Extended Abstracts

presented at the

25th International Symposium on Mathematical Theory of Networks and Systems MTNS 2022

held

12-16 September 2022

in

Bayreuth, Germany,

and

edited by

M. H. Baumann

L. Grüne

B. Jacob

K. Worthmann

MTNS 2022 featured full paper and extended abstract submissions. This part of the proceedings contains the extended abstracts. The full papers presented at MTNS 2022 are available online at https://www.sciencedirect.com/journal/ifac-papersonline/vol/55/issue/30 as Volume 55, No. 30 of IFAC PapersOnline.

The 25th International Symposium on Mathematical Theory of Networks and Systems MTNS 2022 was **co-sponsored** by:

- International Federation of Automatic Control (IFAC)

- Deutsche Forschungsgemeinschaft (DFG; German Research Foundation)

- Oberfrankenstiftung

- University of Bayreuth

Additionally, for their generous support, **thanks** go to:

- Bechtle AG
- Foundation Advancement of Mathematics

The complete lists of program committee members, organizers, etc. can be found in the IFAC PapersOnline volume of MTNS 2022 https://doi.org/10.1016/S2405-8963(22)02792-6.

Foreword

After more than two years of limited social and scientific interactions due to the Covid-19 pandemic, it was a pleasure to welcome more than 300 participants in person and about 60 online participants at MTNS 2022 in Bayreuth. Submissions to MTNS 2022 were possible as extended abstracts and full papers. The accepted full papers that were presented at the conference are published in IFAC PapersOnline https://www.sciencedirect.com/journal/ifac-papersonline/vol/55/issue/30. In this volume you find the extended abstracts that were presented at the conference. Further, you also find the titles of the plenary and semi-plenary talks as well as their abstracts resp. links to the corresponding full papers.

We hope you enjoy these abstracts and to see you in person at MTNS in the future.

The Editors
M. H. Baumann, L. Grüne, B. Jacob, and K. Worthmann

Plenary Talks

- Claudio De Persis (University of Groningen, The Netherlands)

On data-driven control

Abstract. We present a technique to design controllers from data for systems whose model is imprecisely known. The technique is based on collecting measurements of low complexity from the systems and using them for the synthesis of controllers, which is reduced to the solution of data-dependent semidefinite programs. The method provides stability certificates in the presence of perturbations on the dataset.

- Luz de Teresa (National Autonomous University of Mexico, Mexico City, Mexico)

Some results on hierarchical control for parabolic equations

Abstract. In classical control theory, we usually have a state equation or system and just one control, with the mission of achieving a predetermined goal. Sometimes, the goal is to minimize a cost function in a prescribed family of admissible controls; this is the optimal control viewpoint. A more interesting situation arises when several (in general, conflictive or contradictory) objectives are considered. This may happen, for example, if the cost function is the sum of several terms and it is not clear how to average. It can also be expectable to have more than one control acting on the equation.

In this talk, we present an overview of the known results on this subject for the heat equation. We will recall the results of Araruna and collaborators where hierarchic exact controllability results were established for linear and semilinear heat equations. In this research, and in the seminal papers by J.-L. Lions, the main idea is to work with one primary control (the leader) and one or several secondary controls (the followers). For each possible leader, the associated followers try to minimize a functional (or reach equilibrium if there is more than one cost objective function). Then, the leader is chosen such that the associated state satisfies a final time constraint. We will present the recent result with E. Fernández-Cara et al., where we accomplish optimal control and controllability tasks with a hierarchy of controls. This time, however, the controllability goal will be commended to the follower, while the choice of the leader will be subject to an optimal control problem. It will be seen that this makes the problem more difficult to handle (essentially because we must work all the time in a very restrictive class of leader controls).

- Weinan E (Peking University, China and Princeton University, NJ, USA)

Deep Learning and Optimal Control

Abstract. There is a close analogy between deep learning and optimal control. This analogy can be exploited to develop deep learning-based algorithms for optimal control, and optimal control-based algorithms for deep learning. I will discuss the progress made along these directions.

Full paper *Weinan E, Jiequn Han, Jihao Long* "Empowering Optimal Control with Machine Learning: A Perspective from Model Predictive Control" available in the IFAC PapersOnline volume of MTNS 2022 https://doi.org/10.1016/j.ifacol.2022.11.039.

- Maria Elena Valcher (University of Padova, Italy)

Opinion dynamics models: A mathematical abstraction of individuals' behaviours and interactions

Abstract. The talk will focus on the main mechanisms influencing opinion dynamics, like homophily, mutual appraisal, and bounded confidence. Some classic opinion dynamics models, as well as some recent ones, will be presented. Interesting open problems as well as promising research directions will be proposed.

- George Weiss (Tel Aviv University, Israel)

Lax-Phillips semigroups for nonlinear systems

Abstract. We briefly recall the basics about Lax-Phillips semigroups for well-posed linear systems, and the definition of well-posed nonlinear systems via nonlinear Lax Phillips semigroups. Then we concentrate on two results concerning well-posed nonlinear systems:

We investigate a special class of nonlinear systems that are obtained by modifying the second order differential equation that is part of the description of conservative linear systems "out of thin air" introduced by M. Tucsnak and G. Weiss in 2003. The differential equation contains a nonlinear damping term that is maximal monotone and possibly set-valued. We show that this new class of nonlinear systems is incrementally scattering passive (hence well-posed). Our approach uses the theory of maximal monotone operators and the Crandall-Pazy theorem about nonlinear contraction semigroups, which we apply to the Lax-Phillips semigroup of the system.

We investigate the class of incrementally scattering passive nonlinear systems, as defined in some earlier papers of ours. We show that these can be defined by a differential inclusion and a formula defining the current output in term of the current state and the current input. Our approach uses the theory of maximal monotone operators.

The talk is based on joint work with Shantanu Singh.

Semi-Plenary Talks

- Roland Herzog (University of Heidelberg, Germany)

The role of the metric in numerical linear algebra and optimization

Abstract. Many algorithms in everyday use implicitly employ the Euclidean inner product of the underlying space. While this is convenient and user-friendly on the one hand, it also turns out that the Euclidean metric may not be the one yielding the best performance of the respective algorithm. In this talk we revisit the role of the metric in a number of well-known algorithms in numerical linear algebra and optimization, and demonstrate the potential of user-defined metrics in each case.

- Anna-Lena Horlemann-Trautmann (University of St. Gallen, Switzerland)

The densities of good codes in various metric spaces

Abstract. The densities of codes with certain properties have always been of interest in classical coding theory, in particular to understand how many of such codes exist and how likely a random code will have the prescribed properties. Further applications of density results of codes appear in code-based cryptography, where it is important that the set of codes with a certain property is large enough to outgo brute force attacks. In this talk we will present various density results for optimal or close-to-optimal codes in different metric spaces with different types of linearity. In particular, we will show when optimal codes in the Hamming, rank and sum-rank metric are dense and when they are sparse.

- Boris Houska (ShanghaiTech University, China)

Global Optimal Control: Opportunities and Challenges

Abstract. Optimal control theory, algorithms, and software for analyzing and computing local solutions of linear and nonlinear optimal control problems have reached a high level of maturity, finding their way into industry. In the context of many applications, locally optimal control inputs can be computed within the milli- and microsecond range. This is in sharp contrast to the development of algorithms for locating global minimizers of non-convex optimal control problems, which is hindered by several key issues, including the overall complexity of generic optimal control problems and their curse of dimensionality. This talk reviews and discusses recent solutions that address these rather fundamental challenges including novel types of Branch & Lift methods as well as modern Koopman-Pontryagin operator based lifting methods for global optimal control. Various numerical experiments will be used to illustrate the effectiveness of these approaches. The talk concludes with an assessment of the state of the art and highlights important avenues for future research.

- Achim Ilchmann (Technische Universität Ilmenau, Germany)

Funnel control – history and perspectives

Abstract. The control objective in funnel control is output feedback control such that the norm of the error e(t) of the closed-loop system remains inside a prespecified funnel with boundary $\varphi^{-1}(t)$, i.e. $\|e(t)\| < \varphi^{-1}(t)$ for all $t > 0$. In other words, prescribed transient behaviour as well as asymptotic accuracy is achieved. Typical features of funnel control are:

Simplicity of the feedback law. The feedback does not invoke any identification scheme, but is – for example in the relative degree one case – a time-varying error feedback of the form $u(t) = -1 / (1 - \varphi(t)\,\|e(t)\|)\, e(t)$, $e(t) := y(t) - y_{ref}(t)$, where $y_{ref}(\cdot)$ denotes a sufficiently smooth bounded signal with bounded derivative.
Note that the gain $k(t) = -1 / (1 - \varphi(t)\,\|e(t)\|)$ is large if, and only if, the error is close to the funnel boundary.

Funnel control is feasible for a whole class of input-output systems, which is characterized by structural assumptions, e.g., well-defined relative degree and stable zero dynamics.

After two decades of high-gain adaptive control, funnel control was introduced in 2002. First results were on linear, single-input, single-output, time-invariant systems with relative degree one and being minimum phase. From then on feasibility of funnel control was shown for other system classes such as multi-input, multi-output, nonlinear, infinite dimensional, perturbed systems, unknown control directions – provided they have stable zero dynamics and satisfy certain assumptions on the high-frequency gain. A particular challenge was to show feasibility for systems with higher relative degree, and to design a funnel controllers for systems described by partial differential equations. Funnel control was applied to various applications such as control in chemical reactor models, industrial servo-systems, wind turbine systems, electrical circuits, to name but a few. Recently, funnel control has been investigated in combination with model predictive control and applied to magnetic levitation systems.

Discontinuous Feedbacks for Stabilization and Combined Stabilization and Safety

Abstract. It has long been known that asymptotic controllability of a nonlinear system to a desired equilibrium or target set require discontinuous controllers for feedback stabilization, which, in turn, is equivalent to the existence of a nonsmooth control Lyapunov function. More recently, results combining stabilization and safety, captured by so-called barrier functions, have been proposed. This also gives rise to the need for discontinuous feedback controllers, though for slightly different reasons. In this talk, we summarise these results and present a hybrid feedback solution to the combined stabilization and safety problem for a non-trivial class of systems.

- Dante Kalise (Imperial College London, UK)

High-dimensional approximation of Hamilton-Jacobi-Bellman PDEs in deterministic optimal

Abstract. Optimal feedback synthesis for nonlinear dynamics -a fundamental problem in optimal control- is enabled by solving fully nonlinear Hamilton-Jacobi-Bellman type PDEs arising in dynamic programming. While our theoretical understanding of dynamic programming and HJB PDEs has seen a remarkable development over the last decades, the numerical approximation of HJB-based feedback laws has remained largely an open problem due to the curse of dimensionality. More precisely, the associated HJB PDE must be solved over the state space of the dynamics, which is extremely high-dimensional in applications such as distributed parameter systems or agent-based models.

In this talk we will review recent approaches regarding the effective numerical approximation of very high-dimensional HJB PDEs. We will explore modern scientific computing methods based on tensor decompositions of the value function of the control problem, and the construction of data-driven schemes in supervised and semi-supervised learning environments. We will highlight some novel research directions at the intersection of control theory, scientific computing, and statistical machine learning.

- Yann Le Gorrec (National Engineering Institute in Mechanics and Microtechnologies "ENSMM", Besançon, France)

Control design for distributed parameter systems – the port Hamiltonian approach

Abstract. This talk is concerned with the control of distributed parameter systems defined on a 1D spatial domain using the port Hamiltonian framework. We consider two different cases: when actuators and sensors are located within the spatial domain and when the actuator is situated at the boundary of the spatial domain, leading to a boundary control system (BCS). In the first case we show how dynamic extensions and structural invariants can be used to change the internal properties of the system when the system is fully actuated, and how it can be done in an approximate way when the system is actuated using piecewise continuous actuators stemming from the use of patches. Asymptotic stability is achieved using damping injection. In the boundary-controlled case we show how the closed loop energy function can be partially shaped, modifying the minimum and a part of the shape of this function and how damping injection can be used to guarantee asymptotic convergence. We end with some some extensions of the proposed results to irreversible thermodynamic systems.

Compressed sensing and maximum hands-off control

Abstract. Compressed sensing has been actively researched in the field of signal processing and machine learning. More recently, the method has been applied to control problems. In this talk, we will briefly review compressed sensing for vectors, and then introduce the maximum hands-off control for continuous-time systems, which aims at finding the sparsest control under control constraints.

Full paper *Masaaki Nagahara* "Compressed sensing and maximum hands-off control" available in the IFAC PapersOnline volume of MTNS 2022 https://doi.org/10.1016/j.ifacol.2022.11.097.

Scalable distributed control and learning of networked dynamical systems

Abstract. Recent radical evolution in distributed sensing, computation, communication, and actuation has fostered the emergence of cyber-physical network systems. Regardless of the specific application, one central goal is to shape the network collective behavior through the design of admissible local decision-making algorithms. This is nontrivial due to various challenges such as the local connectivity, system complexity and uncertainty, limited information structure, and the complex intertwined physics and human interactions.

In this talk, I will present our recent progress in formally advancing the systematic design of distributed coordination in network systems via harnessing special properties of the underlying problems and systems. In particular, we will present three examples and discuss three type of properties, i) how to use network structure to ensure the performance of the local controllers; ii) how to use the information and communication structure to develop distributed learning rules; iii) how to use domain-specific properties to further improve the efficiency of the distributed control and learning algorithms.

- Jacquelien M. A. Scherpen (University of Groningen, The Netherlands)

Extended (differential) balancing for model reduction of linear and nonlinear dynamical systems

Abstract. In this talk, we will develop extended balancing and its structure preservation possibilities for linear systems, as well as extended balancing theory for nonlinear systems in the contraction framework. For the latter, we introduce the concept of the extended differential observability Gramian and inverse of the extended differential controllability Gramian for nonlinear dynamical systems and show their correspondence with generalized differential Gramians. We also provide how extended (differential) balancing can be utilized for model reduction to get a smaller apriori error bound in comparison with generalized (differential balancing). We will focus on preserving the structure of a port-Hamiltonian system with help of extended balancing in both the linear and nonlinear systems setting.

- Sanne ter Horst (North-West University, Potchefstroom, South Africa)

Convex invertible cones and Nevanlinna-Pick interpolation

Abstract. Nevanlinna-Pick interpolation developed from a topic in classical complex analysis to a useful tool for solving various problems in control theory and electrical engineering. Over the years many extensions of the original problem were considered, including extensions to different function spaces, nonstationary problems, several variable settings and interpolation with matrix and operator points. In this talk we discuss a variation on Nevanlinna-Pick interpolation for positive real odd functions evaluated in real matrix points. This problem was studied by Cohen and Lewkowicz using convex invertible cones and the Lyapunov order, making interesting connections with stability theory. The solution requires an analysis of linear matrix maps using representations that go back to work of R.D. Hill from the 1970s and focusses, in particular, on the question when positive linear matrix maps are completely positive. If time permits, some possible extensions to multidimensional systems will briefly be discussed.

- Claudia Schillings (Free University Berlin, Germany)

A General Framework for Machine Learning-based Optimization Under Uncertainty

Abstract. Approaches to decision making and learning mainly rely on optimization techniques to achieve “best” values for parameters and decision variables. In most practical settings, however, the optimization takes place in the presence of uncertainty about model correctness, data relevance, and numerous other factors that influence the resulting solutions. For complex processes modeled by nonlinear ordinary and partial differential equations, the incorporation of these uncertainties typically results in high or even infinite dimensional problems in terms of the uncertain parameters as well as the optimization variables, which in many cases are not solvable with current state of the art methods. One promising potential remedy to this issue lies in the approximation of the forward problems using novel techniques arising in uncertainty quantification and machine learning.

We propose in this talk a general framework for machine learning based optimization under uncertainty and inverse problems. Our approach replaces the complex forward model by a surrogate, e.g. a neural network, which is learned simultaneously in a one-shot sense when estimating the unknown parameters from data or solving the optimal control problem. By establishing a link to the Bayesian approach, an algorithmic framework is developed which ensures the feasibility of the parameter estimate / control w.r. to the forward model.

This is joint work with Philipp Guth (U Mannheim) and Simon Weissmann (U Heidelberg).

