.

Our definition of solution and the one of (3) are clearly the same outside the discontinuity interfaces, namely classical viscosity solutions. On the interfaces, the definition of subsolution coincides as well, while regarding supersolution, which is the most delicate point, the formulation is different, and our definition is stronger. However, a full comparison between the two notions cannot be done at present since the junctions considered in (3) have unbounded arcs while the arcs of our networks are bounded with two vertices as endpoints.

We think that our pattern is more related to the geometrical sense of the definition, and is more simple to write down, in particular because we take into account, for any arc, also the arc with the opposite orientation. This in particular implies that we do not have boundary vertices since any vertex has a least two adjacent arcs with opposite orientation. We would finally like to point out the fact that testing separately the equations on any arc can be a considerable advantage for a numerical analysis of the topic.

In contrast with (3), we do not need constructing special test functions at the vertices, and we do not use Crandall–Lions doubling variable method to get the comparison result.

Our method is different. We prove a comparison principle by associating the Hamilton–Jacobi equation to a semidiscrete problem posed on the discontinuity interfaces. This is the same road walked in (4), (5) for the stationary case, even if the evolutive setting brings in some complications.

The proof of the comparison result for the semidiscrete problem turns out to be quite simple, and it is then transferred to the initial equation exploiting the fundamental property that a continuous function $u : \Gamma \times [0, +\infty) \to \mathbb{R}$ is solution of the main problem if and only $u(\gamma(s), t)$ solves the HJ equations in the viscosity sense for any γ, and its trace on the discontinuity interfaces is solution of the semidiscrete problem.

A further relevant peculiarity of our techniques with respect to those in (3), is that we do not use special test functions at the vertices, more generally, we do not need functions testing at the same time solutions of equations with different Hamiltonians. For our definition, it is enough to consider viscosity test functions for the equations on the arcs, separately considered, plus test functions on the discontinuity interfaces. Finally, we do not use Perron–Ishii method to prove existence of solutions, but rely on a more constructive technique, showing first existence for small time interval and then gluing together the local solutions to get a solution global in time.

Abstract: We study deterministic Mean Field Games with finite horizon in which the state space of the players is a network. In these games, the generic agent can control its dynamics: inside each edge, it can choose its velocity (which coincides with its control) and it can also choose, when it arrives at a vertex, the edge in which it enters. It will pay a cost which is formed by a running cost and a terminal cost; both these costs depend on the trajectory that it has chosen and on the evolution of the distribution of all agents. On the other hand, its position cannot affect the distribution of the whole population. As in the Lagrangian approach, we introduce a relaxed notion of Mean Field Games equilibria which relies on probability measures on trajectories on the network instead of probability measures on the network. Our main result is to establish the existence of such Mean Field equilibria.
With such an equilibrium at hand, we can introduce the value function and we prove that this function is a generalized solution to the associated first order Hamilton-Jacobi problem on the network.

1. INTRODUCTION

The theory of Mean Field Games studies the asymptotic behaviour of differential games (mainly in terms of their Nash equilibria) as the number of players tends to infinity. This theory started with the seminal papers by Lasry and Lions (2006a), Lasry and Lions (2006b), Lasry and Lions (2007) and by Huang et al. (2006). Models of this type have been intensively studied in the last decade; a detailed description of the achievements obtained in these years goes beyond the scope of this presentation. For a general overview we refer to the monographs by Achdou and Capuzzo Dolcetta (2010), Bensoussan et al. (2013), Cardaliaguet (2012) and Gomes et al. (2016).

In these games, the players are rational and indistinguishable and each one of them aims at choosing its own trajectory so to minimize its own cost which depends on the trajectory itself but also on the distribution of the whole population of agents. The player are "microscopic" and "identical": the position of a single player cannot affect the distribution of the whole population and the cost is the same for each one of them. The dynamics of the agents can be either stochastic or deterministic. Consider the case where the dynamics of the players are deterministic and the interaction among them is given by a nonlocal regularizing operator acting on the distribution of states of the agents. In the Euclidean setting, these models are described by a system of first order partial differential equations; indeed, the systems are formed by a continuity equation for the density of the distribution of the whole population (forward in time) and a Hamilton-Jacobi equation for the optimal value of a representative agent (backward in time), coupled with initial/final data (the initial distribution of the population and the final cost); see the paper by Cardaliaguet (2012).

We focus our attention on deterministic Mean Field Games, with finite horizon and a nonlocal regularizing interaction among the agents, in which the states of the agents are constrained in a network (in our setting, a network is given by a finite collection of vertices connected by continuous edges which cannot self-intersect). In these games, the generic agent can control its dynamics: inside each edge, it can choose its velocity (which coincides with its control) and it can also choose, when it arrives at a vertex, the edge in which it enters; in particular, it can also stop on any point of the network, either a vertex or a

point inside any edge. It will pay a cost which is the same for every agent and it is formed by a running cost and a terminal cost. The running cost is formed by two parts: a kinetic one (penalizing its high velocities) and a part depending on the chosen trajectory and on the evolution of the distribution of all agents; also the terminal cost depends on the distribution of all agents at final time. Moreover the costs (running and terminal) can change from edge to edge and other costs can appear for the times when the trajectories stay in the vertices. All the costs depend on the distribution of agents in a nonlocal regularizing manner. The position of a single agent cannot affect the distribution of the whole population; in other words, if an agent knows the evolution of the distribution of the whole population, then it has only to choose its trajectory so to minimize its cost.

Clearly these problems are encompassed in the framework of deterministic state constrained Mean Field Games. On one hand, even the study of deterministic control problems on networks or other irregular sets is rather recent (see: Achdou et al. (2013), Barles et al. (2014), Imbert et al. (2013), Imbert and Monneau (2017), Lions and Souganidis (2016) and Morfe (2020)) and this topic still displays a lot of interesting open problems. On the other hand, it is worth to recall that an important issue for these Mean Field Games is that the agents could concentrate on the boundary of the constraint (namely, in the vertices of our network). Indeed we provide an example where the distribution of agents develops singular measures immediately after the initial time. This issue makes difficult to characterize the state distribution by means of a partial differential equation. In order to overcome this difficulty, we shall follow the approach introduced by Cannarsa and Capuani (2018) for deterministic Mean Field Games constrained in the closure of a regular bounded open set. This approach is based on the Lagrangian setting rather than in terms of a system of differential equations.