Bayreuth, Germany, 12-16 September 2022

Stability of solutions for controlled nonlinear systems under perturbation of state constraints

Pierre-Cyril Aubin-Frankowski *

* *INRIA Paris, France (e-mail: pierre-cyril.aubin@inria.fr).*

Abstract: This paper tackles the problem of nonlinear systems, with sublinear growth but unbounded control, under perturbation of some time-varying state constraints. It is shown that, given a trajectory to be approximated, one can find a neighboring one that lies in the interior of the constraints, and which can be made arbitrarily close to the reference trajectory both in L^∞-distance and L^2-control cost. This result is an important tool to prove the convergence of approximation schemes of state constraints based on interior solutions and is applicable to control-affine systems.

Keywords: Nonlinear control systems, Control of constrained systems, Time-varying systems, Interior trajectories

1. INTRODUCTION

We consider a nonlinear system with unbounded control and state constraints

$$\mathbf{x}'(t) = \mathbf{f}(t, \mathbf{x}(t), \mathbf{u}(t)), \qquad \text{for a.e. } t \in [0,T], \quad (1)$$
$$\mathbf{x}(t) \in \mathcal{A}_{0,t} := \{\mathbf{x} \,|\, \mathbf{h}(t,\mathbf{x}) \leq 0\}, \qquad \text{for all } t \in [0,T], \quad (2)$$

where $\mathbf{f} : [0,T] \times \mathbb{R}^N \times \mathbb{R}^M \to \mathbb{R}^N$ and $\mathbf{h} : [0,T] \times \mathbb{R}^N \to \mathbb{R}^P$. Given a reference trajectory $\bar{\mathbf{x}}(\cdot)$, such that $\mathbf{h}(0, \bar{\mathbf{x}}(0)) < 0$, with control $\bar{\mathbf{u}}(\cdot)$ satisfying (1)-(2), our goal is to design a trajectory $\mathbf{x}^\epsilon(\cdot)$ with the same initial condition and some control $\mathbf{u}^\epsilon(\cdot)$, chosen such that $\mathbf{x}^\epsilon(\cdot)$ can be made arbitrarily L^∞-close to $\bar{\mathbf{x}}(\cdot)$, with $\mathbf{u}^\epsilon(\cdot)$ having almost the same L^2-norm as $\bar{\mathbf{u}}(\cdot)$, while also satisfying (1) and the following tightened constraints:

$$\mathbf{x}^\epsilon(t) \in \mathcal{A}_{\epsilon,t} := \{\mathbf{x} \,|\, \boldsymbol{\epsilon} + \mathbf{h}(t,\mathbf{x}) \leq 0\} \text{ for all } t \in [0,T]. \quad (3)$$

This construction is crucial to prove the convergence of approximation schemes of the constraints from within, in the sense that if $(\bar{\mathbf{x}}(\cdot), \bar{\mathbf{u}}(\cdot))$ is the solution of some optimal control problem with quadratic cost in control, then $(\mathbf{x}^\epsilon(\cdot), \mathbf{u}^\epsilon(\cdot))$ would be almost optimal while strictly interior. Such schemes were used by the author in Aubin-Frankowski (2021) for linear $\mathbf{f}$ and $\mathbf{h}$, leveraging convexity of the set of trajectories for which (1)-(2) hold. Here we provide instead assumptions on $\mathbf{f}$ and $\mathbf{h}$ designed originally by Bettiol et al. (2012) for bounded differential inclusions with time-invariant constraints. We further improve on their construction to have both an estimate on the L^2-norm and to cover unbounded systems (1) and time-varying constraints (2). This analysis can be related also to Bettiol and Vinter (2011) where time-dependent bounded systems are considered. The prototypical cases we are interested in are constrained nonlinear control-affine systems as studied e.g. in a more restrictive setting in (Cannarsa and Castelpietra, 2008, Section 4).

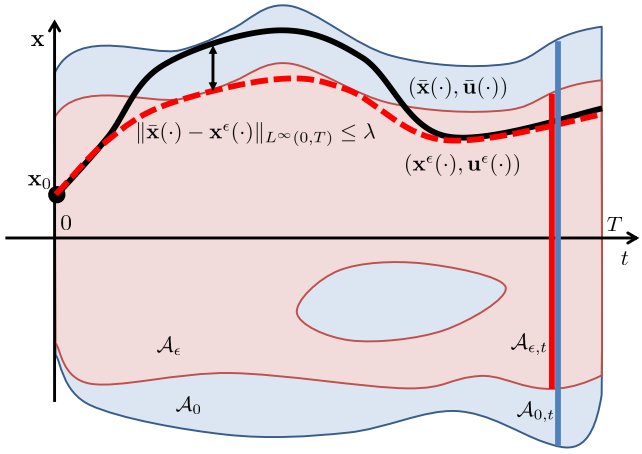

Figure 1. Illustration of the trajectories and constraints considered in Theorem 1.

2. MAIN RESULT

Notations. The integer interval is written $[\![i,j]\!] = \{i, i+1, \dots, j\}$. We denote by $\mathbb{R}_+$ the set of nonnegative reals, and use the shorthand $L^p(0,T)$ for $L^p([0,T],\mathbb{R}^d)$ with $p \in \{1,2,\infty\}$, and L^p_+ when the output set is $\mathbb{R}^d_+$. The set $\mathbb{B}_d$ is the closed Euclidean unit ball of $\mathbb{R}^d$ of center $\mathbf{0}$. Given a set $\mathcal{A} \subset \mathbb{R}^d$, $\mathrm{Int}(\mathcal{A})$ designates its interior, $\partial\mathcal{A}$ its boundary, and $d_\mathcal{A}(\cdot)$ is the Euclidean distance to $\mathcal{A}$.

We call $\mathbf{f}$-trajectories the solutions of (1) for measurable controls $\mathbf{u}(\cdot)$. For any $\boldsymbol{\epsilon} \in \mathbb{R}^P_+$, define

$$\mathcal{A}_\epsilon := \{(t,\mathbf{x}) \,|\, t \in [0,T],\, \mathbf{x} \in \mathcal{A}_{\epsilon,t}\}.$$

A trajectory is said to be $\mathcal{A}_\epsilon$-feasible if (3) holds, for instance $\bar{\mathbf{x}}(\cdot)$ is $\mathcal{A}_0$-feasible by assumption. We define the maximal constraint violation $\rho_{\epsilon,[t_0,t_1]}(\mathbf{x}(\cdot))$ of a trajectory on an interval $[t_0,t_1] \subset [0,T]$ as follows

$$\rho_{\epsilon,[t_0,t_1]}(\mathbf{x}(\cdot)) := \sup_{t\in[t_0,t_1]} d_{\mathcal{A}_{\epsilon,t}}(\mathbf{x}(t)).$$

We assume from now on that the control $\bar{\mathbf{u}}(\cdot)$ belongs to $L^\infty(0,T)$. This restriction is due to (H-6) below since we use a time-delay in the construction of the control $\mathbf{u}^\epsilon(\cdot)$ that is ill-suited to track the distance between controls. If $\mathbf{f}(t,\cdot,\mathbf{u})$ is $k_f(t)$-Lipschitz for any $\mathbf{u}\in\mathbb{R}^M$, then we may just assume that $\bar{\mathbf{u}}(\cdot)\in L^2(0,T)$.

(H-1) (Regular perturbation of $\mathcal{A}$)
$$\forall\,\lambda>0,\ \exists\,\boldsymbol{\epsilon}>0,$$
$$\forall\,(t,\mathbf{x})\in\mathcal{A}_0\cap([0,T]\times\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)}\mathbb{B}_N),$$
$$d_{\mathcal{A}_{\epsilon,t}}(\mathbf{x})\le\lambda.$$

(H-2) (Uniform continuity from the right of $d_{\partial\mathcal{A}_{\epsilon,t}}$ w.r.t. ϵ and t) There exist $\boldsymbol{\epsilon}_0>0$, $\Delta_0>0$, and a continuous function $\omega_{\mathcal{A}}(\cdot)\in\mathcal{C}^0(\mathbb{R}_+,\mathbb{R}_+)$ such that $\omega_{\mathcal{A}}(0)=0$ and, for all $\boldsymbol{\epsilon}\le\boldsymbol{\epsilon}_0$, and all $(t,\mathbf{x})\in\mathcal{A}_0\cap([0,T]\times 2\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)}\mathbb{B}_N)$,
$$\forall\,\delta\in[0,\min(\Delta_0,T-t)],\ \|d_{\partial\mathcal{A}_{\epsilon,t+\delta}}(\mathbf{x})-d_{\partial\mathcal{A}_{\epsilon,t}}(\mathbf{x})\|\le\omega_{\mathcal{A}}(\delta).$$

(H-3) (Sublinear growth of $\mathbf{f}$ w.r.t. $\mathbf{x}$ and $\mathbf{u}$)
$$\exists\,\theta(\cdot)\in L^2_+(0,T),\ \forall\,t\in[0,T],\ \forall\,\mathbf{x}\in\mathbb{R}^N,\ \forall\,\mathbf{u}\in\mathbb{R}^M,$$
$$\|\mathbf{f}(t,\mathbf{x},\mathbf{u})\|\le\theta(t)(1+\|\mathbf{x}\|+\|\mathbf{u}\|).$$

(H-4) (Inward-pointing condition) There exist $\boldsymbol{\epsilon}_0>0$, $M_u>0$, $M_v>0$, $\xi>0$, and $\eta>0$ such that for all $\boldsymbol{\epsilon}\le\boldsymbol{\epsilon}_0$ and all $(t,\mathbf{x})\in(\partial\mathcal{A}_\epsilon+(0,\eta\mathbb{B}_N))\cap\mathcal{A}_\epsilon\cap([0,T]\times(1+2\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)})\mathbb{B}_N)$, we can find $\mathbf{u}\in M_u\mathbb{B}_M$ such that $\mathbf{v}:=\mathbf{f}(t,\mathbf{x},\mathbf{u})$ belongs to $M_v\mathbb{B}_N$ and
$$\mathbf{y}+\delta(\mathbf{v}+\xi\mathbb{B}_N)\subset\mathcal{A}_{\epsilon,t+\delta}\tag{4}$$
for all $\delta\in[0,\xi]$ and all $\mathbf{y}\in(\mathbf{x}+\xi\mathbb{B}_N)\cap\mathcal{A}_{\epsilon,t}$.

(H-5) (Left local absolute continuity of $\mathbf{f}$ w.r.t. t)
$$\exists\,\gamma(\cdot)\in L^1_+(0,T),\ \exists\,\beta_u(\cdot)\in L^2_+(0,T),$$
$$\forall\,0\le s<t\le T,\ \forall\,\mathbf{x}\in(1+2\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)})\mathbb{B}_N,$$
$$\forall\,\mathbf{u}_s\in(M_u+\|\bar{\mathbf{u}}(s)\|)\mathbb{B}_M,\ \exists\,\mathbf{u}_t\in\mathbf{u}_s+\beta_u(s)\mathbb{B}_M,$$
$$\|\mathbf{f}(t,\mathbf{x},\mathbf{u}_t)-\mathbf{f}(s,\mathbf{x},\mathbf{u}_s)\|\le\int_s^t\gamma(\sigma)\,d\sigma.$$

Let $R:=e^{\|\theta(\cdot)\|_{L^1(0,T)}}\big[1+\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)}$
$+(1+M_u)\|\theta(\cdot)\|_{L^1(0,T)}$
$+\|\theta(\cdot)\|_{L^2(0,T)}(\|\bar{\mathbf{u}}(\cdot)\|_{L^2(0,T)}+\|\beta_u(\cdot)\|_{L^2(0,T)})\big]$. (5)

(H-6) (Local Lipschitz continuity of $\mathbf{f}$ w.r.t. $\mathbf{x}$)
$$\exists\,k_f(\cdot)\in L^2_+(0,T),\ \forall\,t\in[0,T],\ \forall\,\mathbf{x},\mathbf{y}\in R\mathbb{B}_N,$$
$$\forall\,\mathbf{u}\in(M_u+\|\bar{\mathbf{u}}(\cdot)\|_{L^\infty(0,T)})\mathbb{B}_M,$$
$$\|\mathbf{f}(t,\mathbf{x},\mathbf{u})-\mathbf{f}(t,\mathbf{y},\mathbf{u})\|\le k_f(t)\|\mathbf{x}-\mathbf{y}\|.$$

(H-7) (Hölderian selection of the controls in (H-5))
$$\exists\,\gamma(\cdot)\in L^1_+(0,T),\ \exists\,\alpha\in]0,1],\ \exists\,k_u(\cdot)\in L^2_+(0,T),$$
$$\forall\,0\le s<t\le T,\ \forall\,\mathbf{x}\in(1+2\|\bar{\mathbf{x}}(\cdot)\|_{L^\infty(0,T)})\mathbb{B}_N,$$
$$\forall\,\mathbf{u}_s\in(M_u+\|\bar{\mathbf{u}}(s)\|)\mathbb{B}_M,\ \exists\,\mathbf{u}_t\in\mathbf{u}_s+(t-s)^\alpha k_u(s)\mathbb{B}_M,$$
$$\|\mathbf{f}(t,\mathbf{x},\mathbf{u}_t)-\mathbf{f}(s,\mathbf{x},\mathbf{u}_s)\|\le\int_s^t\gamma(\sigma)\,d\sigma.$$

Theorem 1. Under assumptions (H-1)-(H-6), for any $\lambda>0$, there exists $\boldsymbol{\epsilon}>0$ and a $\mathbf{f}$-trajectory $\mathbf{x}^\epsilon(\cdot)$ on $[0,T]$ such that $\mathbf{x}^\epsilon(0)=\bar{\mathbf{x}}(0)$, $\mathbf{x}^\epsilon(t)\in\operatorname{Int}\mathcal{A}_{\epsilon,t}$ for all $t\in[0,T]$, and
$$\|\bar{\mathbf{x}}(\cdot)-\mathbf{x}^\epsilon(\cdot)\|_{L^\infty(0,T)}\le\lambda.$$
Moreover if (H-7) is satisfied, then, for any mapping $\mathbf{R}(\cdot)\in\mathcal{C}^0([0,T],\mathbb{R}^{M,M})$ with positive semidefinite matrix values, one can choose $\boldsymbol{\epsilon}>0$ and $\mathbf{x}^\epsilon(\cdot)$ such that the controls $\mathbf{u}^\epsilon(\cdot)$ satisfy
$$\left|\|\mathbf{R}(\cdot)^{1/2}\bar{\mathbf{u}}(\cdot)\|^2_{L^2(0,T)}-\|\mathbf{R}(\cdot)^{1/2}\mathbf{u}^\epsilon(\cdot)\|^2_{L^2(0,T)}\right|\le\lambda.$$

Discussion of the assumptions: The properties (H-1) and (H-2) imposed on the constraint set can for instance be derived from the $\mathcal{C}^{1,1}$-regularity of $\mathbf{h}$, coupled with the assumptions that the Jacobian $\frac{\partial\mathbf{h}(t,\mathbf{x})}{\partial\mathbf{x}}$ of $\mathbf{h}$ at all $(t,\mathbf{x})\in\partial\mathcal{A}_0$ is surjective. The classical growth assumption (H-3) prevents in turn finite-time explosion of the trajectories. The Lipschitzianity (H-6) guarantees their uniqueness and was designed to encompass control-affine systems of the form $\mathbf{x}'(t)=\mathbf{a}(t,\mathbf{x})+\mathbf{b}(t,\mathbf{x})\mathbf{u}$ with $\tilde{k}_f(t)$-Lipschitz functions $\mathbf{a}(t,\cdot)$ and $\mathbf{b}(t,\cdot)$, for some $\tilde{k}_f(\cdot)\in L^2(0,T)$. The other assumptions are more technical and inspired by Bettiol et al. (2012). Inward-pointing conditions such as (H-4), which can be deduced from a normal cone formulation (Bettiol et al., 2012, Lemma 5.3), have been shown to yield the L^∞-bounds we seek. The time regularity (H-5) was introduced to tackle discontinuities in the dynamics, and showcased on a civil engineering example (Bettiol et al., 2012, Section 4). We adapt it to control systems and refine it in (H-7).

Note that state constraints of order 2 (or more), e.g. $\ddot{x}=u$ with x constrained, do not enter into the proposed framework as the inward-pointing assumption does not hold in these cases, being limited to "order 1 constraints". The proof can in principle be adapted to systems $\tilde{\mathbf{f}}$ with control constraints following a Lipschitz (or Hölderian) closed-valued map $t\rightsquigarrow U(t)$ by considering the projection over $U(t)$ and $\mathbf{f}(t,\mathbf{x},\mathbf{u})=\tilde{\mathbf{f}}(t,\mathbf{x},\operatorname{proj}_{U(t)}(\mathbf{u}))$ assuming that this $\mathbf{f}$ satisfies the above assumptions.

Idea of the proof: The overall strategy to construct a neighboring $\mathcal{A}_\epsilon$-feasible trajectory can be related to that of Bettiol et al. (2012). Modifying it to unbounded controls and time-varying constraints is however not straightforward. We start by considering small subintervals $[0,T]=\bigcup_{i\in[\![0,N_0-1]\!]}[t_i,t_{i+1}]$ and proceed iteratively. If the ith-trajectory stays in $\mathcal{A}_\epsilon$ over $[t_i,t_{i+1}]$, we move to the next time interval. Otherwise for the $(i+1)$th-trajectory over $[t_i,t_{i+1}]$, (H-4) provides us with an inward-pointing control to stay in $\mathcal{A}_\epsilon$ for a short time. Then we apply a delayed control of the ith-trajectory for the rest of $[t_i,t_{i+1}]$, and the original control $\bar{\mathbf{u}}(\cdot)$ over $[t_{i+1},T]$. By monitoring several quantities, we can show that the resulting control after N_0 iterations is L^2-close from $\bar{\mathbf{u}}(\cdot)$ and that the obtained trajectory is in $\mathcal{A}_\epsilon$.

Example: Consider an electric motor
$$x'(t)=a(t,x)+b(t,u),$$
with a bounded $a\in C^{1,1}([0,2]\times\mathbb{R},\mathbb{R})$ and constraints $h(x)=1-|x|$, for controls $u\in\mathbb{R}$. The motor suffers an incident at $T=1$. If it is a power surge

$$b(t,u) = \tilde{b}(t)u = \begin{cases} u & \text{if } t \in [0,1] \\ u/\sqrt[4]{t-1} & \text{if } t \in]1,2] \end{cases},$$

then (H-3) holds for $\theta \equiv \tilde{b} + \|f\|_\infty$. It remains to check (H-7). For $s < t \leq 1$, take $u_t = u_s$. For $s < 1 < t$, set $u_t = \sqrt[4]{t-1}u_s$, so $|u_t - u_s| \leq |u_s| \leq \frac{\sqrt[4]{t-s}}{\sqrt[4]{|1-s|}}|u_s|$. For $s = 1 < t$, take also $u_t = \sqrt[4]{t-1}u_s$, thus $|u_t - u_s| \leq |u_s|$. For $1 < s \leq t$, set $u_t = \frac{\sqrt[4]{t-1}}{\sqrt[4]{s-1}}u_s$, so, by subadditivity of $\sqrt[4]{\cdot}$,

$$|u_t - u_s| \leq \frac{\sqrt[4]{t-1} - \sqrt[4]{s-1}}{\sqrt[4]{|1-s|}}|u_s| \leq \frac{\sqrt[4]{t-s}}{\sqrt[4]{|1-s|}}|u_s|.$$

Hence (H-7) is indeed satisfied for $\gamma \equiv 0$, $k_u(s) = \frac{1}{\sqrt[4]{|1-s|}}(M_u + |\bar{\mathbf{u}}(s)|)$ and $\alpha = \frac{1}{4}$. If the incident consists in a power decline

$$b(t,u) = \begin{cases} \arctan(u) & \text{if } t \in [0,1] \\ (1 - \frac{\sqrt{t-1}}{2})\arctan(u) & \text{if } t \in]1,2] \end{cases},$$

then the system is bounded and (H-7) holds with $u_t = u_s$, $\gamma(\sigma) = \frac{1}{4\sqrt{\sigma-1}}$ for $\sigma \in]1,2]$ and $\gamma(\sigma) = 0$ otherwise. In both cases (H-4) is satisfied, so perturbing the constraints still allows for a trajectory and control close to the reference ones as per Theorem 1.

Separating invariants for matrix tuples up to similarity

J. Volčič *

* *Department of Mathematics, Drexel University, PA, USA*

Abstract: The talk considers evaluations of linear matrix pencils $L = T_0 + x_1T_1 + \cdots + x_mT_m$ on matrix tuples as $L(X_1, \ldots, X_m) = I \otimes T_0 + X_1 \otimes T_1 + \cdots + X_m \otimes T_m$. It is shown that ranks of linear matrix pencils constitute a collection of separating invariants for simultaneous similarity of matrix tuples. That is, m-tuples X and Y of $n \times n$ matrices are simultaneously similar if and only if $\mathrm{rk}L(X) = \mathrm{rk}L(Y)$ for all linear matrix pencils L of size mn. Variants of this property for some other group actions are also discussed.

Keywords: Simultaneous similarity, linear matrix pencil, rank-preserving map.

Two tuples of $n \times n$ matrices $X = (X_1, \ldots, X_m)$ and $Y = (Y_1, \ldots, Y_m)$ over a field are *(simultaneously) similar* if there exists $P \in \mathrm{GL}_n$ such that $Y_i = PX_iP^{-1}$ for $i = 1, \ldots, m$. The classification of matrix tuples up to similarity has been deemed a "hopeless problem". Nevertheless, the study of simultaneous similarity and related group actions on matrix tuples is crucial in multiple areas of mathematics, ranging from operator theory, invariant and representation theory and algebraic geometry to algebraic statistics and computational complexity. A prominent facet of simultaneous similarity is finding a (natural) collection of separating invariants, which is the topic of this talk. A related problem is that of the orbit closure inclusion: determine whether a matrix tuple X belongs to the closure of the similarity orbit of a matrix tuple Y. This problem is fundamental to geometric invariant theory and geometric complexity theory. Note that X and Y are similar if and only if X is in the orbit closure of Y and Y is in the orbit closure of X.

Curto and Herrero (1985) conjectured that X lies in the closure of the similarity orbit of Y if and only if $\mathrm{rk}f(X) \leq \mathrm{rk}f(Y)$ for every noncommutative polynomial f in m variables. Hadwin and Larson (2003) gave a counterexample to the (even weaker) two-sided Curto–Herrero conjecture: they presented matrix tuples x and Y that are not similar but $\mathrm{rk}f(X) = \mathrm{rk}f(Y)$ for every noncommutative polynomial f. Furthermore, they proposed an ameliorated conjecture: X lies in the closure of the similarity orbit of Y if and only if $\mathrm{rk}F(X) \leq \mathrm{rk}F(Y)$ for every *matrix noncommutative polynomial* F (i.e., a matrix of noncommutative polynomials).

This talk presents the affirmative answer to two-sided version of the Hadwin–Larson conjecture.

Theorem 1. [Derksen et al. (2021)] The following are equivalent for $X, Y \in \mathrm{Mat}_n^m$:

(1) X and Y are similar;
(2) for every $T = (T_0, \ldots, T_m) \in \mathrm{Mat}_{mn}^{m+1}$,

$$\begin{aligned} &\mathrm{rk}\,(I \otimes T_0 + X_1 \otimes T_1 + \cdots X_m \otimes T_m) \\ &= \mathrm{rk}\,(I \otimes T_0 + Y_1 \otimes T_1 + \cdots Y_m \otimes T_m)\,. \end{aligned}$$

In other words, ranks of linear matrix pencils evaluated at matrix tuples constitute a collection of separating invariants for simultaneous similarity. Similar results hold for the actions of unitary, orthogonal and symplectic groups, and for the left-right action of the general linear group.

Moreover, the talk provides a counterexample to the general version of the Hadwin–Larson conjecture: there are two pairs X and Y of 4×4 matrices such that $\mathrm{rk}F(X) \leq \mathrm{rk}F(Y)$ for all matrix noncommutative polynomials F but X does not lie the closure of the similarity orbit of Y.

This talk is based on joint work with Harm Derksen, Igor Klep and Visu Makam.

Globally positive trace polynomials

J. Volčič *

* *Department of Mathematics, Drexel University, PA, USA*

Abstract: A trace polynomial is a polynomial in noncommuting variables and traces of their products. It is positive if its evaluations on all symmetric matrices, or more generally, self-adjoint operators from tracial von Neumann algebras, attain only positive semidefinite values. A Positivstellensatz for positive univariate trace polynomials is presented, and a characterization of trace-positive multivariate noncommutative polynomials is discussed.

Keywords: Trace polynomial, Positivstellensatz, moment problem.

Trace polynomials are real polynomials in noncommuting variables $x_1, \dots, x_d$ and their formal traces $\mathrm{tr}(x_{i_1} \dots x_{i_\ell})$. Such expressions can be naturally evaluated on tuples of matrices, where the trace symbols are evaluated as normalized traces; or more generally, on tuples of operators from a tracial von Neumann algebra. Trace polynomials as matricial/operator functions originated in invariant theory, and more recently emerged in free probability and quantum information theory.

This talk discusses positive trace polynomials, i.e., those that can attain only positive semidefinite values when evaluated on tuples of symmetric matrices, or more generally self-adjoint operators. This topic is well understood when evaluations are restricted to either matrix tuples of a fixed dimension (Klep et al. (2018)) or bounded domains in tracial von Neumann algebras (Klep et al. (2022)). On the other hand, results are very scarce in the global case, when restrictions on dimensions and boundedness are dropped.

The majority of the talk is dedicated to the univariate case ($d = 1$ and $x_1 = x$). Univariate trace polynomials form a commutative polynomial ring (in countably many variables), and several sum-of-squares positivity certificates (Positivstellensätze) in commutative rings are provided by real algebraic geometry. However, this theory does not appear to directly apply to our setup. First, matrix evaluations of trace polynomials are just a special class of homomorphisms on trace polynomials. Second, the dimension-free context addresses positivity on matrices of all sizes, hence on a countable disjoint union of real affine spaces; there is no bound (with respect to the degree of a univariate trace polynomial) on the size of matrices for which positivity needs to be verified.

Therefore a different approach is required. To demonstrate it, consider the inequality

$$\begin{aligned} &\mathrm{tr}(X^4)\mathrm{tr}(X^2) + 2\mathrm{tr}(X^3)\mathrm{tr}(X^2)\mathrm{tr}(X) \\ \geq\ &\mathrm{tr}(X^4)\mathrm{tr}(X)^2 + \mathrm{tr}(X^3)^2 + \mathrm{tr}(X^2)^3 \end{aligned} \tag{1}$$

for all symmetric matrices X (and normalized trace tr). One way to certify (1) is by noticing that the trace polynomial $f = \mathrm{tr}(x^4)(\mathrm{tr}(x^2) - \mathrm{tr}(x)^2) + 2\mathrm{tr}(x^3)\mathrm{tr}(x^2)\mathrm{tr}(x) - \mathrm{tr}(x^3)^2 - \mathrm{tr}(x^2)^3$ satisfies

$$\begin{aligned} &\mathrm{tr}\Big(\Big(x - \mathrm{tr}(x)\Big)^2\Big) \cdot f \\ =\ &\mathrm{tr}\Big(\Big((\mathrm{tr}(x)^2 - \mathrm{tr}(x^2))x^2 + (\mathrm{tr}(x^3) - \mathrm{tr}(x^2)\mathrm{tr}(x))x \\ &\quad + \mathrm{tr}(x^2)^2 - \mathrm{tr}(x^3)\mathrm{tr}(x)\Big)^2\Big), \end{aligned}$$

where we view tr as an idempotent linear endomorphism of trace polynomials in a natural way. More generally, the following tracial analog of Artin's solution to Hilbert's 17th problem holds.

Theorem 1. [Klep et al. (2021)] A univariate trace polynomial is positive on all symmetric matrices if and only if it is a quotient of sums of products of traces of squares of trace polynomials.

It turns out that in the multivariate case ($d > 1$), traces of squares of polynomials are are not sufficient for describing positivity. For example, the tracial analog of Motzkin's example,

$$\mathrm{tr}(x_1x_2^4x_1 + x_2x_1^4x_2 - 3x_1x_2^2x_1 + 1)$$

is positive for all pairs of symmetric matrices, but cannot be described by traces of squares of noncommutatve polynomials. Nevertheless, a characterization of trace-positive noncommutative polynomials in terms of noncommutative rational functions is given, based on a solution of the unbounded tracial moment problem.

This talk is based on joint work with Igor Klep and James Pascoe.

Bézout Identity in Pseudoratoinal Transfer Functions

Extended abstract for MTNS 2022

Yutaka Yamamoto [*,1]

Abstract: Coprime factorizations of transfer functions play various important roles, e.g., minimality of realizations, stabilizability of systems, etc. This paper studies the Bézout condition over the ring $\mathscr{E}'(\mathbb{R}_-)$ of distributions of compact support and the ring $\mathfrak{M}(\mathbb{R}_-)$ of measures with compact support. These spaces are known to play crucial roles in minimality of state space representations and controllability of behaviors. We give a detailed review of the results obtained thus far, as well as discussions on a new attempt of deriving general results from that for measures. It is clarified that there is a technical gap in generalizing the result for $\mathfrak{M}(\mathbb{R}_-)$ to that for $\mathscr{E}'(\mathbb{R}_-)$. A detailed study of a concrete example is given.

Keywords: Bézout identity, pseudorationality, distributions, Gel'fand representation, delay-differential systems
AMS subject classification: 46F10, 46J15

1. INTRODUCTION

This short note studies the issue of coprimeness for a certain class of infinite-dimensional systems.

In particular, we study the Bézout identity (or Bézout condition)

$$px+qy=1 \tag{1}$$

in an algebra appropriate for a class of distributed parameter systems.

The first author has introduced the class of *pseudorational* impulse responses or transfer functions, and developed realization theory, various spectral analysis, and coprimeness conditions Yamamoto (1988, 1989). The present article is an extended abstract version of the paper for MTNS 2020. For more background explanations, we refer the reader to Yamamoto and Bonnet (2021).

2. PSEUDORATIONALITY

Let $\mathscr{D}'$ denotes the space of distributions on $\mathbb{R}$. Let $\mathscr{E}'(\mathbb{R})$ be its subspace consisting of those having compact support. $\mathscr{E}'(\mathbb{R}_-)$ is also its subspace with support contained in the negative half line $(-\infty,0]$. $\mathscr{D}'_+$ denotes the subspace of $\mathscr{D}'$ consisting of elements having support bounded on the left. Distributions such as Dirac's delta δ_a placed at $a\in\mathbb{R}$, its derivative δ'_a are examples of elements in $\mathscr{E}'(\mathbb{R})$. If $a\le 0$, then they belong to $\mathscr{E}'(\mathbb{R}_-)$.

We consider fraction representations over $\mathscr{E}'(\mathbb{R}_-)$.

Definition 2.1. An impulse response function G ($\operatorname{supp} G\subset[0,\infty)$) is said to be *pseudorational* (Yamamoto (1988)) if there exist $q,p\in\mathscr{E}'(\mathbb{R}_-)$ such that

(1) $G=q^{-1}*p$ where the inverse is taken with respect to convolution and belongs to $\mathscr{D}'_+$;
(2) $\operatorname{ord} q^{-1}=-\operatorname{ord} q$, where $\operatorname{ord} q$ denotes the order of a distribution q (Schwartz (1966)). [2]

If this condition is satisfied, we call (p,q) a *pseudorational pair*. The Laplace transform $\hat{q}^{-1}\hat{p}$ is called a *pseudorational transfer function*.

The delay-differential equation:

$$\dot{x}(t)=x(t-1)+u(t)$$
$$y(t)=x(t),$$

admits the representation

$$y=(\delta'_{-1}-\delta)^{-1}*\delta_{-1}*u,$$

and hence it is pseudorational.

[⋆] The present article is an extended abstract version of the paper Yamamoto and Bonnet (2021) for MTNS 2020.

The author also wishes to thank DIGITEO and Laboratoire des Signaux et Systemes (L2S, UMR CNRS), CNRS-CentraleSupelec-University Paris-Sud and Inria Saclay for their financial support while part of this research was conducted.

[2] Roughly speaking, the order of a distribution α is the least integer r such that $\alpha=(d/dt)^r\beta$ for some measure β.

The main problem that concerns us here is the following:
Problem *Given a pseudorational pair* $(p,q) \in \mathscr{E}'(\mathbb{R}_-) \times \mathscr{E}'(\mathbb{R}_-)$*, characterize a condition under which p and q satisfy the Bézout identity:*

$$p*x+q*y=\delta \tag{2}$$

for some $x,y \in \mathscr{E}'(\mathbb{R}_-)$.