As in the Lagrangian approach (see also Benamou and Brenier (2000), Benamou and Carlier (2015) and Cardaliaguet et al. (2016)), we shall describe the evolution of the game in terms of a probability measures on the set of admissible trajectories on the network instead of a probability measure on the network. Roughly speaking, to each probability measure on the set of admissible trajectories, we associate a time-dependent family of probabilities on the network which, in turns, permits to define a running cost and a terminal cost. A *Mean Field equilibrium* is a probability on the set of admissible trajectories whose support is contained in the set of optimal trajectories for the cost associated to that probability.

Our main result is the existence of such a Mean Field equilibrium. The proof is based on the application of Kakutani fixed point theorem. To this end, we shall need some properties of optimal control problems on networks with finite horizon: existence of optimal trajectories and an approximation result for trajectories on the network.

With such an equilibrium at hand, the costs for the agents are well defined and, consequently a value function can be introduced. We also prove that this value function is a generalized solution to the associated first order Hamilton-Jacobi problem on the network.

Abstract: We study some models of evolutive deterministic mean field games with finite time horizon where the Hamiltonian is not coercive in the gradient term because the dynamic of the generic player has some forbidden directions. We study the existence of weak solutions and their representation by means of relaxed equilibria in the Lagrangian setting which are described by a probability measure on optimal trajectories.

Keywords: Mean Field Games, first order Hamilton-Jacobi equations, continuity equation, Fokker-Planck equation, noncoercive Hamiltonian.

1. INTRODUCTION

We study evolutive first order mean field games (MFG) systems where the Hamiltonian is neither strictly convex nor coercive. They are described by a system of PDEs coupling a continuity equation for the density of the distribution of the states (forward in time) and a Hamilton-Jacobi equation for the optimal value of a representative agent (backward in time).
We consider systems in $R^n \times (0,T)$ of the form

$$\begin{cases} (i) \quad -\partial_t u + \dfrac{|D_{\mathcal{H}} u|^2}{2} = F[m(t)](x) \\ (ii) \quad \partial_t m - div_{\mathcal{H}}(m D_{\mathcal{H}} u) = 0 \\ (iii) \quad m(x,0) = m_0(x), u(x,T) = G[m(T)](x), \end{cases} \tag{1}$$

where $D_{\mathcal{H}}$ and $div_{\mathcal{H}}$ are respectively the so called *horizontal gradient* and the *horizontal divergence*, i.e. the gradient and the divergence along n_0 prescribed vector fields, with $n_0 \leq n$. More precisely, we consider n_0 vector fields $X_i(x)$, $i = 1, \cdots, n_0$ in R^n and we call $B(x)$ the $n \times n_0$ matrix whose columns are X_i. Using the matrix B we can write:

$$D_{\mathcal{H}} u = DuB, \; div_{\mathcal{H}}(m D_{\mathcal{H}} u) = div(mDuBB^T).$$

These MFG systems arise when the generic player can move in the whole space but it must follow *horizontal curves* with respect to the vector fields X_i :

$$x'(s) = B(x(s))\alpha(s), \quad x(t) = x \tag{2}$$

where $\alpha \in R^{n_0}$. Each agent wants to choose the control α in $L^2([t,T]; R^{n_0})$ in order to minimize the cost

$$J^m_{x,t}(\alpha) := \int_t^T \left[\frac{1}{2}|\alpha(\tau)|^2 + F[m(\tau)](x(\tau))\right] d\tau + G[m(T)](x(T)) \tag{3}$$

where $m(\cdot)$ is the evolution of the whole population's distribution while $(x(\cdot), \alpha(\cdot))$ is a trajectory obeying to (2).

We suppose that the coefficients of the matrix B have at most a linear growth with respect to the space variable x.

Let us observe three important issues of these MFG systems: (i) the Hamiltonian $H(x,p) = \frac{1}{2}|p\,B(x)|^2$ is not coercive in p, (ii) the system is in the whole space, (iii) in equation (1)-(ii) the coefficient of the first order term may have quadratic growth in x.
Point (i) prevents the application of standard approaches for first order MFG (for instance, see (BFY; C)) because they require uniform coercivity of the Hamiltonian.

On the other hand, points (ii) and (iii) give rise to some difficulties for applying the vanishing viscosity method, especially for the Cauchy problem for equation (1)-(ii) with the viscosity term. Actually in this problem the coefficients grow "too much at infinity" and one cannot invoke nor standard results for the well-posedness of the problem neither its interpretation in terms of a stochastic optimal control problem.

We get two results: the former one is to prove the existence of a weak solution to system (1) while the latter, and main, one is to prove that this weak solution is also a *mild* solution in the sense introduced by Cannarsa and Capuani (CC) for the case of state-constrained MFG where the agents control their velocity. Roughly speaking, as in

⋆ The first and the second authors were partially supported by GNAMPA-INdAM by the research project of the University of Padova "Mean-Field Games and Nonlinear PDEs", by the Fondazione CaRiPaRo Project "Nonlinear Partial Differential Equations: Asymptotic Problems and Mean-Field Games" and by KAUST project OSR-2017-CRG6-3452.01. The third author has been partially funded by the ANR project ANR-16-CE40-0015-01.

the Lagrangian approach for MFG, this property means that, for a.e. starting state, the agents follow optimal trajectories for the optimal control problem associated to the Hamilton-Jacobi equation.

In order to obtain the existence of a weak solution, we establish several properties of the solution to the Hamilton-Jacobi equation (1)-(i) (as semiconcavity, Lipschitz continuity, regularity of the optimal trajectories for the associated optimal control problem). Afterwards, we adapt the techniques introduced by PL. Lions in his lectures at Collège de France, see (C), and also (AMMT; AMMT2; MMMT) for similar approaches for some noncoercive Hamiltonians). To get the result we perform three approximations: a completion B^ε of B, a vanishing viscosity procedure with the *Euclidean* Laplacian and a truncation argument of the coefficients of matrix B. The completion B^ε fulfills $\det B^\varepsilon (B^\varepsilon)^T \neq 0$ for any $x \in R^n$ which is a crucial property for getting uniqueness of optimal trajectory for m_0-a.e. starting point. The vanishing viscosity procedure permits to exploit the regularity results of the Laplacian while the truncation argument permits to avoid parabolic Cauchy problems with coefficients growing "too much" at infinity.
Finally, we shall prove that this weak solution is also a *mild* solution in the sense introduced in (CC). In order to prove that our solution is in fact a mild solution, we shall use the superposition principle obtained in (AGS).