If we consider $\mathscr{E}'(\mathbb{R})$ instead of $\mathscr{E}'(\mathbb{R}_-)$, it gives a necessary and sufficient condition for the controllability of the behavior defined over $\mathscr{D}'$ (Yamamoto (2016)). Actually, the Bézout condition over $\mathscr{E}'(\mathbb{R})$ is in close relationship with that in $\mathscr{E}'(\mathbb{R}_-)$ (Yamamoto (2016)).

3. COPRIMENESS IN $\mathscr{E}'(\mathbb{R}_-)$

We first translate (2) to a divisibility condition by considering the principal ideal $(q)=q*\mathscr{E}'(\mathbb{R}_-)$ generated by q in $\mathscr{E}'(\mathbb{R}_-)$. Note first that (2) is easily seen to be equivalent to

$$p*\phi=\delta \mod q. \tag{3}$$

for some $\phi \in \mathscr{E}'(\mathbb{R}_-)$. In other words,

$$[p]*[\phi]=[\delta] \tag{4}$$

in $\mathscr{E}'(\mathbb{R}_-)/(q)$. This means that the equivalence class $[p]$ is invertible in the quotient algebra $\mathscr{E}'(\mathbb{R}_-)/(q)$.

Condition (4) by itself is not so easy to handle because of the intricate topology of $\mathscr{E}'(\mathbb{R}_-)$. However, because q has compact support, the following remarkable property holds:

Proposition 3.1. Take any $T>0$ such that $\operatorname{supp} q \subset (-T,0]$. Then

$$\mathscr{E}'(\mathbb{R}_-)/(q) \cong \mathscr{E}'([-T,0])/(q) \tag{5}$$

Proof Let π be the projection operator

$$\pi : \mathscr{D}' \to \mathscr{D}'_{(0,\infty)} : \psi \mapsto \psi|(0,\infty) \tag{6}$$

where $\mathscr{D}'_{(0,\infty)}$ is the space of distributions with support contained in $(0,\infty)$. Given $\psi \in \mathscr{D}'$, define the following operator π^q as

$$\pi^q : \mathscr{E}'(\mathbb{R}_-) \to \mathscr{E}'(\mathbb{R}_-) : \psi \mapsto q*\pi(q^{-1}*\psi). \tag{7}$$

Now for a distribution $\psi \in \mathscr{D}'_+$, define $\ell(\psi)$ as

$$\ell(\psi) := \inf\{t \in \operatorname{supp}\psi\} \tag{8}$$

where $\operatorname{supp}\psi$ denotes the support of ψ. We note from Yamamoto and Bonnet (2021) that $\ell(\alpha*\beta)=\ell(\alpha)+\ell(\beta)$ for $\alpha,\beta \in \mathscr{D}'_+$.

Take any $x \in \mathscr{E}'(\mathbb{R}_-)$ along with $\pi^q x$. We claim that $\pi^q x$ belongs to $\mathscr{E}'(\mathbb{R}_-)$ (hence (7) is well defined as a map from $\mathscr{E}'(\mathbb{R}_-)$ into itself) and that $x \cong \pi^q x \bmod q$. We have

$$q^{-1}*(x-\pi^q x)=q^{-1}*x-q^{-1}*q*\pi(q^{-1}x)=q^{-1}*x-\pi(q^{-1}*x).$$

The last term $\phi := q^{-1}*x-\pi(q^{-1}*x)$ belongs to $\mathscr{E}'(\mathbb{R}_-)$ because $q^{-1}*x-\pi q^{-1}*x$ must be zero on $(0,\infty)$. That is to say,

$$x-\pi^q x = q*\phi \in q*\mathscr{E}'(\mathbb{R}_-)=(q).$$

This also shows that $\pi^q x = x-q*\phi \in \mathscr{E}'(\mathbb{R}_-)$. In other words, $[x]=[\pi^q x]$ in $\mathscr{E}'(\mathbb{R}_-)/(q)$. Moreover, since $\ell(\pi(q^{-1}*x)) \geq 0$ and $\ell(q) \geq -T$, the support of $\pi^q x = q*\pi(q^{-1}*x)$ must be contained in $[-T,0]$ by $\ell(q*\pi(q^{-1}*x))=\ell(q)+\ell(\pi(q^{-1}*x))$. That is, for every $x \in \mathscr{E}'(\mathbb{R}_-)$, there always exists an element $\pi^q x$ such that $\operatorname{supp}\pi^q x \subset [-T,0]$, and $x \cong \pi^q x \bmod q$. This proves (5). □

Remark 3.2. Proposition 3.1 claims that as far as a pseudorational impulse response is concerned, we can confine our attention to those inputs with support contained in $[-T,0]$ with $-T<\ell(q)$. This result is not so surprising if we pay proper attention to the compact-support property of q. Since q has bounded support, its maximum length should determine the maximum length of memory needed to reconstruct the state or future outputs. This can be easily guessed once we resort to the analogy with realization theory for discrete-time linear systems: The degree of the denominator polynomial $q(z)$ determines the dimension of the state in the standard reachable realization, and the degree here exactly corresponds to the length of the support of q here. The projection scheme used above is an analogy to the finite-dimensional theory developed by Fuhrmann (1976).

4. GEL'FAND ALGEBRA STRUCTURE OF THE SPACE OF MEASURES

We have seen that the existence of the Bézout condition reduces to the invertibility of $[p]$ in the quotient algebra $\mathscr{E}'(\mathbb{R}_-)/(q)$. It is also seen that this space $\mathscr{E}'(\mathbb{R}_-)/(q)$ is isomorphic to $\mathscr{E}'([-T,0])/(q)$ for some $T>0$ so that its structure is quite simplified. However, the space $\mathscr{E}'(\mathbb{R}_-)/(q)$ is still not that easy to tackle due to a rather complex topological structure of $\mathscr{E}'(\mathbb{R}_-)/(q)$.

We now choose to confine ourselves to the subspace $\mathfrak{M}(\mathbb{R}_-)$ that is the subspace of $\mathscr{E}'(\mathbb{R}_-)$ consisting of measures, i.e., those with elements of order 0. As shown in Proposition 3.1, $\mathfrak{M}(\mathbb{R}_-)/(q) \cong \mathfrak{M}([-T,0])/(q)$ for some $T>0$. (Proposition 3.1 claims this fact for $\mathscr{E}'(\mathbb{R}_-)$, but the proof remains essentially the same.) Note that $\operatorname{ord} q^{-1} = -\operatorname{ord} q = 0$ by condition (2) of Definition 2.1, so that q^{-1} is also a measure.) We here observe that the space $\mathfrak{M}([-T,0])/(q)$ has a remarkable advantage over $\mathscr{E}'([-T,0])/(q)$ in that it can be regarded as a Banach space with respect to the strong dual topology as the dual space of the space of continuous functions $C[-T,0]$. Furthermore, it inherits a natural algebra structure induced from $\mathfrak{M}(\mathbb{R}_-)$ (with respect to convolution) with the unity element $[\delta]$. In other words, it is a Gel'fand algebra (Gel'fand et al. (1964); Berberian (1973)).

A Gel'fand algebra is known to have a remarkable property in that the invertibility of an element can be well tested by characterizing the space of its maximal ideals (Berberian (1973); Gel'fand et al. (1964)). This fact is best suited to study the invertibility condition (4).

Let us now make the following Assumption:

Assumption 1 There exists $\sigma \in \mathbb{R}$ such that $\hat{p}(s)$ and $\hat{q}(s)$ do not vanish on $\{s|\operatorname{Re} s \geq \sigma\}$.

For the validity of Assumption 1, we note the following. Since (p,q) is a pseudorational pair, $q^{-1} \in \mathscr{D}'_+$. Then there exists $\sigma \in \mathbb{R}$ such that $1/\hat{q}(s)$ is of polynomial order for $\operatorname{Re} s \geq \sigma$ according to Schwartz (1961). Hence $\hat{q}(s)$ do not vanish for $\operatorname{Re} s \geq \sigma$. Likewise, if there exists $p^{-1} \in \mathscr{D}'_+$, the same is true of $\hat{p}(s)$.

If Assumption 1 is satisfied we may assume that σ can be taken to be zero, without loss of generality. For if necessary, we can always shift the complex variable as $s \mapsto s-\sigma$, and this clearly does not affect the coprimeness relationship.

The following theorem was first given in Yamamoto (2007), but we here give a more complete proof for the sake of completeness.

Theorem 4.1. Let $p,q \in \mathfrak{M}(\mathbb{R}_-)$, and satisfy Assumption 1. Suppose that there exists $c > 0, a \in \mathbb{R}$ such that

$$|\hat{p}(s)| + |\hat{q}(s)| \geq c > 0 \tag{9}$$

for every $s \in \mathbb{C}_- = \{s \in \mathbb{C} | \operatorname{Re} s \leq 0\}$. Then the (p,q) is a Bézout pair, i.e., satisfies the Bézout identity (2).

For the proof, we need some preliminaries. The question here is to find a condition under which $[p]$ is invertible in $\mathfrak{M}([-T,0])/(q)$. By Gel'fand representation theory (Berberian (1973); Gel'fand et al. (1964)), an element $[p]$ is invertible if and only if it belongs to no maximal ideals.

Consider the Laplace transform of elements in $\mathfrak{M}(\mathbb{R}_-)$. It is easy to see that this is a subalgebra of $H^\infty(\mathbb{C}_-)$. Then, as in Hoffman (1962), we see that the correspondence

$$\psi \mapsto \hat{\psi}(s)$$

considered for $s \in \mathbb{C}_-$ gives the Gel'fand representation.

What is then a maximal ideal in $\mathfrak{M}(\mathbb{R}_-)$? Take any $\lambda \in \mathbb{C}_-$, and consider the point evaluation

$$\phi_\lambda : f \mapsto \hat{f}(\lambda). \tag{10}$$

It is easy to see that ϕ_λ is a complex homomorphism (i.e., homomorphism from $\mathfrak{M}(\mathbb{R}_-)$ to $\mathbb{C}$), and hence $\ker \phi_\lambda$ is a maximal ideal of $\mathfrak{M}(\mathbb{R}_-)$. Observe however that this does not necessarily yield a maximal ideal in $\mathfrak{M}(\mathbb{R}_-)/(q)$, because in order to be an ideal in this space, this ideal should contain (q). In other words, $\hat{q}$ should vanish there. If M is given by

$$M_\lambda = \{f | \hat{f}(\lambda) = 0\},$$

then this means that λ should be a zero of $\hat{q}$ for $M_\lambda \supset (q)$. Now let

$$\lambda_1, \lambda_2, \ldots, \lambda_n, \ldots \tag{11}$$

be the set of zeros of $\hat{q}$. Then we have maximal ideals

$$M_{\lambda_1}, M_{\lambda_2}, \ldots, M_{\lambda_n}, \ldots$$

of $\mathfrak{M}(\mathbb{R}_-)/(q)$. But these are not all. There are other maximal ideals that are centered at "infinity".

To see this, let us first start with the following proposition:

Proposition 4.2. Let $f \in \mathfrak{M}(\mathbb{R}_-)$, and suppose that $\phi(f) = 0$ for some complex homomorphism, i.e., f belongs to a maximal ideal $\ker \phi$. Suppose also that ϕ does not agree with any of M_{λ_n} as given above. Then there exists a sequence μ_n such that

- $\mu_n \to \infty$ and
- $\hat{f}(\mu_n) \to 0$ as $n \to \infty$

Proof Suppose there exists no such μ_n. Then there exists $\delta > 0$ and $R > 0$ such that $|\hat{f}(s)| \geq \delta$ for $|s| \geq R$. In view of the Hadamard factorization that gives rise to an infinite product representation of $\hat{q}(s)$ as linear factors of $1 - s/\mu_n$ (Boas (1954)), it follows that either

(1) $\hat{f}(s)$ has infinitely many zeros, or
(2) $\hat{f}(s)$ has only finitely many zeros.

The first case is clearly impossible by $|\hat{f}(s)| \geq \delta$. Hence $\hat{f}$ has only finitely many zeros. But this yields $\hat{f}(s) = e^{\alpha s} P(s)$ where P is a polynomial. Note that $\alpha \geq 0$ because the inverse Laplace transform of $\hat{f}$ is a measure in $\mathfrak{M}(\mathbb{R}_-)$. Since $\alpha = 0$ just corresponds to a constant, we assume $\alpha \neq 0$, so that $\alpha > 0$. But then $e^{\alpha s}$ can have infinitely many zeros along the imaginary axis, and this contradicts $|\hat{f}(s)| \geq \delta$ for $|s| \geq R$. Hence $\hat{f}$ must be a polynomial. But this is again impossible unless $\hat{f}$ is a (nonzero) constant because the inverse Laplace transform of $\hat{f}$ must be a measure. Therefore $\hat{f}$ must be a constant. But this yields $\phi(1) = 0$, which clearly means that ϕ annihilates the whole space, and this contradicts the fact that ϕ is a nontrivial complex homomorphism (or $\ker \phi$ is a maximal ideal). □

In particular, this holds also for q. Then if M is a maximal ideal of $\mathfrak{M}(\mathbb{R}_-)/(q)$, then $\pi^{-1}(M)$ is clearly a maximal ideal of $\mathfrak{M}(\mathbb{R}_-)$, and this should contain (q).

We are now ready to prove Theorem 4.1.

Proof of Theorem 4.1 Suppose (9) holds, but p belongs to a maximal ideal in $\mathfrak{M}(\mathbb{R}_-)/(q)$. If p belongs to one of M_{λ_n}, then this would clearly contradict (9). Hence assume that $\hat{p}$ vanishes at no λ_n, $n = 1, 2, \ldots$. Then by Proposition 4.2, there exists μ_n such that $\mu_n \to \infty$ and $\hat{p}(\mu_n) \to 0$. Since this maximal ideal should contain q, $\hat{q}$ should also vanish there, and hence a suitable subsequence of $\hat{q}(\mu_n)$ should go to 0. This clearly contradicts (9). □

Here are some examples:

Example 4.3. The pair $(e^{s/2} - 1, e^s - 1)$ is not a Bezout pair. The pair possesses infinitely many common zeros.

Example 4.4. The pair $(e^s, e^{s/2} - 1)$ is a Bezout pair. It is easy to check (9). This can also be directly verified by $e^s - (e^{s/2} - 1)(e^{s/2} + 1) = 1$.

Remark 4.5. Condition (9) is the same as that in the celebrated Corona theorem by Carleson for H^∞ (Duren (1970); Garnett (1981)). One should of course be careful not to confuse the present result with the Corona theorem, because such conditions crucially depend on the choice of a ring. The proof here is good deal simpler than that of the monstrous Corona theorem (Duren (1970); Garnett (1981)). This is because the algebra $\mathfrak{M}(\mathbb{R}_-)/(q)$ is much "smaller" than H^∞, and the way it yields "cancellation at infinity" is quite much restricted by the discrete zeros $\{\lambda_n\}$ whereas in the case of the Corona theorem, there are almost arbitrary ways in which such sequences go to infinity.

5. EXTENSION TO $\mathscr{E}'(\mathbb{R}_-)$

It is thus quite tempting to try to generalize the above result to the general case of $\mathscr{E}'(\mathbb{R}_-)$ or $\mathscr{E}'(\mathbb{R})$.

We first make the following assumption:

Assumption 2: The algebraic multiplicity of each zero λ_n of $\hat{q}(s)$ is globally bounded.

Observe the following Theorem 5.1 obtained in Yamamoto (2007, 2016).

Theorem 5.1. Let $q^{-1} * p$ be pseudorational, and suppose that there exists a nonnegative integer m such that

$$|\lambda_n^m \hat{p}(\lambda_n)| \geq c > 0, n = 1, 2, \ldots \tag{12}$$

Then the pair (p,q) satisfies the Bézout identity (2) for some $\phi, \psi \in \mathscr{E}'(\mathbb{R}_-)$.

The proof given in Yamamoto (2007, 2016) is fairly complicated and highly technical. It does involve some elaborate analysis of complex analytic functions of exponential type, and some deep facts of their growth orders.

It is thus tempting to try to give a proof by using Theorem 4.1, extending the result for $\mathfrak{M}(\mathbb{R}_-)$ to $\mathscr{E}'(\mathbb{R}_-)$.