It is worth noting that our techniques relies on some compactness of initial distribution of players and on sublinear growth of the coefficients of B.

Uniqueness holds under classical hypothesis on the monotonicity of F and G as in (C).

Some examples Our result can be applied to the following examples:

– Completely degenerate case. In the state space R^n:

$$B(x) = \begin{pmatrix} I_{n_0} & 0_{n_0,(n-n_0)} \\ 0_{(n-n_0),n_0} & 0_{(n-n_0),(n-n_0)} \end{pmatrix}$$

where I_i is the identity matrix $i \times i$ while $0_{i,j}$ is the null matrix $i \times j$, $i, j = n_0, n-n_0$. With this matrix, the generic player in the MFG controls only its first n_0 coordinates.
For example for $n = 2$ and $n_0 = 1$ the dynamics and the Hamiltonian assume the following form

$$x_1' = \alpha_1,\ x_2' = 0.$$
$$H(x,p) = \frac{1}{2}p_1^2 = \frac{|pB(x)|^2}{2}.$$

– Grushin case. In the state space R^2:

$$B(x) = \begin{pmatrix} 1 & 0 \\ 0 & x_1 \end{pmatrix}.$$

In this case the dynamics and the Hamiltonian assume the following form

$$x_1' = \alpha_1,\ x_2' = x_1\alpha_2.$$
$$H(x,p) = \frac{1}{2}(p_1^2 + (x_1p_2)^2) = \frac{|pB(x)|^2}{2}.$$

– Heisenberg case. In the state space R^3:

$$B(x) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ -x_2 & x_1 \end{pmatrix}.$$

In this case the dynamics and the Hamiltonian assume the following form

$$x_1' = \alpha_1,\ x_2' = \alpha_2,\ x_3' = -x_2\alpha_1 + x_1\alpha_2.$$
$$H(x,p) = \frac{1}{2}((p_1 - x_2p_3)^2 + (p_2 + x_1p_3)^2) = \frac{|pB(x)|^2}{2}.$$

Abstract: In his 1932 paper, Carleman proposes a linearization method to transform a given finite-dimensional nonlinear system defined by an analytic function into an equivalent infinite-dimensional linear system with (usually) unbounded operators. Finite truncation of the transformed system has been used to study dynamical properties, learning, and control of such nonlinear systems. One of the fundamental problems in this context is to quantify the effectiveness of such finitely truncated models. In this paper, we provide explicit error bounds and prove that the trajectory of the truncated system stays close to that of the original nonlinear system over a quantifiable time interval. This is particularly important in several applications, including Model Predictive Control, to choose proper truncation lengths for a given sampling period and employ the resulting truncated system as a good approximation of the nonlinear system.

Keywords: Application of nonlinear analysis and design, Model reduction, Lifting Operators, Carleman Linearization, Nonlinear System

1. INTRODUCTION

Almost all natural, physical, and engineered systems are time-varying and nonlinear, and often they need to be modeled using partial differential equations. The nonlinear nature of models has imposed fundamental challenges for the analysis and design of real-world systems. Some traditional design methods rely on a linear system obtained from the first-order approximation of the nonlinear system's right-hand side. To study the properties of a nonlinear system, researchers have developed several frameworks over the past century Koopman (1931); Carleman (1932); Isidori (2013); Arnold et al. (1988); Wiggins et al. (1990); Khalil (2002). One of the mainstream approaches, which has attracted researchers' attention for decades, represents a finite-dimensional nonlinear system as an infinite-dimensional linear system using lifting operators. Carleman linearization Carleman (1932) and Koopman operator Koopman (1931) are two of the most prominent examples closely connected in spirit. Carleman linearization is a procedure, also referred to as lifting, that transforms a finite-dimensional nonlinear system into an infinite-dimensional linear system Kowalski and Steeb (1991); Carleman (1932). Several follow-up works have tried to address various aspects of this method Bellman and Richardson (1963); Brockett (2014); Steeb and Wilhelm (1980); Bertsekas (2011). Albeit the lifting procedure results in a linear system, one usually has to deal with systems with unbounded operators and their associated convergence issues.

Although Carleman linearization appears to be very appealing for analyzing and controlling nonlinear systems, one should take extra care when working with unbounded infinite-dimensional matrices. Unless there are some useful structures, handling systems with unbounded infinite-dimensional matrices is exceptionally challenging. A common remedy is to truncate the infinite-dimensional system and then utilize the truncated system for analysis and control purposes. Several stories reported about the successful employment of Carleman linearization in the control systems community. The author of Banks (1992) identifies relationships between Carleman linearization and Lie series and then utilizes it to design optimal control laws for infinite-dimensional systems. In Svoronos et al. (1994), a straightforward method for discretizing nonlinear continuous-time systems via Carleman approximation is provided. By exploiting the lifted system's structure, the authors of Amini et al. (2020a,b) propose an efficient method to quadratize and solve the Hamilton-Jacobi-Bellman (HJB) through an exact iterative method.

Despite numerous Carleman linearization applications in nonlinear control systems, the convergence of finite truncation of the lifting system was not addressed for general nonlinear systems. Reference Forets and Pouly (2017) finds some approximation bounds for the class of polynomial systems, i.e. systems whose right-hand sides are finite order polynomials. To the best of our knowledge, our

work is the first to quantify error bounds for the general class of time-varying nonlinear systems whose right-hand sides are analytic. We prove that the first block of the truncated system (which provides an estimate of the actual state) converges exponentially fast to the original system's solution when the order of truncation increases. In this extended abstract we only included our main result and removed the proofs due to the page limitation.

2. BACKGROUND: CARLEMAN LINEARIZATION

We consider the class of nonlinear systems whose dynamics are governed by

$$\dot{\mathbf{x}} = \mathbf{f}(t, \mathbf{x}) \tag{2.1}$$

for all $t \geq t_0$ with a nonzero initial condition $\mathbf{x}(t_0) = \mathbf{x}_0$, at a neighborhood of its equilibrium at the origin, where the state of the system is denoted by $\mathbf{x} = [x_1, \ldots, x_d]^T \in \mathbb{R}^d$ and the components of function

$$\mathbf{f}(t, \mathbf{x}) = \big[f_1(t, \mathbf{x}), \ldots, f_d(t, \mathbf{x})\big]^T,\ t \geq t_0$$

are analytic on a neighborhood of the equilibrium. Without loss of generality, it is assumed that $\mathbf{f}(t, \mathbf{0}) = \mathbf{0}$. For a given multi-index vector $\boldsymbol{\alpha} = [\alpha_1, \ldots, \alpha_d]^T \in \mathbb{Z}_+^d$, let us define $\mathbf{x}_{\boldsymbol{\alpha}} = x_1^{\alpha_1} \cdots x_d^{\alpha_d}$ and express the Maclaurin series expansion of the vector-valued function $\mathbf{f}(t, \mathbf{x})$ by

$$\mathbf{f}(t, \mathbf{x}) = \sum_{\boldsymbol{\alpha} \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}} \mathbf{f}_{\boldsymbol{\alpha}}(t) \mathbf{x}_{\boldsymbol{\alpha}} \tag{2.2}$$

in which $\mathbf{f}_{\boldsymbol{\alpha}}(t) = [f_{1,\boldsymbol{\alpha}}(t), \ldots, f_{d,\boldsymbol{\alpha}}(t)]^T$. The conventional Carlemen linearization of the nonlinear dynamic system (2.1) starts from the reformulation

$$\dot{x}_j = \sum_{\alpha \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}} f_{j,\alpha}(t)\, \mathbf{x}_{\boldsymbol{\alpha}} \tag{2.3}$$

for every $j = 1, \ldots, d$. The standard Euclidean basis for $\mathbb{R}^d$ is denoted by $\mathbf{e}_j = [0, \cdots, 0, 1, 0, \cdots, 0]^T$ for $j = 1, \ldots, d$ and it is assumed that

$$f_{j,\boldsymbol{\alpha}} = 0 \ \text{ if } \ \boldsymbol{\alpha} \notin \mathbb{Z}_+^d \setminus \{\mathbf{0}\}. \tag{2.4}$$

From (2.3), the derivative of monomial $\mathbf{x}_{\boldsymbol{\alpha}}$ for every $\boldsymbol{\alpha} = [\alpha_1, \ldots, \alpha_d] \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}$, can be calculated as

$$\begin{aligned}\dot{\mathbf{x}}_\alpha &= \sum_{j=1}^{d} \alpha_j\, \mathbf{x}_{\boldsymbol{\alpha}-\mathbf{e}_j} \dot{x}_j = \sum_{j=1}^{d} \alpha_j \mathbf{x}_{\boldsymbol{\alpha}-\mathbf{e}_j} \sum_{\boldsymbol{\gamma} \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}} f_{j,\boldsymbol{\gamma}}(t) \mathbf{x}_{\boldsymbol{\gamma}} \\ &= \sum_{\boldsymbol{\beta} \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}} \left(\sum_{j=1}^{d} \alpha_j f_{j,\boldsymbol{\beta}-\boldsymbol{\alpha}+\mathbf{e}_j}(t) \right) \mathbf{x}_{\boldsymbol{\beta}}\end{aligned}$$

with initial condition $\mathbf{x}_{\boldsymbol{\alpha}}(t_0) = \mathbf{x}_{\boldsymbol{\alpha}}^0 = x_1^{\alpha_1}(t_0) \cdots x_d^{\alpha_d}(t_0)$. Let us define $|\boldsymbol{\alpha}| = \alpha_1 + \cdots + \alpha_d$ for $\boldsymbol{\alpha} = [\alpha_1, \ldots, \alpha_d]^T \in \mathbb{Z}_+^d$ and

$$\mathbb{Z}_k^d = \Big\{ \boldsymbol{\alpha} \in \mathbb{Z}_+^d \ \Big|\ |\boldsymbol{\alpha}| = k \Big\}$$

for $k \geq 0$. Regrouping all $\boldsymbol{\alpha} \in \mathbb{Z}_k^d$ for every $k \geq 1$ and defining $\mathbf{z}_k = \big[\mathbf{x}_{\boldsymbol{\alpha}}\big]_{\boldsymbol{\alpha} \in \mathbb{Z}_k^d}$ yields the following infinite-dimensional linear dynamical system

$$\dot{\mathbf{z}}_k = \sum_{l=k}^{\infty} \mathbf{A}_{k,l}(t)\, \mathbf{z}_l \tag{2.5}$$

for all $t \geq t_0$ and $k \geq 1$ with initial condition $\mathbf{z}_k(t_0) = \big[\mathbf{x}_{\boldsymbol{\alpha}}^0\big]_{\boldsymbol{\alpha} \in \mathbb{Z}_k^d}$, where

$$\mathbf{A}_{k,l}(t) = \left[\sum_{j=1}^{d} \alpha_j f_{j,\boldsymbol{\beta}-\boldsymbol{\alpha}+\mathbf{e}_j}(t) \right]_{\boldsymbol{\alpha} \in \mathbb{Z}_k^d,\ \boldsymbol{\beta} \in \mathbb{Z}_l^d} \tag{2.6}$$

for all $k, l \geq 1$ are matrices of size $\binom{k+d-1}{d-1} \times \binom{l+d-1}{d-1}$. By defining the infinite-dimensional state vector $\mathbf{z} = \big[\mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_N, \ldots\big]^T$, the set of linear systems (2.5) can be rewritten in compact form

$$\dot{\mathbf{z}} = \mathbf{A}(t)\mathbf{z} \tag{2.7}$$

for $t \geq t_0$ with initial condition $\mathbf{z}(t_0) = \big[\mathbf{x}_{\boldsymbol{\alpha}}^0\big]_{\boldsymbol{\alpha} \in \mathbb{Z}_+^d \setminus \{\mathbf{0}\}}$, where

$$\mathbf{A}(t) = \begin{bmatrix} \mathbf{A}_{1,1}(t) & \mathbf{A}_{1,2}(t) & \cdots & \mathbf{A}_{1,N}(t) & \cdots \\ \mathbf{0} & \mathbf{A}_{2,2}(t) & \cdots & \mathbf{A}_{2,N}(t) & \cdots \\ \vdots & & \ddots & \vdots & \ddots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{A}_{N,N}(t) & \cdots \\ \mathbf{0} & \vdots & & & \ddots \end{bmatrix} \tag{2.8}$$

is a block upper-triangular matrix. The resulting linear system (2.7) is referred to as the Carleman linearization of the nonlinear dynamical system (2.1).