Let us first prepare some pertinent facts on the structure of $\mathscr{E}'(\mathbb{R}_-)$. Since every element of $\mathscr{E}'(\mathbb{R}_-)$ has compact support,

it is of finite order (Schwartz (1966)). That is, for every $\psi \in \mathscr{E}'(\mathbb{R}_-)$, there exists $r \geq 0$ such that

$$\psi = (d/dt)^r \psi_0 \tag{13}$$

for some $\psi_0 \in \mathfrak{M}(\mathbb{R}_-)$ and $r \geq 0$. This readily implies

$$\mathscr{E}'(\mathbb{R}_-) = \cup_{r=0}^{\infty}(d/dt)\mathfrak{M}(\mathbb{R}_-). \tag{14}$$

In other words, the algebra $\mathscr{E}'(\mathbb{R}_-)$ is derived as the differentiated union of measures.

We now suppose that we are given a pseudorational pair (p,q) belonging to $\mathscr{E}'(\mathbb{R}_-)$. Since $\mathscr{E}'(\mathbb{R}_-)$ is the nested union of differentiated measures, we may hope that we can reduce the coprimeness problem of $\mathscr{E}'(\mathbb{R}_-)$ into that of $\mathfrak{M}(\mathbb{R}_-)$. A procedure like the Euclid division algorithm can be a hint for this.

Suppose for the moment that p is of order 0 and q is of order 1. Suppose also that $\hat{q}(s)$ has one real zero, say, λ. Then the inverse Laplace transform of $\hat{q}(s)/(s-\lambda)$ should be of order zero because the division by $s-\lambda$ should act as an integration. Therefore, both p and $L^{-1}[\hat{q}(s)/(s-\lambda)]$ should be of order zero, i.e., measure.

Then it is naturally expected that the coprimeness of (p,q) should reduce to that of $(p, L^{-1}[\hat{q}(s)/(s-\lambda)])$.

In fact, if $(p, q_0 * q_1)$ is coprime in a ring R, (p,q_1) is coprime and vice versa. So it is natural to expect that the Bézout condition of (p,q) is translated to that of $(p, L^{-1}[\hat{q}(s)/(s-\lambda)])$ where the latter belong to the space of measures $\mathfrak{M}(\mathbb{R}_-)$, where Theorem 4.1 is available.

However, this seemingly reasonable idea unfortunately does not work. The following counterexample shows why.

Example 5.2. Consider the pair $(\delta'_{-1} - \delta, \delta_{-1})$. This pair is clearly pseudorational. The element $\delta'_{-1} - \delta$ has order 1, and δ_{-1} has order 0, i.e., measure. They admit Laplace transforms $se^s - 1$ and e^s, respectively. They satisfy the Bézout identity

$$(se^s - 1)\cdot(-1) + s \cdot e^s = 1, \tag{15}$$

or

$$(\delta'_{-1} - \delta) * (-\delta) + \delta' * \delta_{-1} = \delta, \tag{16}$$

and hence the pair is coprime over $\mathscr{E}'(\mathbb{R}_-)$.

The former element $se^s - 1$ has one positive zero, say α. This means that $(se^s - 1)/(s-\alpha)$ (or its inverse Laplace transform) has order 0 because division by $s-\alpha$ entails in integration of $\delta'_{-1} - \delta$ once, whereby yielding an element of order zero, i.e., a measure.

In other words, the pair (or the respective inverse Laplace transforms) $(se^s - 1)/(s-\alpha), e^s)$ belongs to $\mathfrak{M}(\mathbb{R}_-)$, and they are coprime over $\mathscr{E}'(\mathbb{R}_-)$. However, this does not guarantee that this pair admits a coprime factorization over $\mathfrak{M}(\mathbb{R}_-)$ in the sense of Theorem 4.1.

To see this, observe that $se^s - 1$ admits infinitely many zeros λ_n such that $\mathrm{Re}\,\lambda_n \to -\infty$. (This can easily be seen by noting that it is the characteristic function of the retarded delay-differential equation $\dot{x} = x(t-1) + u$.) Indeed, $\lambda_n e^{\lambda_n} = 1$ admits infinitely many solutions such that $e^{\lambda_n} = 1/\lambda_n, n = 1, 2, \ldots$. This also implies that $\hat{p}(\lambda_n) \to 0$ as $n \to \infty$. That is, it contradicts condition (9) of Theorem 4.1, and cannot be a Bézout pair in $\mathfrak{M}(\mathbb{R}_-)$.

In other words, the pair can admit a Bézout identity over $\mathscr{E}'(\mathbb{R}_-)$ with $x, y \in \mathscr{E}'(\mathbb{R}_-)$, but it cannot satisfy a Bézout condition over the algebra of $\mathfrak{M}(\mathbb{R}_-)$ because the latter algebra is much smaller than $\mathscr{E}'(\mathbb{R}_-)$ and does not give as much freedom as that induced by $\mathscr{E}'(\mathbb{R}_-)$. This can be more directly seen by noting the identity $s \cdot e^s + (se^s - 1)/(s-\alpha) \cdot (\alpha - s) = 1$ This looks trivial and not any different from (15). The difference here is that the multiplying factor $\alpha - s$ that makes the pair $(se^s - 1)/(s-\alpha), e^s)$ satisfy the Bézout identity does not belong to (the Laplace transform of) $\mathfrak{M}(\mathbb{R}_-)$. To cover this situation, we do need Theorem 5.1, which cannot be, unfortunately, covered as a natural variant of Theorem 4.1.

In fact, at the zeros λ_n of $\hat{q}$, $e^{\lambda_n} = 1/\lambda_n$ holds, so that the $\hat{p}(\lambda_n)$ clearly satisfy condition (12) for $m = 1$. This condition can also be rewritten as

$$|s\hat{p}(s)| + |s\hat{q}(s)| \geq c > 0, \forall s \in \mathbb{C}_-. \tag{17}$$

6. CONCLUDING REMARKS

We have seen that the space $\mathfrak{M}(\mathbb{R}_-)$ of measures admits a Gel'fand algebra structure, and it yields a concrete Corona-like condition (9) for the Bézout identity for a pseudorational pair (p,q). We have also pursued to derive the general condition (12) for the Bézout identity over $\mathscr{E}'(\mathbb{R}_-)$, but also seen that a straightforward reduction idea does not work. The modified generalized Corona-like condition (17) may, however, suggest that there could still be a possibility of generalizing (9) to a more general context in $\mathscr{E}'(\mathbb{R}_-)$.

Funnel control with internal model and anti-windup for input-saturated mechatronic systems

Christoph M. Hackl *

* *Hochschule München University of Applied Sciences, Lothstr. 64, 80335 München, Germany (e-mail: christoph.hackl@hm.edu).*

Abstract: Funnel control (FC) in combination with internal model (IM) achieves asymptotic tracking but feasibility of IM-FC in presence of input saturation (if e.g. a feasibility condition is satisfied) is unclear. Here, both aspects are brought together to obtain a closed-loop system comprising of funnel controller, serial interconnection of internal model with anti-windup and input-saturated high-gain stabilizable system which achieves prescribed transient and asymptotic accuracy if a feasibility conditions is satisfied (Hackl, 2017, Chapter 10). It will be illustrated that in presence of actuator saturation, funnel control with internal model but without anti-windup might exhibit integrator windup deteriorating control performance and resulting in instability of the closed-loop system. The theory of funnel control of input-saturated systems will be extended to allow for the application of funnel control with internal model to input-saturated systems by introducing an anti-windup strategy called conditional integration. The proposed approach is implemented and illustrated for a simple relative-degree-two system.

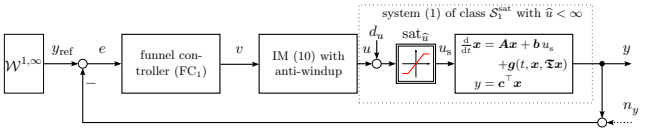
Keywords: adaptive control, funnel control, input saturation, anti-windup, internal model, feasibility condition

1. INTRODUCTION

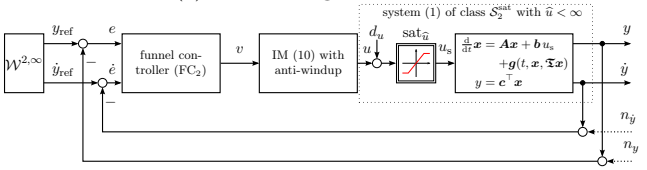
The use of funnel control (see Ilchmann et al. (2002)) in combination with internal model emerges from the well known fact that e.g. proportional-integral (PI) controllers or internal models in general are very beneficial to improve the control performance and, in particular, the *asymptotic accuracy* of closed-loop systems (see Wonham (1985); Isidori and Byrnes (1990)). That is why PI controllers are so popular in industry (see (Schröder, 2009, p. 81-82)). For speed control of mechatronic systems, this idea of connecting a PI-like internal model in series to a non-identifier based adaptive controller was first published in Schuster et al. (2004). For position control, a similar result has been published in Hackl (2011). Funnel control in conjunction with a linear internal model, i.e. *IM-funnel control*, applied to linear systems, can achieve asymptotic tracking and prescribed transient accuracy (see Ilchmann and Ryan (2006)). For mechatronic systems, funnel control with PI-like internal model, i.e. *PI-funnel control* gives steady state accuracy as well. However, it is not proven that steady state will be reached (see e.g. Ilchmann and Schuster (2009); Hackl et al. (2011); Hackl and Kennel (2012)). Except the publications Hackl (2013, 2015) on PI-funnel control *with anti-windup*, this far, from a theoretical point of view, funnel control with internal model is solely admissible for mechatronic systems *without* input saturation. In this extended abstract, it will be shown that the advantageous effects of IM-FC remain even in presence of actuator saturation if a simple conditional integration anti-windup strategy is implemented; as without it, the internal model might lead to instability of the input-saturated closed-loop system.

2. FUNNEL CONTROL WITH INTERNAL MODEL & ANTI-WINDUP FOR *INPUT-SATURATED* SYSTEMS

Funnel control is a *proportional* (and, for higher relative degrees, a proportional-derivative) control strategy. However, no integral control action is incorporated. It is well known (see Khalil (2000)) that already for exogenous signals which asymptotically converge to constant limits (e.g. *constant* references and/or disturbances), simple proportional controllers do *not* achieve steady state accuracy, i.e. $\lim_{t\to\infty} e(t) \neq 0$; the tracking error $e(t) := y_{\mathrm{ref}}(t) - y(t)$ does not tend to zero. To achieve that, at least, integral control action is required. For more complex



(a) Relative-degree-one case.



(b) Relative-degree-two case.

Fig. 1. Funnel control *with* internal model and anti-windup of *input-saturated* systems of form (1).

references and/or disturbances (e.g. for sinusoidal or ramp-like signals), internal models are beneficial and can be used in combination with funnel control. Howoever, for input-saturated systems, the interconnection of internal model

and system does *not* work as easily as for unsaturated systems (see (Hackl, 2017, Chapter 7 & 10)). The input saturation is located between internal model and input-saturated system (see Fig. 1) and might yield windup of (one or several of) the states of the internal model. Therefore, oscillations in the system output and/or system states will occur (see (Åström and Murray, 2008, Section 10.4)). Moreover, boundedness of the states of the internal model and/or closed-loop system stability are not guaranteed for input-saturated systems. It will be shown that the internal model affects the feasibility condition and a simple anti-windup strategy (conditional integration) must be adopted to ensure boundedness of the internal model states and closed-loop stability.

2.1 Considered system class

In mechatronics, the dominant dynamics of most systems can be modelled as relative-degree-one or relative-degree-two systems with stable internal dynamics (minimum-phase property), known sign of the high-frequency gain and exponentially bounded perturbation (see Hackl (2017)). The following system classes $\mathcal{S}_1^{\text{sat}}$ and $\mathcal{S}_2^{\text{sat}}$ are considered:

Let $n, m \in \mathbb{N}$, $h \geq 0$, $(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}) \in \mathbb{R}^{n\times n} \times \mathbb{R}^n \times \mathbb{R}^n$ and $\boldsymbol{g}\colon [-h, \infty) \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$. A dynamical system, given by the functional differential equation

$$\left.\begin{aligned} \dot{\boldsymbol{x}}(t) &= \boldsymbol{A}\boldsymbol{x}(t) + \boldsymbol{b}\,\text{sat}_{\widehat{u}}\big(u(t) + d_u(t)\big) + \boldsymbol{g}\big(t, \boldsymbol{x}(t), (\mathfrak{T}\boldsymbol{x})(t)\big) \\ y(t) &= \boldsymbol{c}^\top \boldsymbol{x}(t), \qquad \boldsymbol{x}|_{[-h,0]} = \boldsymbol{x}_0(\cdot) \in \mathcal{C}\big([-h, 0]; \mathbb{R}^n\big) \end{aligned}\right\} \tag{1}$$

with input saturation

$$\text{sat}_{\widehat{u}}\colon \mathbb{R} \to [-\widehat{u}, \widehat{u}],\ x \mapsto \text{sat}_{\widehat{u}}(x) := \begin{cases} \widehat{u} & , x \geq \widehat{u} \\ x & , -\widehat{u} < x < \widehat{u} \\ -\widehat{u} & , x \leq -\widehat{u} \end{cases},$$

saturation level $0 < \widehat{u} \leq \infty$, input disturbance $d_u\colon [-h, \infty) \to \mathbb{R}$, operator $\mathfrak{T}\colon \mathcal{C}([-h, \infty); \mathbb{R}^n) \to \mathcal{L}^\infty_{\text{loc}}(\mathbb{R}_{\geq 0}; \mathbb{R}^m)$, control input $u\colon \mathbb{R}_{\geq 0} \to \mathbb{R}$ and regulated output $y(\cdot)$, is of Class $\mathcal{S}_1^{\text{sat}}$ or $\mathcal{S}_2^{\text{sat}}$ *iff the following system properties (sp) hold:*

(sp_1) *For $\mathcal{S}_1^{\text{sat}}$, the relative degree is one and the sign of the high-frequency gain is known, i.e.*

$$r = 1 \iff \gamma_0 := \boldsymbol{c}^\top \boldsymbol{b} \neq 0 \quad \textit{and} \quad \text{sign}(\gamma_0) \textit{ known}; \tag{2}$$

or, for $\mathcal{S}_2^{\text{sat}}$, the relative degree is two and the sign of the high-frequency gain is known, i.e.

$$\begin{aligned} r = 2 \iff \boldsymbol{c}^\top \boldsymbol{b} = 0 \ \wedge\ \gamma_0 := \boldsymbol{c}^\top \boldsymbol{A}\boldsymbol{b} \neq 0 \\ \wedge\ \forall (t, \boldsymbol{x}, \boldsymbol{w}) \in [-h, \infty) \times \mathbb{R}^n \times \mathbb{R}^m\colon \\ \boldsymbol{c}^\top \boldsymbol{g}(t, \boldsymbol{x}, \boldsymbol{w}) = 0 \quad \textit{and} \quad \text{sign}(\gamma_0) \textit{ known}; \end{aligned} \tag{3}$$

(sp_2) *the unperturbed system is minimum-phase, i.e.*

$$\forall\, s \in \mathbb{C}_{\geq 0}\colon \qquad \det \begin{bmatrix} s\boldsymbol{I}_n - \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{c}^\top & 0 \end{bmatrix} \neq 0; \tag{4}$$

(sp_3) *the operator is of class $\mathcal{T}$ (see Ilchmann et al. (2002)) and the input disturbance is bounded, i.e.*

$$\mathfrak{T} \in \mathcal{T} \ \textit{ and } \ d_u(\cdot) \in \mathcal{L}^\infty([-h, \infty); \mathbb{R}); \tag{5}$$

(sp_4) *the function $\boldsymbol{g}\colon [-h, \infty) \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ is a Caratheodory function (see Ilchmann et al. (2002)) and exponentially bounded with respect to the output $y = \boldsymbol{c}^\top \boldsymbol{x}$, i.e. for unknown $q \geq 0$, the following holds*

$$\begin{aligned} \exists M_{\boldsymbol{g}} > 0\, \exists q \geq 0 \,\text{for a.a. } t \in [-h, \infty)\, \forall (\boldsymbol{x}, \boldsymbol{w}) \in \mathbb{R}^n \times \mathbb{R}^m\colon \\ \|\boldsymbol{g}(t, \boldsymbol{x}, \boldsymbol{w})\| \leq M_{\boldsymbol{g}}\big[1 + \exp\big(|\boldsymbol{c}^\top \boldsymbol{x}|^q\big)\big]; \end{aligned} \tag{6}$$

(sp_5) *for $\mathcal{S}_1^{\text{sat}}$, the regulated output $y(\cdot)$ is available for feedback; or, for $\mathcal{S}_2^{\text{sat}}$, the regulated output $y(\cdot)$ and its derivative $\dot{y}(\cdot)$ are available for feedback*

System (1) can represent nonlinear input-saturated dynamical mechatronic systems with bounded input disturbance and exponentially bounded nonlinear perturbations. System examples are speed, position or current controlled electrical drives or elastic servo systems (see Hackl (2017)). Due to the nonlinear perturbation function $\boldsymbol{g}(\cdot, \cdot, \cdot)$, the system dynamics are nonlinear in exogenous (time-varying) signals, system state $\boldsymbol{x}(\cdot)$ and functional perturbation $(\mathfrak{T}\boldsymbol{x})(\cdot)$. Input disturbance $d_u(\cdot)$ in (1) allows to incorporate bounded actuator deviations and/or feedforward commands, whereas time-dependent and functional perturbations in (1) account for e.g. time-varying electrical/mechanical loads and nonlinear friction effects.