While the original d-dimensional dynamical systems (2.1) is nonlinear, its lifted form (2.5) is an infinite-dimensional linear system whose state matrix $\mathbf{A}$ is an upper-triangular block matrix with special structure and initial condition is of exponential type. On the other hand, the apparent disadvantage of the Carleman linearization is that the resulting state matrix $\mathbf{A}$ is not a bounded operator on $\ell^2(\mathbb{Z}_+^d \setminus \{\mathbf{0}\})$, the Hilbert space of all square-summable sequences on $\mathbb{Z}_+^d \setminus \{\mathbf{0}\}$. Moreover, the initial condition has exponential decay when $\|\mathbf{x}_0\| < 1$ and exponential growth when $\|\mathbf{x}_0\| > 1$, which prevents the direct application of existing theories to analyze the infinite-dimensional linear system on Hilbert spaces $\ell^2(\mathbb{Z}_+^d \setminus \{\mathbf{0}\})$.

A natural question about the original nonlinear system (2.1) and its Carleman linearization (2.5) is how effective the finite section (truncation) of the linearized counterpart is and whether the first component of the solution of the truncated system converges to the solution of the original nonlinear system. Our main contribution shows that if the convergence radius of function $\mathbf{f}(t, \mathbf{x})$ is finite, then the finite section of the Carlemen linearization converges exponentially only when the initial condition is close enough to the equilibrium.

3. CONVERGENCE OF FINITE-SECTIONING OF THE CARLEMAN LINEARIZATION

Denote the bounded norm for $\mathbf{x} = (x_1, \ldots, x_d)^T \in \mathbb{R}^d$ by $\|\mathbf{x}\|_\infty = \max_{1 \leq j \leq d} |x_j|$. In this section, we show that the first component of the solution of the finite section approach to the the Carlemen linearization (2.5) converges to the solution of the nonlinear dynamic system (2.1) exponentially when the initial is not too far away from the equilibrium.

The finite section approach to the Carlemen linearization (2.5) can be solved as a linear dynamic system

$$\begin{bmatrix} \dot{\mathbf{y}}_{1,N}(t) \\ \dot{\mathbf{y}}_{2,N}(t) \\ \vdots \\ \dot{\mathbf{y}}_{N,N}(t) \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{1,1}(t) & \mathbf{A}_{1,2}(t) & \cdots & \mathbf{A}_{1,N}(t) \\ & \mathbf{A}_{2,2}(t) & \cdots & \mathbf{A}_{2,N}(t) \\ & & \ddots & \vdots \\ & & & \mathbf{A}_{N,N}(t) \end{bmatrix} \begin{bmatrix} \mathbf{y}_{1,N}(t) \\ \mathbf{y}_{2,N}(t) \\ \vdots \\ \mathbf{y}_{N,N}(t) \end{bmatrix} \tag{3.9}$$

of dimension $d\binom{N+d}{d} - d$ with initial $\mathbf{y}_{k,N}(t_0) = \left[\mathbf{x}_0^{\boldsymbol{\alpha}}\right]_{\boldsymbol{\alpha}\in\mathbb{Z}_k^d}$ for $1 \le k \le N$.

Assumption 1. The function $\mathbf{f}(t,\mathbf{x})$ in (2.1) is a time-varying analytic function near the origin such that $\mathbf{f}(t,\mathbf{0}) = \mathbf{0}$ for all $t \ge t_0$ and coefficients $\mathbf{f}_{\boldsymbol{\alpha}}(t)$ in its Marclaurin expansion (2.2) satisfy uniform exponential decay property

$$\sup_{t\ge t_0} \sum_{j=1}^{d} \sum_{\boldsymbol{\alpha}\in\mathbb{Z}_k^d} |f_{j,\boldsymbol{\alpha}}(t)| \le D_0 R^{-k} \tag{3.10}$$

for all $k \ge 1$ and some positive constants D_0 and R.

Theorem 2. Suppose that Assumption 1 holds and $\mathbf{x}(t)$ for $t \ge t_0$ is a continuous solution of the nonlinear system (2.1) with initial condition $\mathbf{x}(t_0) = \mathbf{x}_0$ that satisfies

$$0 < \|\mathbf{x}_0\|_\infty < \frac{R}{e}. \tag{3.11}$$

Then, the first component of the solution of the finite section of the Carleman linearization (3.9), i.e., $\mathbf{y}_{1,N}(t)$, converges to $\mathbf{x}(t)$ exponentially as the truncation length N increases for all $t_0 \le t < t_0 + T^*$, i.e., for every $t_0 < t_1 < t_0 + T^*$ there exist a positive constant C such that

$$\sup_{t_0\le t\le t_1} \|\mathbf{y}_{1,N}(t) - \mathbf{x}(t)\|_\infty \le C e^{D_0(t_1-t_0-T^*)N/R} \tag{3.12}$$

for all $N \ge 1$, where

$$T^* = \frac{(e-1)R}{(2e-1)D_0} \ln\left(\frac{R}{e\|\mathbf{x}_0\|_\infty}\right). \tag{3.13}$$