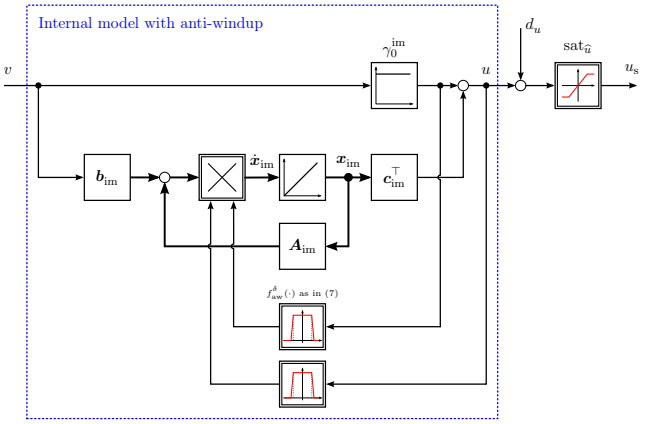


Fig. 2. Internal model (10) with anti-windup due to decision functions (7).

2.2 Funnel controllers for systems of class $\mathcal{S}_1^{\text{sat}}$ and $\mathcal{S}_2^{\text{sat}}$

Despite the existence of several funnel controller variants, in this paper, the most simple funnel controllers with gain scaling for systems of class $\mathcal{S}_1^{\text{sat}}$ and $\mathcal{S}_2^{\text{sat}}$ with tracking error $e(t) = y_{\text{ref}}(t) - y(t)$ are considered:

- Funnel controller for systems of class $\mathcal{S}_1^{\text{sat}}$:

$$v(t) = \text{sign}(\gamma_0) k(t) e(t) \ \textit{ where } \ k(t) = \frac{\varsigma(t)}{\psi(t) - |e(t)|} \tag{FC$_1$}$$

- Funnel controller for systems of class $\mathcal{S}_2^{\text{sat}}$:

$$\begin{aligned} &v(t) = \text{sign}(\gamma_0)\Big(k_0(t)^2 e(t) + k_0(t) k_1(t) \dot{e}(t)\Big) \text{ where} \\ &k_0(t) = \frac{\varsigma_0(t)}{\psi_0(t) - |e(t)|} \text{ and } k_1(t) = \frac{\varsigma_1(t)}{\psi_1(t) - |\dot{e}(t)|}. \end{aligned} \tag{FC$_2$}$$

The gain scaling functions $\varsigma(\cdot)$, $\varsigma_1(\cdot)$ and $\varsigma_2(\cdot)$ and the funnel boundaries $\psi(\cdot)$, $\psi_0(\cdot)$ and $\psi_1(\cdot)$ are element of the Sobolov space (i.e. $\mathcal{W}^{1,\infty}(\mathbb{R}_{\geq 0}, [\lambda, \infty))$), bounded away from zero and have essentially bounded derivatives (for details see (Hackl, 2017, Chapter 9)). The reference signals $y_{\text{ref}}(\cdot)$ are element of $\mathcal{W}^{1,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$ for $\mathcal{S}_1^{\text{sat}}$ systems and of $\mathcal{W}^{2,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R})$ for $\mathcal{S}_2^{\text{sat}}$ systems (see Ilchmann et al. (2002) and Hackl et al. (2013), respectively).

2.3 Internal model with anti-windup

In order to guarantee anti-windup and boundedness of the states of the internal model, a simple conditional integration approach is proposed. To do so, the internal model must be equipped with two anti-windup decision functions (see Fig. 2). The proposed *anti-windup decision functions* are Lipschitz continuous. i.e. $f^{\delta(\cdot)}_{\Delta,\widehat{u}}\colon \mathbb{R}\to[0,1]$,

$$u \mapsto f^{\delta(\cdot)}_{\Delta,\widehat{u}}(u) := \begin{cases} 0, & u < -\widehat{u} \\ \delta(u), & -\widehat{u} \le u \le -\widehat{u}+\Delta \\ 1, & -\widehat{u}+\Delta < u < \widehat{u}-\Delta \\ \delta(-u), & \widehat{u}-\Delta \le u \le \widehat{u} \\ 0, & u > \widehat{u}, \end{cases} \tag{7}$$

where $\Delta > \widehat{u}$ and, for $\mathbb{I}_\Delta := [-\widehat{u}, -\widehat{u}+\Delta] \cup [\widehat{u}-\Delta, \widehat{u}]$,

$$\delta(\cdot) \in \left\{ f(\cdot) \in \mathcal{C}^{\mathrm{L}}\big(\mathbb{I}_\Delta;[0,1]\big) \;\middle|\; \begin{array}{l} f(-\widehat{u}) = f(\widehat{u}) = 0, \;\text{ and} \\ f(\Delta-\widehat{u}) = f(\widehat{u}-\Delta) = 1 \end{array} \right\}.$$

For examples, please refer to (Hackl, 2017, Chapter 10). The following lemma shows that for a proper internal model design in combination with two decision functions, the output of the internal will remain bounded for all time and for any continuous input.

Lemma 1. (Internal model with anti-windup). For $p \in \mathbb{N}$,

$$\left.\begin{aligned} \boldsymbol{A}_{\mathrm{im}} &:= \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ 0 & \dots & \dots & 0 & 1 \\ -\widehat{a}_0 & -\widehat{a}_1 & \dots & -\widehat{a}_{p-2} & -\widehat{a}_{p-1} \end{bmatrix} \in \mathbb{R}^{p\times p}, \\ \boldsymbol{b}_{\mathrm{im}} &:= \begin{pmatrix} 0, & \cdot, & \cdot, & 0, & 1 \end{pmatrix}^\top \in \mathbb{R}^p, \;\text{ and} \\ \boldsymbol{c}_{\mathrm{im}} &:= \begin{pmatrix} \widehat{c}_0, & \dots, & \widehat{c}_{p-1} \end{pmatrix}^\top \in \mathbb{R}^p, \end{aligned}\right\} \tag{8}$$

let the internal model

$$\left.\begin{aligned} \tfrac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x}_{\mathrm{im}}(t) &= \boldsymbol{A}_{\mathrm{im}}\boldsymbol{x}_{\mathrm{im}}(t) + \boldsymbol{b}_{\mathrm{im}}\, v(t) \\ u(t) &= \boldsymbol{c}_{\mathrm{im}}^\top \boldsymbol{x}_{\mathrm{im}}(t) + \gamma_0^{\mathrm{im}} v(t) \end{aligned}\right| \begin{array}{l} \deg(D_{\mathrm{im}}) =: p \in \mathbb{N}, \\ \boldsymbol{x}_{\mathrm{im}}(0) = \boldsymbol{x}^0_{\mathrm{im}} \in \mathbb{R}^p, \\ \operatorname{sign}(\gamma_0^{\mathrm{im}}) = \operatorname{sign}(\gamma_0) \end{array} \tag{9}$$

be a minimal realization. With *anti-windup*, it is given by

$$\left.\begin{aligned} \tfrac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x}_{\mathrm{im}}(t) &= f^{\delta(\cdot)}_{\Delta,\widehat{u}}\Big(\boldsymbol{c}_{\mathrm{im}}^\top \boldsymbol{x}_{\mathrm{im}}(t) + \gamma_0^{\mathrm{im}} v(t)\Big) \cdot f^{\delta(\cdot)}_{\Delta,\widehat{u}}\Big(\gamma_0^{\mathrm{im}} v(t)\Big) \cdot \\ &\quad \cdot \Big[\boldsymbol{A}_{\mathrm{im}}\boldsymbol{x}_{\mathrm{im}}(t) + \boldsymbol{b}_{\mathrm{im}}\, v(t)\Big] \\ u(t) &= \underbrace{\boldsymbol{c}_{\mathrm{im}}^\top \boldsymbol{x}_{\mathrm{im}}(t)}_{=:u_{\mathrm{im}}(t)} + \gamma_0^{\mathrm{im}} v(t), \;\; \boldsymbol{x}_{\mathrm{im}}(0) = \boldsymbol{x}^0_{\mathrm{im}} \in \mathbb{R}^p \end{aligned}\right| \text{with } (\boldsymbol{A}_{\mathrm{im}}, \boldsymbol{b}_{\mathrm{im}}, \boldsymbol{c}_{\mathrm{im}}) \text{ as in (8) and } f^{\delta(\cdot)}_{\Delta,\widehat{u}}(\cdot) \text{ as in (7)} \tag{10}$$

and, for $\widehat{u} > \Delta > 0$, $v(\cdot) \in \mathcal{C}(\mathbb{R}_{\ge 0};\mathbb{R})$, the following hold:

(i) there exists a unique solution $\boldsymbol{x}_{\mathrm{im}}\colon [0,T) \to \mathbb{R}^p$, $T \in (0,\infty]$ which can be maximally extended;
(ii) the solution $\boldsymbol{x}_{\mathrm{im}}\colon [0,T) \to \mathbb{R}^p$ is global, i.e. $T = \infty$;
(iii) the sub-output $u_{\mathrm{im}}(\cdot) = \boldsymbol{c}_{\mathrm{im}}^\top \boldsymbol{x}_{\mathrm{im}}(\cdot)$ of the internal model (10) is uniformly bounded, i.e.

$$\forall\, t \ge 0\colon\; |u_{\mathrm{im}}(t)| \le M_{u_{\mathrm{im}}} := \max\{\widehat{u}, |\boldsymbol{c}_{\mathrm{im}}^\top \boldsymbol{x}^0_{\mathrm{im}}|\} + \widehat{u}; \tag{11}$$

(iv) there exists $M_{\boldsymbol{x}_{\mathrm{im}}} \ge 1$ such that $\|\boldsymbol{x}_{\mathrm{im}}(t)\| \le M_{\boldsymbol{x}_{\mathrm{im}}}$ for all $t \ge 0$, if the polynomial $\widehat{N}_{\mathrm{im}}(s) = \widehat{c}_{p-1}\, s^{p-1} + \dots + \widehat{c}_1\, s + \widehat{c}_0$ is Hurwitz.

The proof can be found in (Hackl, 2017, Lemma 10.6).

2.4 Closed-loop system

In Hopfe et al. (2010) and Hackl et al. (2013), it was shown that funnel control is applicable for input-saturated relative-degree-one and relative-degree-two systems (of e.g. class $\mathcal{S}_1^{\mathrm{sat}}$ or $\mathcal{S}_2^{\mathrm{sat}}$), if a feasibility condition $\boxed{\widehat{u}_{\mathrm{feas}} \le \widehat{u} < \infty}$ is satisfied. The feasibility bound $\widehat{u}_{\mathrm{feas}}$ depends on system parameters, disturbances, perturbations, internal dynamics and controller design (e.g. funnel boundary). It is usually (very) conservative. In view of Lemma 1, the internal model with anti-windup is uniformly bounded and can be considered as globally bounded input perturbation to the input-saturated system of class $\mathcal{S}_1^{\mathrm{sat}}$ or $\mathcal{S}_2^{\mathrm{sat}}$. Therefore, the feasibility bound $\widehat{u}_{\mathrm{feas}}$ must be adjusted and will also depend on the output bound $M_{u_{\mathrm{im}}}$ as in (11) of the internal model. Due to space limitations, full theorems and proofs are omitted but can be found in Chapter 10 of Hackl et al. (2017) for system class $\mathcal{S}_1^{\mathrm{sat}}$ and $\mathcal{S}_2^{\mathrm{sat}}$ (see Theorem 10.7 and Theorem 10.9, respectively).

3. IMPLEMENTATION AND SIMULATION RESULTS

To illustrate the difference between the closed-loop performance of IM-funnel controller (FC$_2$)+(9) *without* anti-windup [——] and IM-funnel controller (FC$_2$)+(10) *with* anti-windup [——], both are applied to a simple system

$$\left.\begin{aligned} \ddot{y}(t) &= \gamma_0 \underbrace{\operatorname{sat}_{\widehat{u}}\big(u(t)\big)}_{=:u_{\mathrm{s}}(t)}, \\ &\text{with } \gamma_0 = 3 \text{ and } \widehat{u} = 7, \end{aligned}\right| \; (y(0),\dot{y}(0))^\top = (0,0)^\top \in \mathbb{R}^2, \tag{12}$$

with relative degree two and input saturation. The saturated input is denoted by u_{s}. Output $y(\cdot)$ and its derivative $\dot{y}(\cdot)$ are available for feedback. It is easy to see that, for known $\operatorname{sign}(\gamma_0)$, system (12) is element of class $\mathcal{S}_2^{\mathrm{sat}}$ and, hence, IM-funnel control (FC$_2$)+(10) *with* anti-windup is admissible if $\widehat{u}$ is sufficiently large. The chosen reference $y_{\mathrm{ref}}(\cdot)$ (see Fig. 3a) allows for an internal model design to reduplicate a constant signal and a sinusoidal signal with angular frequency $\omega_0 = 2\pi 0.5 = \pi\,\frac{\mathrm{rad}}{\mathrm{s}}$. The design yields

$$F_{\mathrm{im}}(s) = 1 + \frac{9\,s^2 + (27-\omega_0^2)\,s + 27}{s^3 + \omega_0^2 s} =: 1 + \frac{\widehat{N}_{\mathrm{im}}(s)}{D_{\mathrm{im}}(s)} \tag{13}$$

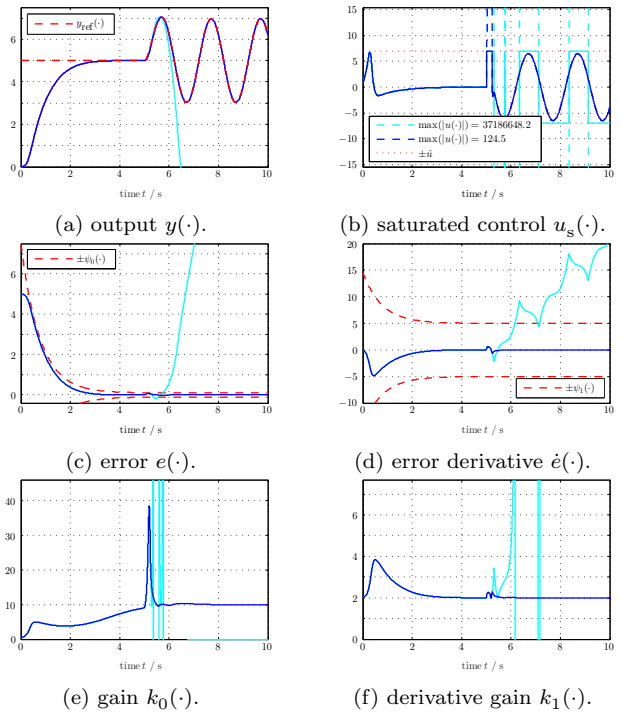
in the frequency domain. Clearly, (13) has positive high-frequency gain $\gamma_0^{\mathrm{im}} = 1$ and it is minimum-phase as the numerator $\widehat{N}_{\mathrm{im}}(s) = 9\,s^2 + (27-\omega_0^2)\,s + 27$ is Hurwitz for all $\omega_0^2 < 27$. To implement the internal model (10) with anti-windup in state space, a minimal realization of (13) must be found resulting in the following internal model system matrix and input and output coupling vectors

$$\boldsymbol{A}_{\mathrm{im}} := \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & -\omega_0^2 & 0 \end{bmatrix},\; \boldsymbol{b}_{\mathrm{im}} := \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \text{ and } \boldsymbol{c}_{\mathrm{im}} := \begin{pmatrix} 27 \\ (27-\omega_0^2) \\ 9 \end{pmatrix}. \tag{14}$$

The implemented anti-windup decision function $f^{\delta(\cdot)}_{\Delta,\widehat{u}}(\cdot)$ has the parameters $\Delta = 0.5$ and $\widehat{u} = 7$ and the function

$$\delta\colon \mathbb{I}_\Delta \to [0,1],\; u \mapsto \delta(u) := \tfrac{1}{2}\Big(\sin\big(\tfrac{\pi}{\Delta}(u+\widehat{u}) - \tfrac{\pi}{2}\big) + 1\Big)$$

was used. The funnel controller (FC$_2$) is equipped with exponential funnel boundary $(\psi_0(t), \psi_1(t)) := \big((\Lambda_0 - \lambda_0)\exp\left(-\frac{t}{T_{\mathrm{exp}}}\right) + \lambda_0,\, \frac{\Lambda_0-\lambda_0}{T_{\mathrm{exp}}}\exp\left(-\frac{t}{T_{\mathrm{exp}}}\right) + \lambda_1\big)^\top$ (with $\Lambda_0 = 7.5$, $\lambda_0 = 0.1$, $T_{\mathrm{exp}} = 0.77\,\mathrm{s}$ and $\lambda_1 = 5$) and gain scaling functions $\varsigma_0(t) = \psi_0(t)$ and $\varsigma_1(t) = 2\,\psi_1(t) =$

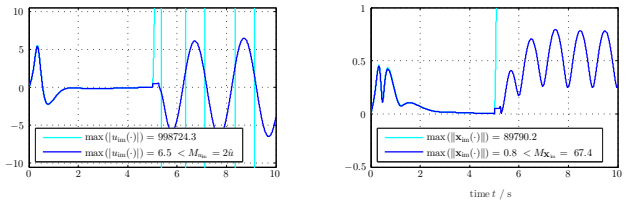


(a) output $y(\cdot)$. (b) saturated control $u_{\mathrm{s}}(\cdot)$.

(c) error $e(\cdot)$. (d) error derivative $\dot{e}(\cdot)$.

(e) gain $k_0(\cdot)$. (f) derivative gain $k_1(\cdot)$.

Fig. 3. Simulation results for set-point tracking of input-saturated closed-loop systems (12), (FC_2)+(9) *without* anti-windup [——] and (12), (FC_2)+(10) *with* anti-windup [——].



(a) IM sub-output $u_{\mathrm{im}}(\cdot)$. (b) norm of IM state $\|\boldsymbol{x}_{\mathrm{im}}(\cdot)\|$.

Fig. 4. Simulation results for internal model (IM) sub-output and state of input-saturated closed-loop systems (12), (FC_2)+(9) *without* anti-windup [——] and ——(12), (FC_2)+(10) *with* anti-windup [——].

$2\psi_1(t)$. The closed-loop systems (12), (FC_2)+(9) [——] and (12), (FC_2)+(10) [——] are implemented in Matlab/Simulink with numerical solver `ode4 (Runge-Kutta)` and fixed-step size of $1\cdot10^{-4}$ s. The comparative simulation is run for 10 s. Control objective is reference tracking of $y_{\mathrm{ref}}(\cdot)$ as depicted in Fig. 3a. The simulation results are shown in Fig. 3 and Fig. 4. Due to *windup* of the internal model state $\boldsymbol{x}_{\mathrm{im}}(\cdot)$, the IM-funnel controller (FC_2)+(9) *without* anti-windup [——] becomes unstable. Its control action $u(\cdot)$ is saturated for almost all time $t \geq 5$ s. The error and its derivative cross their respective funnel boundaries at ≈ 5.8 s and ≈ 6.2 s, respectively. Accordingly, the gains $k_0(\cdot)$ and $k_1(\cdot)$ of the IM-funnel controller (FC_2)+(9) *without* anti-windup [——] change their signs and eventually diverge. In contrast, the IM-funnel controller (FC_2)+(10) *with* anti-windup [——] ensures tracking with prescribed transient accuracy. Its gains remain bounded. Moreover, due to conditional integration, the norm of the state $\|\boldsymbol{x}_{\mathrm{im}}(\cdot)\|$ and the output $u_{\mathrm{im}}(\cdot)$ of the internal model (10) *with* anti-windup [——] remains much smaller than that of IM-funnel controller (FC_2)+(9) *without* anti-windup [——]. Both bounds, $M_{u_{\mathrm{im}}} = 2\widehat{u} = 14$ and $M_{\boldsymbol{x}_{\mathrm{im}}} = 67.4$ are by far exceeded by the IM-funnel control (FC_2)+(9) *without* anti-windup [——], whereas the closed-loop system with IM-funnel controller (FC_2)+(10) *with* anti-windup [——] does *not* get close to both bounds.

4. CONCLUSION

Funnel control with internal model and anti-windup for input-saturated systems with relative degree one or two has been discussed. It has been shown that internal models are beneficial to improve asymptotic accuracy of the closed-loop system. However, in presence of input saturation the internal model must be equipped with an anti-windup strategy (conditional integration) to assure uniform boundedness of the internal model and to avoid instability of the closed-loop system. The well-known feasibility condition of funnel control for input-saturated systems must be adjusted in view of the ultimate boundedness of the internal model. Then, available results (theorems) can be re-applied to establish closed-loop system stability. Simulation results were presented to illustrate the beneficial aspects of internal models with anti-windup. The talk will discuss several mechatronic applications in more detail.

Input-constrained funnel control of nonlinear systems ⋆

Thomas Berger *

* *Institut für Mathematik, Universität Paderborn, Warburger Str. 100, 33098 Paderborn, Germany (e-mail: thomas.berger@math.upb.de).*

Abstract: We consider tracking control for uncertain nonlinear multi-input, multi-output systems modelled by functional differential equations, in the presence of input constraints. The objective is to guarantee the evolution of the tracking error within a performance funnel with prescribed asymptotic shape. We design a novel funnel controller which, in order to satisfy the input constraints, contains a dynamic component which widens the funnel boundary whenever the input saturation is active. This design is model-free, of low-complexity and extends earlier funnel control approaches.

Keywords: nonlinear systems, adaptive control, funnel control, input constraints, functional differential equations
AMS subject classifications: 93B52, 93C10, 93C40

1. INTRODUCTION

We study funnel control for the class of nonlinear systems modelled by the r-th order functional differential equation

$$\begin{aligned} y^{(r)}(t) &= f\big(d(t), T(y, \dot{y}, \ldots, y^{(r-1)})(t), u(t)\big), \\ y|_{[-h,0]} &= y^0 \in C^{r-1}([-h,0], \mathbb{R}^m), \end{aligned} \tag{1}$$

with unknown nonlinear function $f \in C(\mathbb{R}^p \times \mathbb{R}^q \times \mathbb{R}^m, \mathbb{R}^m)$ and unknown operator T which satisfy a sector bound property (see Section 1.1), unknown bounded disturbance d and unknown initial trajectory y^0 in the presence of input constraints

$$u(t) = \mathrm{sat}(v(t)) \tag{2}$$

with *known* saturation function sat and control function v provided by the to-be-designed controller. Here, we propose a novel control design, which is feasible for the aforementioned class of systems, i.e., it satisfies the input constraints imposed by (2), and achieves tracking of a given reference signal with prescribed performance of the tracking error whenever the saturation is not active, that is $u(t) = v(t)$ – in this case the controller exhibits the same performance as the funnel controllers proposed in Berger et al. (2021, 2018). When the saturation is active the performance funnel, which defines the domain for the evolution of the tracking error, is widened according to a dynamic equation describing the funnel boundaries, so that the input constraints are still met. As soon as the saturation becomes inactive again, the performance funnel recovers its desired shape exponentially fast.

The concept of funnel control was developed in the seminal work (Ilchmann et al., 2002) (see also the recent survey in Berger et al. (2021)) and proved advantageous in a variety of applications such as control of industrial servo-systems (Hackl, 2017), electrical circuits (Berger and Reis, 2014), peak inspiratory pressure (Pomprapa et al., 2015) and adaptive cruise control (Berger and Rauert, 2020).

Funnel control with input saturation was first investigated in Ilchmann and Trenn (2004) for the specific application of chemical reactor models and in a more general context in Hopfe et al. (2010a,b) for systems with relative degree one and in Hackl et al. (2013) for systems with relative degree two; this approach has been applied to funnel control with anti-windup for synchronous machines in Hackl (2015). However, in the aforementioned works it was simply shown that classical funnel control is feasible for a sufficiently large saturation bound – here this bound can be arbitrarily small. Another approach to funnel control with guaranteed input constraints is bang-bang funnel control, introduced in Liberzon and Trenn (2013) for (undisturbed) nonlinear single-input, single-output systems with arbitrary relative degree. However, the bang-bang funnel control design requires various complicated feasibility assumptions and in particular the two control values must be sufficiently large.

A relative of funnel control is prescribed performance control, developed in Bechlioulis and Rovithakis (2008), see also the important work Bechlioulis and Rovithakis (2014) where the complexity issue of this approach has been solved. The problem of input constraints has been addressed within this approach e.g. in Li and Xiang (2018), where neural networks are used to approximate the nonlinearities, and in Cheng et al. (2019), where additionally a neural observer is incorporated in the controller design. In the work Wang et al. (2019) no approximations are needed (and hence the controller is of low complexity), however the proof contains an error and simulations also show that the proposed controller is infeasible in general. The problem is that the scaling parameter κ in the χ-dynamics is chosen as a constant, but actually it needs to depend on the input.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Funnel control for systems with arbitrary relative degree was considered in Berger et al. (2021, 2018). The novel input-constrained funnel control design that we propose here extends these approaches in the following aspects:

- Compared to Berger et al. (2018) a much more general class of systems is allowed here, similar to Berger et al. (2021). However, we do not require the restrictive high-gain property of the nonlinearity f or the minimum phase property (characterized by a BIBO property of the operator T) imposed in Berger et al. (2021). On the other hand, we require a sector bound property of f and T. This condition cannot be dispensed in general, because of the input saturation.
- The new controller is able to handle arbitrary input constraints (2). Even if the saturation is never active, i.e., $u(t) = v(t)$ for all $t \geq 0$ for any solution of the closed-loop system, then the new controller is able to guarantee a prescribed performance of the tracking error as in Berger et al. (2021, 2018), with exponentially decaying funnel boundaries.

1.1 System Class

We consider functional differential equations of the form (1) incorporating an operator T of the following class.

Definition 1. For $n, q \in \mathbb{N}$ and $h \geq 0$ the set $\mathbb{T}_h^{n,q}$ denotes the class of operators $T\colon C([-h,\infty),\mathbb{R}^n) \to L^\infty_{\mathrm{loc}}(\mathbb{R}_{\geq 0},\mathbb{R}^q)$ with the following properties.

(P1) T is causal, i.e., for all ζ, $\xi \in C([-h,\infty),\mathbb{R}^n)$ and all $t \geq 0$,

$$\zeta|_{[-h,t]} = \xi|_{[-h,t]} \quad \Longrightarrow \quad T(\zeta)|_{[0,t]} = T(\xi)|_{[0,t]}.$$

(P2) T is locally Lipschitz, i.e., for each $t \geq 0$ and all $\xi \in C([-h,t],\mathbb{R}^n)$, there exist positive constants $c_0, \delta, \tau > 0$ such that, for all $\zeta_1, \zeta_2 \in C([-h,\infty),\mathbb{R}^n)$ with $\zeta_i|_{[-h,t]} = \xi$ and $\|\zeta_i(s) - \xi(t)\| < \delta$ for all $s \in [t, t+\tau]$ and $i = 1, 2$, we have

$$\operatorname*{ess\,sup}_{s\in[t,t+\tau]} \|T(\zeta_1)(s) - T(\zeta_2)(s)\| \leq c_0 \sup_{s\in[t,t+\tau]} \|\zeta_1(s) - \zeta_2(s)\|.$$

(P3) T locally maps bounded functions to bounded functions, i.e., for all $\tau > 0$ and all $c_1 > 0$, there exists $c_2 > 0$ such that, for all $\zeta \in C([-h,\tau],\mathbb{R}^n)$,

$$\sup_{t\in[-h,\tau]} \|\zeta(t)\| \leq c_1 \quad \Longrightarrow \quad \operatorname*{ess\,sup}_{t\in[0,\tau]} \|T(\zeta)(t)\| \leq c_2.$$

We stress that property (P3) in the operator class $\mathbb{T}_h^{n,q}$ is weaker than the respective property required in Berger et al. (2021, 2018), where it essentially needs to hold for "$\tau = \infty$" (and hence corresponds to a minimum phase property), while for our purposes a local version suffices.

Next we introduce a sector bound property of $f \in C(\mathbb{R}^p \times \mathbb{R}^q \times \mathbb{R}^m, \mathbb{R}^m)$ and $T \in \mathbb{T}_h^{rm,q}$ as follows.

(P4) For all $y^0 \in C^{r-1}([-h,0],\mathbb{R}^m)$ there exist $M_1, \ldots, M_{r+1} \in C(\mathbb{R}_{\geq 0} \times \mathbb{R}^p \times \mathbb{R}^m, \mathbb{R}_{\geq 0})$ such that for all $t \geq 0$, all $(d, v) \in \mathbb{R}^p \times \mathbb{R}^m$ and all $\zeta_1, \ldots, \zeta_r \in C([-h,t],\mathbb{R}^m)$ we have:

$$\|f(d, T(\zeta_1, \ldots, \zeta_r)(t), v)\| \leq M_1(t,d,v) + M_2(t,d,v)\|\zeta_1|_{[-h,t]}\|_\infty + \ldots + M_{r+1}(t,d,v)\|\zeta_r|_{[-h,t]}\|_\infty$$

Note that the functions M_i in (P4) depend on the initial history y^0 in (1). We like to note that the sector bound property (P4) cannot be dispensed in the presence of (arbitrary) input constraints in general. Otherwise, already for simple system of the form

$$\dot{y}(t) = y(t)^2 + u(t), \quad y(0) = 1, \quad u(t) = \mathrm{sat}(v(t))$$

solutions may exhibit a blow-up when the input constraints are "too tight".

We are now in the position to define the class of systems to be considered here. We stress that the high-gain property of system (1) required in earlier approaches, see e.g. Berger et al. (2021), is not needed here.

Definition 2. For $m, r \in \mathbb{N}$ we say that system (1) belongs to the system class $\mathcal{N}^{m,r}$, written $(d, f, T) \in \mathcal{N}^{m,r}$, if $d \in L^\infty(\mathbb{R}_{\geq 0},\mathbb{R}^p)$, $f \in C(\mathbb{R}^p \times \mathbb{R}^q \times \mathbb{R}^m, \mathbb{R}^m)$, $T \in \mathbb{T}_h^{rm,q}$ for some $p, q \in \mathbb{N}$, $h \geq 0$ and (f, T) satisfy property (P4).

In contrast to earlier approaches as in Berger et al. (2021, 2018), here we consider an additional function sat in (1), which represents an input saturation. If $\mathrm{sat} = \mathrm{id}_{\mathbb{R}^m}$, then the results from Berger et al. (2021, 2018) could be applied. For this reason, we consider a proper input saturation, which has the following, quite general, property.

(P5) $\mathrm{sat} \in C(\mathbb{R}^m, \mathbb{R}^m)$ is bounded and there exists $\theta > 0$ such that for all $v \in \mathbb{R}^m$ with $\|v\| \leq \theta$ we have $\mathrm{sat}(v) = v$.

We stress that the input saturation function sat must be known to the controller and it can be viewed as a design parameter, chosen according to the specific requirements of the application at hand. The above property (P5) allows for a large variety of possible saturations, apart from the standard saturation $\mathrm{sat}_i(v) = v_i$ for $|v_i| \leq M$ and $\mathrm{sat}_i(v) = \mathrm{sgn}(v_i)M$ for $|v_i| > M$ for all $i = 1, \ldots, m$.