The convergence of the finite section scheme has been studied before by Forets and Pouly (2017), when the right-hand side of the nonlinear system (2.1) is a time-varying polynomial

$$\mathbf{p}_L(t,\mathbf{x}) = \sum_{1\le|\boldsymbol{\alpha}|\le L} \mathbf{p}_{\boldsymbol{\alpha}}(t)\mathbf{x}^{\boldsymbol{\alpha}} \tag{3.14}$$

with degree $L \ge 1$, where $\mathbf{p}_{\boldsymbol{\alpha}}(t) = \left[p_{1,\boldsymbol{\alpha}}(t), \ldots, p_{d,\boldsymbol{\alpha}}(t)\right]^T$. If $L = 1$, it can be verified that the corresponding state matrix $\mathbf{A}(t)$ in the Carlemen linearization (2.8) will be a block diagonal matrix. Hence, the first component $\mathbf{y}_{1,N}(t)$ of the solution of the finite section scheme (3.9) will be equal to the continuous solution $\mathbf{x}(t)$ for all $t \ge t_0$ of the original nonlinear dynamic system (2.1). Now, consider the case that the degree of the polynomial $\mathbf{P}_L$ is at least two, i.e., $L \ge 2$. Define

$$D_0(\mathbf{p}_L, R) = \sup_{1\le k\le L} R^k \sup_{t\ge t_0} \sum_{j=1}^{d} \sum_{\boldsymbol{\alpha}\in\mathbb{Z}_k^d} |p_{j,\boldsymbol{\alpha}}(t)| \tag{3.15}$$

For every $R > 0$, the uniform exponential decay property (3.10) holds for the time-varying polynomial $\mathbf{p}_L(t,\mathbf{x})$ with D_0 replaced by $D_0(\mathbf{p}_L, R)$ and the requirement (3.11) is satisfied for all nonzero initial $\mathbf{x}_0$ when R is chosen appropriately.

Corollary 3. If the right-hand side of system (2.1) is a time-varying polynomial $\mathbf{p}_L(t,\mathbf{x})$ with $L \ge 2$ given by (3.14), then the first component $\mathbf{y}_{1,N}(t)$ of the solution of the truncated system (3.9) will converge to the continuous solution $\mathbf{x}(t)$ of the original nonlinear dynamical system (2.1) for all $t_0 < t < t_0 + T^*(\mathbf{p}_L, e\|\mathbf{x}_0\|_\infty)$, where

$$T^*(\mathbf{p}_L, e\|\mathbf{x}_0\|_\infty) = \sup_{R>s} \frac{(e-1)R}{(2e-1)D_0(\mathbf{p}_L, R)} \ln\left(\frac{R}{e\|\mathbf{x}_0\|_\infty}\right). \tag{3.16}$$

for some $s > 0$.

Let us define quantity

$$a_k := \sup_{t\ge t_0} \sum_{j=1}^{d} \sum_{\boldsymbol{\alpha}\in\mathbb{Z}_k^d} |p_{j,\boldsymbol{\alpha}}(t)|,$$

for all $1 \le k \le L$. One may verify that $D_0(\mathbf{p}_L, R) = a_L R^L$ hold for all $R \ge \max_{1\le k\le L-1}(a_k/a_L)^{1/(L-k)}$. Therefore, when the initial condition satisfies

$$\|\mathbf{x}_0\|_\infty \ge e^{-1} \max_{1\le k\le L-1} \left(\frac{a_k}{a_L}\right)^{1/(L-k)},$$

the maximal achievable time range in (3.16) is

$$T^*(\mathbf{p}_L, e\|\mathbf{x}_0\|_\infty) = \frac{(e-1)(L-1)}{(2e-1)e^{L^2-L} \sup_{t\ge t_0} \sum_{j=1}^{d} \sum_{\boldsymbol{\alpha}\in\mathbb{Z}_L^d} |p_{j,\boldsymbol{\alpha}}(t)|} \|\mathbf{x}_0\|_\infty^{1-L}. \tag{3.17}$$

4. CONCLUSION

For a given time-varying nonlinear system, We proved that under some mild assumptions, the Carelman truncation of the lifted system converges exponentially fast to the original nonlinear system's solution. Explicit error bounds are characterized under the boundedness of the trajectories and initial conditions. Our theoretical results have the potentials to pave the way to prove stability and convergence of Carleman-based methods for optimal control design, e.g., model predictive control of nonlinear systems using the finite truncated system.

Abstract: The relationship between nonnegative polynomials and sums of squares on semi-algebraic set S is one of the central questions in real algebraic geometry. The (convex) dual side of this story is important in analysis, where it is known as the truncated S-moment problem, and it considers the truncated cones of moments which are dual to nonnegative polynomials, and "pseudo-moments" which are dual to sums of squares. We bring a new tool for understanding of these classical problems: tropicalization. While extensively studied in complex algebraic geometry, tropicalization is rarely applied to semialgebraic sets. We provide explicit combinatorial descriptions of tropicalizations of the moment and pseudo-moment cones, and demonstrate their usefulness in distinguishing between nonnegative polynomials and sums of squares, proving results limiting the power of sums of squares approximations of nonnegative polynomials. We believe that this just scratches the surface of applications of tropicalization in semi-algebraic geometry.

Keywords: Moments, pseudomonents, nonnegative polynomials, sums of squares, inequalities, tropicalization.

1. INTRODUCTION

Understanding nonnegativity of polynomials in terms of sums of squares has been a central challenge in real algebraic geometry dating back to the work of Hilbert. The dual side of this problem is important in analysis and known as the moment problem. We now take a moment to introduce it.

For a semialgebraic set $S \subseteq \mathbb{R}^n$ and a finite subset $A \subset \mathbb{N}^n$, we consider the convex cone $M_A(S)$ of A-moments of measures supported on S. Despite extensive work this cone can be explicitly described in very few situations even when $S = \mathbb{R}^n$ and A corresponds on to all moments of degree at most $2d$ Curto and Fialkow (1996, 1991); di Dio and Schmüdgen (2018); Schmüdgen (2017). An important tool for understanding $M_A(S)$ comes from *Positivstellensätze* in real algebraic geometry: theorems on representing the dual cone of polynomials with support in A which are nonnegative on S via sums of squares Schmüdgen (1991); Putinar (1993). We denote the cone of linear functionals dual to the cone of "obviously nonnegative" polynomials generated by sums of squares by $\Sigma(S)_A^\vee$ and call such functionals "pseudo-moments". Tropicalization of the cones of moments and pseudo-moments gives us "combinatorial shadows" of these sets. Our explicit descriptions of these shadows lead to interesting combinatorial questions, some of which have been considered in the context of SONC polynomials Reznick (1989); Iliman and de Wolff (2016); Katthän et al. (2021).

Another way of understanding our results is through binomial inequalities in moments and pseudo-moments of measures supported on S. When the semialgebraic set S is closed under Hadamard multiplication, the tropicalization $\operatorname{trop} M_A(S)$ of the moment cone is a rational polyhedral cone. Its dual cone $(\operatorname{trop} M_A(S))^\vee$ encodes all of the binomial inequalities in A-moments. Similarly, binomial moment inequalities that can proved via sums of squares correspond to another rational polyhedral cone, which may depend on a degree bound for the sums of squares construction. While polynomial inequalities valid on $M_A(S)$ are difficult to characterize, we explicitly describe all binomial inequalities in moments and pseudo-moments by finding the extreme rays of the corresponding rational polyhedral cones. The use of tropicalizations to analyze the power of sums of squares method was first introduced in Blekherman et al. (2020) for analyzing graph density inequalities, and further developed in Blekherman and Raymond (2021). We take inspiration from some of their results and techniques, for instance the use of the

Hadamard property to ensure that the tropicalization is a convex cone. However, to the best of our knowledge, this is the first instance where tropicalization is used to study the relationship between the moment and pseudo-moment cones.

We start with a pair of examples which illustrate our setup and results

Example 1.1. (Motzkin Configuration on Orthant). Let $S = \mathbb{R}^2_{\geq 0}$ be the nonnegative orthant and let A be the *Motzkin configuration*: $A = \{(0,0),(1,2),(2,1),(1,1)\}$, which gives us the exponents of moments we are recording:

$$m_{00} = \int_S 1\, d\mu,\ m_{12} = \int_S xy^2\, d\mu,$$
$$m_{21} = \int_S x^2 y\, d\mu,\ m_{11} = \int_S xy\, d\mu.$$

There is only one binomial inequality satisfied by A-moments of measures supported on S:

$$m_{00}m_{12}m_{21} \geq m_{11}^3. \tag{1}$$

If we regard moments as functions on A, then we see that moments are nonnegative *log-convex functions* on A, and in fact inequalities coming from log-convexity are the only possibly binomial inequalities in A-moments for measures supported on the nonnegative orthant $\mathbb{R}^n_{\geq 0}$ (see thm:genmom).

We now consider A-pseudo-moments of measures supported on $\mathbb{R}^n_{\geq 0}$. Pseudo-moments are defined as linear functionals that are nonnegative on "obviously" nonnegative polynomials coming from sums of squares (see sec:SOS). We show in tropicalizationpseudononneg that A-pseudo-moments of measures supported on $\mathbb{R}^n_{\geq 0}$ satisfy *log-midpoint-convexity inequalities*:

$$m_\alpha m_\beta \geq m^2_{\left(\frac{\alpha+\beta}{2}\right)}, \tag{2}$$

with $\alpha, \beta, \frac{\alpha+\beta}{2} \in A$. Moreover these inequalities generate all possible binomial inequalities valid on A-pseudomoments. Since the Motzkin configuration contains no midpoints, we see that there are no binomial inequalities valid on A-pseudomoments. ◇

Remark 1.2. The combinatorial notions of convex and midpoint-convex functions on A are quite similar to what has been developed for analyzing certain sparse globally nonnegative polynomials and sums of squares arising from the arithmetic mean-geometric mean inequality. Such polynomials were originally called AGI-forms by Reznick in Reznick (1989) and were later called Sum of Nonnegative Circuit Polynomials (SONC) in Iliman and de Wolff (2016). The only difference is that for analyzing global nonnegativity, it makes a difference whether points in A have all even coordinates or not, and for instance midpoints convexity has to hold only between even points in A. As we will see in thm:whole and tropicalizingpseudomoments this is precisely what happens for us as well when analyzing measures supported on all of $\mathbb{R}^n$. ◇

Example 1.3. (Motzkin Configuration on Square.). Let $S = [0,1]^2 \subset \mathbb{R}^2$ be the unit square given by inequalities $0 \leq x \leq 1$, $0 \leq y \leq 1$. Let $A \subset \mathbb{N}^2$ again be the Motzkin configuration. In addition to the log-convexity inequality (1) the following binomial moment inequalities are naturally valid on the unit square, since all variables lie between 0 and 1:

$$m_{11} \geq m_{12},\ m_{11} \geq m_{21}\ m_{00} \geq m_{11}.$$

Any binomial inequality in A-moments of measures supported on S can be obtained from the above inequalities and (1) via exponentiation and multiplication (See Example 1.3).

As we increase the degree d, sums of squares provide increasingly better approximations to polynomials supported on A that are nonnegative on S, and thus can, in principle, be used to provide increasingly sharper binomial inequalities for pseudo-moments. If we regard pseudo-moments as functions on A then increasing the degree allows us to use moments that lie outside of A. For instance we can show that $m_{00}m_{12} \geq 2m_{11}$ by combining the inequality $m_{12} \geq m_{22}$ with the log-midpoint-convexity inequality (2): $m_{00}m_{22} \geq m_{11}^2$.

We show that the binomial A-pseudo-moment inequalities *stabilize*, and only the following binomial inequalities can be learned via sums of squares (regardless of the degree d):

$$m_{11} \geq m_{12},\ \ m_{11} \geq m_{21},\ \ m_{00}m_{12} \geq m_{11}^2,$$
$$\text{and}\ \ m_{00}m_{21} \geq m_{11}^2.$$

Therefore for any degree d sums of squares cannot prove the moment inequality $m_{00}m_{12}m_{21} \geq m_{11}^3$, and moreover, sums of squares remain *quantifiably far away* from certifying this inequality. ◇

Remark 1.4. Since the unit square is compact, it follows that from Schmüdgen's Positivstellensatz Schmüdgen (1991) that any polynomial f strictly positive on the unit square has a sum of squares certificate. Therefore, as degree increases sums of squares provide an increasingly better approximation to all nonnegative polynomials supported on A. However, as we have seen, tropicalizations stabilize, and higher degree sums of squares do not have larger tropicalizations. This is due to the fact that $\mathrm{trop}(S)$ only depends on the neighborhood of zero and the "neighborhood of infinity" contained in S. We give a simple example of this phenomenon below: Let S be the planar triangle with vertices $(0,0)$, $(1,0)$ and $(1,1)$ and let S_ε be the quadrilateral with vertices $(0,0)$, $(1,0)$, $(1,1)$ and $(0,\varepsilon)$. The we have $S_\varepsilon \to S$ as $\varepsilon \to 0$, however $\mathrm{trop}(S_\varepsilon)$ is the entire plane for all $\varepsilon > 0$. ◇

Remark 1.5. The unit square is special in that all nonnegative polynomials have a sum of squares certificate. Example 1.3 also shows that even though every nonnegative polynomial is a sum of squares, there does not exist a degree bound for the certificate even for just the A-supported polynomials (Marshall, 2008, 9.4.6 Example (1)). ◇

1.1 Main Results in Detail:

We say that a subset S of $\mathbb{R}^n_{\geq 0}$ has the Hadamard property if S is closed under coordinatewise (Hadamard multiplication). Our main results are about the tropicalizations

of moment cones and pseudo-moment cones for semialgebraic sets with the Hadamard property. Concretely, we focus on nonnegative orthants, hypercubes, and toric cubes to discuss our general results. Throughout, we fix a finite set $A \subset \mathbb{Z}^n_{\geq 0}$ of exponents and consider the A-moments, that is to say $\int_S x^a$ for $a \in A$ (also known as truncated moment sequences).

We think of elements of the tropicalization of the moment cone (resp. pseudo-moment cone) as functions $h\colon A \to \mathbb{R}$ and describe the tropicalization mainly in terms of discrete convexity properties of these functions. For the moment cone, we have a general description of the tropicalization of $M_A(S)$ for any subset of the nonnegative orthant with the Hadamard property:

Theorem 1.6. Let $S \subset \mathbb{R}^n_{\geq 0}$ be a semialgebraic set with the Hadamard property such that the intersection of S with the positive orthant is dense in S. The tropicalization of the A-moment cone $M_A(S)$ is the rational polyhedral cone of functions $h\colon A \to \mathbb{R}$ satisfying the following linear inequalities:

(1) (Convexity:) $\sum_{i=1}^r \lambda_i h(a_i) \geq h(b)$ for all $a_1, \ldots, a_r, b \in A$, $\lambda_i \geq 0$, $\sum_{i=1}^r \lambda_i = 1$;
(2) (Nonincreasing:) $h(a) \geq h(b)$ whenever $a - b \in \operatorname{trop}(S)^\vee$.

The first type of inequality is the naive form of discrete convexity that arises in this context. The second type of inequality is where the set S enters: The tropicalization of S is a rational polyhedral cone and $\operatorname{trop}(S)^\vee$ is its dual cone, which defines a partial order of $\mathbb{R}^A$ – and the second inequality says that the functions in the tropicalization are order preserving in this sense. Below, we combine these two types by writing the inequality description as $\sum \lambda_i h(a_i) \geq h(b)$ whenever $\sum \lambda_i a_i - b \in \operatorname{trop}(S)^\vee$. In case $S = \mathbb{R}^n_{\geq 0}$, we have $\operatorname{trop}(S)^\vee = \{0\}$ so that the tropicalizations of the A-moment cones do not include inequalities of type (2). For $S = [0,1]^n$, we get $\operatorname{trop}(S)^\vee = \mathbb{R}^n_{\leq 0}$ and the inequalities of type (2) say that the functions $h \in \operatorname{trop}(M_A(S))$ are non-increasing in coordinate directions.

We can also think of this result as an elegant description of all binomial inequalities valid on the moment (by exponentiation). With the analogous result for pseudo-moment cones, we will see that these inequalities suffice in distinguishing moments from pseudo-moments in many important cases. Moreover, there is a rich combinatorial interplay between geometry of the moment configuration A and geometry and algebraic description of S.

We now move on to pseudo-moment cones, which are the dual cones to truncated preorderings or quadratic modules. We describe in detail how we truncate (in a total degree version) at the beginning of sec:tsos. For pseudo-moment cones, we focus on the case that the semialgebraic set S has an inequality description in terms of pure binomial inequalities.

Theorem 1.7. Let $S \subset \mathbb{R}^n_{\geq 0}$ be a semi-algebraic set defined by pure binomial inequalities $g_i = x^{a_i} - x^{b_i}$ such that $S \subset \overline{S \cap \mathbb{R}^n_{>0}}$. Assume that the exponent vectors $a_i - b_i$ of the binomials defining S generate the semigroup $N = \operatorname{trop}(S)^\vee \cap \mathbb{Z}^n$. For all sufficiently large d the tropicalization of $\mathrm{QM}_d(g_i)^\vee$ is the rational polyhedral cone $F(S)_d$ given by the following inequalities:

(1) (Midpoint convexity:) $h(a_1) + h(a_2) \geq 2h(b)$ for all a_1, a_2, b such that $|a_i| \leq d$, $|b| \leq d$ and $a_1 + a_2 = 2b$;
(2) (Nonincreasing:) $h(a) \geq h(b)$ whenever $a - b \in \operatorname{trop}(S)^\vee$.

The inequalities in A-pseudo-moments provable by sums of squares of degree at most d are dual to the coordinate projection of $F(S)_d$ onto the coordinates of A.

In the case of pseudo-moments, we need the additional assumption on the inequality description of S that the exponent vectors of the inequalities generate the semigroup of lattice points in the convex cone $\operatorname{trop}(S)^\vee$ to give the same inequalities of type (2) as in the case of moment cones. This is an assumption that, from a purely theoretical point of view, can be made without loss of generality by adding valid and redundant inequalities, if necessary. Without this assumption, we only get some inequalities of type (2), namely those corresponding to the lattice points in $\operatorname{trop}(S)^\vee$ that also lie in the semigroup generated by the exponent vectors.

Our most intriguing observation is that tropicalizations of pseudomoment cones *stabilize* as the degree bound d grows. This means that for sufficiently large d the tropicalizations of pseudomoment cones remain the same, even though pseudomoments themselves provide a convergent approximation to the moment cone. This phenomenon was already observed in Example 1.3. We provide an explicit description of when stabilization occurs for the hypercube $[0,1]^n$ and provide examples of stabilization and a general theorem.