1.2 Control objective

The objective is to design a dynamic output derivative feedback strategy such that for any reference signal $y_{\mathrm{ref}} \in C^r(\mathbb{R}_{\geq 0},\mathbb{R}^m)$ the tracking error $e = y - y_{\mathrm{ref}}$ evolves within a performance funnel

$$\mathcal{F}_\psi := \{\, (t,e) \in \mathbb{R}_{\geq 0} \times \mathbb{R}^m \mid \|e\| < \psi(t) \,\},$$

see Fig. 1, which has a prescribed shape of the form $\psi(t) = ae^{-bt} + c$ whenever the saturation in (2) is not active, i.e., $\mathrm{sat}(v(t)) = v(t)$, and $\psi(t)$ is allowed to become larger when the saturation is active. The specific shape of the performance funnel should be determined by a dynamic part of the control law.

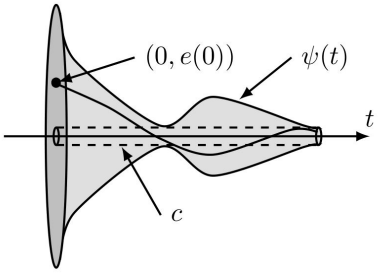

Fig. 1. Error evolution in a funnel $\mathcal{F}_\psi$ with boundary $\psi(t)$.

It is usually the hallmark of funnel control that the funnel boundary is prescribed a priori and can be freely chosen by

the designer, see e.g. Berger et al. (2021, 2018); Ilchmann et al. (2002). Here we do not allow for an arbitrary funnel boundary in order to be able to change its shape by means of a differential equation. However, we allow to prescribe the "asymptotic shape" $\psi(t) = ae^{-bt} + c$ under inactive saturation, that is the positive parameters a, b, c can be chosen as desired.

2. FUNNEL CONTROL STRUCTURE

We introduce the following input-constrained funnel controller for systems (1), (2).

$$\begin{aligned}
e_1(t) &= e(t) = y(t) - y_{\mathrm{ref}}(t),\\
e_{i+1}(t) &= e^{(i)}(t) + k_i(t)e_i(t), \quad i = 1, \dots, r-1,\\
k_i(t) &= \Big(1 - \tfrac{\|e_i(t)\|^2}{\psi_i(t)^2}\Big)^{-1}, \quad i = 1, \dots, r,\\
\dot{\psi}_i(t) &= p_i\psi_{i+1}(t) - \alpha_i\psi_i(t) + \beta_i - p_i\tfrac{\beta_{i+1}}{\alpha_{i+1}},\\
\psi_i(0) &= \psi_i^0, \qquad\qquad i = 1, \dots, r-1,\\
\dot{\psi}_r(t) &= -\alpha_r\psi_r(t) + \beta_r + \psi_r(t)\tfrac{\kappa(v(t))}{\|e_r(t)\|},\\
\psi_r(0) &= \psi_r^0,\\
\kappa(v(t)) &= \|v(t) - \mathrm{sat}(v(t))\|,\\
v(t) &= N\big(k_r(t)\big)e_r(t)
\end{aligned} \tag{3}$$

with the controller design parameters

$$\begin{aligned}
&\alpha_1 > \alpha_2 > \ldots > \alpha_r > 0,\ p_i > 1 \ \text{ for } i = 1, \dots, r-1,\\
&\beta_i > 0,\ \psi_i^0 > \frac{\beta_i}{\alpha_i} \ \text{ for } i = 1, \dots, r,\\
&N \in C(\mathbb{R}_{\geq 0}, \mathbb{R}) \ \text{ a surjection.}
\end{aligned} \tag{4}$$

Furthermore in (3) we assume that the instantaneous values of the output $y(t)$ and its derivatives $\dot{y}(t), \dots, y^{(r-1)}(t)$ are available for feedback, thus (3) is a dynamic output derivative feedback controller.

The first three equations of the controller (3) are basically a combination of the two designs from Berger et al. (2021, 2018), appended by the dynamics for the funnel boundaries in the subsequent three equations. This contrasts classical funnel control approaches, where the performance funnels are always prescribed a priori. Here, they are determined by a dynamical system, which is influenced by the input and an auxiliary error variable. Since the funnel functions are then used to determine these quantities in turn, a feedback structure arises, for which we seek to prove existence of global solutions.

The surjective function N in (4) serves the purpose of accommodating for possibly unknown control directions. With its help the controller is able to "probe" for the appropriate sign of the control signal. For more details see also (Berger et al., 2021, Rem. 1.8).

The distinguishing feature of the novel control design (3) is that it is feasible under arbitrary input constraints (2). The controller (3) always guarantees the evolution of the tracking error within a performance funnel, whose boundary is determined by a dynamic part of the controller as mentioned above. If the saturation is not active, then (asymptotically) the funnel boundary is of the form $\psi(t) = ae^{-bt} + c$ with positive design parameters a, b, c; if the saturation is active, i.e., $v(t) \neq \mathrm{sat}(v(t))$, then the boundary is widened by the dynamics of the controller in order to guarantee the input constraints. After a period of active saturation, the boundary recovers to its prescribed shape exponentially fast.

We emphasize that the controller (3) introduces several possible singularities in the closed-loop differential equation. In order to prove the existence of a global solution, it must be ensured that $\|e_i(t)\| \leq \varepsilon_i\psi_i(t)$ for some $\varepsilon_i \in (0,1)$ and that $\kappa(v(t)) = 0$ whenever $\|e_r(t)\| < \delta$ for some $\delta > 0$. Furthermore, compared to classical funnel control approaches as in Berger et al. (2021, 2018), the funnel boundaries ψ_i are not prescribed here, and in particular it is not known a priori that they are bounded. Hence, solutions may potentially get unbounded in finite time, i.e., exhibit a blow-up. Therefore, the feasibility proof of the control design is a highly nontrivial task.

3. FUNNEL CONTROL – MAIN RESULTS

In this section we show that the application of the funnel controller (3) to a system (1) under input constraints (2) leads to a closed-loop initial-value problem which has a global solution. By a solution of (1), (2), (3) on $[-h, \omega)$ we mean a tuple of functions $(y, \psi_1, \dots, \psi_r) \in C^{r-1}([-h,\omega), \mathbb{R}^m) \times C([-h,\omega), \mathbb{R})^r$ with $\omega \in (0, \infty]$, which satisfies $y|_{[-h,0]} = y^0$, $\psi_i(0) = \psi_i^0$ for all $i = 1, \dots, r$ and $(y^{(r-1)}, \psi_1, \dots, \psi_r)|_{[0,\omega)}$ is locally absolutely continuous and satisfies the differential equations in (1) and (3) with u defined by (2), (3) for almost all $t \in [0, \omega)$; $(y, \psi_1, \dots, \psi_r)$ is called maximal, if it has no right extension that is also a solution.

Next we present the main result.

Theorem 3. Consider a system (1) with $(d, f, T) \in \mathcal{N}^{m,r}$ for $m, r \in \mathbb{N}$, under input saturation (2) with saturation function sat that satisfies (P5). Let $y^0 \in C^{r-1}([-h, 0], \mathbb{R}^m)$ be the initial trajectory, $y_{\mathrm{ref}} \in C^r(\mathbb{R}_{\geq 0}, \mathbb{R}^m)$ the reference signal and choose funnel control design parameters as in (4). Set $e = y - y_{\mathrm{ref}}$ and assume that the instantaneous values $e(t), \dot{e}(t), \dots, e^{(r-1)}(t)$ are available for feedback and satisfy, using the variables $e_1, \dots, e_r$ defined in (3), that

$$\forall\, i = 1, \dots, r: \ \|e_i(0)\| < \psi_i^0. \tag{5}$$

Then the funnel controller (3) applied to (1), (2) yields an initial-value problem which has a solution, every solution can be maximally extended and every maximal solution $(y, \psi_1, \dots, \psi_r) : [-h, \omega) \to \mathbb{R}^{m+r}$, $\omega \in (0, \infty]$, has the following properties:

(1) global existence: $\omega = \infty$;
(2) the functions $e_1, \dots, e_r$ evolve in their respective performance funnels in the sense:
$$\forall\, i = 1, \dots, r-1\ \exists\, \varepsilon_i \in (0,1)\ \forall\, t \geq 0: \\ \|e_i(t)\| \leq \varepsilon_i\psi_i(t) \quad \text{and} \quad \|e_r(t)\| < \psi_r(t);$$
(3) if the saturation is not active on some interval $[t_0, t_1) \subseteq \mathbb{R}_{\geq 0}$ with $t_1 \in (t_0, \infty]$, i.e., $v(t) = \mathrm{sat}(v(t))$ for all $t \in [t_0, t_1)$, then the performance funnels exponentially recover to their prescribed shape, i.e.,
$$\psi_i(t) \leq \tfrac{\beta_i}{\alpha_i} + \sum\nolimits_{j=i}^{r} \mu_j(t_0)\nu_{ij}e^{-\alpha_j(t-t_0)}$$

for all $i = 1, \dots, r$ and all $t \in [t_0, t_1)$, where $\mu_i(t_0) := \psi_i(t_0) - \frac{\beta_i}{\alpha_i}$, $\nu_{ii} := 1$ and $\nu_{ij} := \prod_{k=i}^{j-1} \frac{p_k}{\alpha_k - \alpha_j}$ for $i = 1, \dots, r$ and $j = i+1, \dots, r$.

We stress that although Theorem 3 provides the existence of a global solution of the closed-loop system, it cannot be concluded that the funnel boundaries $\psi_1, \dots, \psi_r$ are bounded in general. However, statement (iii) provides that *a posteriori* the funnel boundaries recover to their prescribed shape on any interval where the saturation is not active; in particular, if $t_1 = \infty$, then they are bounded.

Nevertheless, it is possible to show global boundedness of $\psi_1, \dots, \psi_r$ for sufficiently large saturation bound, i.e., $\mathrm{sat}(v) = v$ for all $v \in \mathbb{R}^m$ with $\|v\| \leq M$ and $M > 0$ sufficiently large. For this we require additional assumptions, i.e., a bounded reference signal with bounded derivatives and the system class $\mathcal{N}_{\mathrm{BIR}}^{m,r}$ considered for funnel control in Berger et al. (2021). We do not recall the precise definition of $\mathcal{N}_{\mathrm{BIR}}^{m,r}$ here, which can be found in (Berger et al., 2021, Def. 1.5), but only highlight the differences with $\mathcal{N}^{m,r}$: For $\mathcal{N}_{\mathrm{BIR}}^{m,r}$ property (P3) needs to hold with "$\tau = \infty$" (and hence becomes a bounded-input, bounded-output stability property) and system (1) needs to satisfy an additional high-gain property.

Theorem 4. Consider a system (1) with $(d, f, T) \in \mathcal{N}_{\mathrm{BIR}}^{m,r}$ for $m, r \in \mathbb{N}$. Choose funnel control design parameters as in (4), $\varepsilon \in (0,1)$ and $K > 0$. Then there exists $M > 0$ (depending on ε and K) such that

- for all saturation functions sat which satisfy (P5) with $\theta = M$,
- for all $y^0 \in C^{r-1}([-h, 0], \mathbb{R}^m)$ with $\|e_i(0)\| \leq \varepsilon \psi_i^0$, $i = 1, \dots, r$, and
- for all $y_{\mathrm{ref}} \in W^{r,\infty}(\mathbb{R}_{\geq 0}, \mathbb{R}^m)$ with $\|y_{\mathrm{ref}}^{(i)}\|_\infty \leq K$, $i = 0, \dots, r$,

there exists a solution $(y, \psi_1, \dots, \psi_r) : [-h, \omega) \to \mathbb{R}^{m+r}$, $\omega \in (0, \infty]$, of (1), (2), (3) which can be maximally extended to a global solution (i.e., $\omega = \infty$) that satisfies

(1) $y \in W^{r,\infty}([-h, \infty), \mathbb{R}^m)$ and $\psi_i \in L^\infty(\mathbb{R}_{\geq 0}, \mathbb{R})$ for $i = 1, \dots, r$;
(2) $k_i \in L^\infty(\mathbb{R}_{\geq 0}, \mathbb{R})$ for $i = 1, \dots, r$ and $v \in L^\infty(\mathbb{R}_{\geq 0}, \mathbb{R}^m)$ with $\|v(t)\| \leq M$ for all $t \geq 0$, for the quantities defined in (3).

We stress that Theorem 4 provides an explicit relation between the initial values and the saturation bound M. The initial values $y(0), \dot{y}(0), \dots, y^{(r-1)}(0)$ are essentially confined to a bounded set, the size of which is quantified by $\varepsilon \in (0,1)$, for which the relations $\|e_i(0)\| \leq \varepsilon \psi_i^0$ hold for $i = 1, \dots, r$. If ε is made smaller, allowing only a smaller set of initial values, then it is also possible to choose a smaller saturation bound M in general (although $M \geq M^* > 0$ even for $\varepsilon \to 0$ and $K \to 0$, where M^* depends on the system and controller parameters).

Abstract: We consider tracking control of linear minimum phase systems with known arbitrary relative degree which are subject to possible output measurement losses. We provide a control law which guarantees the evolution of the tracking error within a (shifted) prescribed performance funnel whenever the output signal is available. The result requires a maximal duration of measurement losses and a minimal time of measurement availability, which both strongly depend on the internal dynamics of the system, and are derived explicitly.

Keywords: linear systems, funnel control, output tracking, measurement losses, minimum phase
AMS subject classifications: 93B52, 93C05, 93C40

1. INTRODUCTION

We study output tracking for linear minimum phase systems with arbitrary relative degree under possible output measurement losses. Such phenomena are of significant practical relevance whenever signals are transmitted over large distances or via digital communication networks and may hence be prone to signal losses or package dropouts. In the presence of output measurement losses the performance of closed-loop control strategies may seriously deteriorate and even lead to instability. In the present paper we present a reliable strategy for linear systems which is able to guarantee a prescribed margin for the tracking error and after any period of possible output measurement losses it is able to recapture the error within this time-varying margin by appropriately shifting it.

Output measurement losses are typically considered within the framework of networked control systems, see e.g. García-Rivera and Barreiro (2007); Wang and Yang (2009); Cloosterman et al. (2010); Nešić and Teel (2004). Within this approach, event-triggered controllers have been designed in order to guarantee global asymptotic stability, see Lehmann and Lunze (2012); Blind and Allgöwer (2014); Linsenmayer et al. (2019) for linear systems and Wang and Lemmon (2011); Dolk and Heemels (2017) for nonlinear systems. H_∞ control approaches have been considered in Gao and Chen (2008); Tang et al. (2016) and model predictive control in de la Pena and Christofides (2007); Lješnjanin et al. (2014). However, as far as the authors are aware, tracking control with prescribed performance bounds for the tracking error has not yet been considered. To achieve this, in the present paper we use the methodology of funnel control.

The concept of funnel control goes back to the seminal work Ilchmann et al. (2002), see also the survey in Berger et al. (2021c). The funnel controller proved to be the appropriate tool for tracking problems in various applications such as control of industrial servo-systems Hackl (2017) and underactuated multibody systems Berger et al. (2021b, 2019), control of electrical circuits Berger and Reis (2014); Senfelds and Paugurs (2014), control of peak inspiratory pressure Pomprapa et al. (2015), adaptive cruise control Berger and Rauert (2020) and even the control of infinite-dimensional systems such as a boundary controlled heat equation Reis and Selig (2015), a moving water tank Berger et al. (2022) and defibrillation processes of the human heart Berger et al. (2021a).

The novel funnel control design that we present in this paper relies on an intrinsic "availability function" which encodes (as a binary value) whether the output measurement is available at some time instant, or if the measurement is lost. As a consequence, no *a priori* information about the time instants where the measurement is lost or recaptured is necessary. Then the basic idea for the control design is simply to employ a classical funnel controller on each interval where the output is available, set the input to zero when it is not available and restart the controller when the output signal is received again. Because we restrict ourselves to linear systems no blow-up may occur when the input is zero. The crucial obstacle in the feasibility proof of the control design in our main result Theorem 5 is to show that the resulting control input in the closed-loop system is globally bounded. To this end, we require appropriate assumptions on the maximal duration of measurement losses and the minimal time of measurement availability, which we summarize in Section 1.2. The bounds for these durations essentially depend on the internal dynamics of the system – if the internal dynamics are absent, no restrictions must be made. However, if they are present a key step is to find an invariant set for the internal dynamics and to choose the initial width of the performance funnel large enough – this is elaborated in Section 1.3.

1.1 Nomenclature

We use the following notation, where $I \subseteq \mathbb{R}$ denotes an interval and $\mathbb{R}_{\geq 0} := [0, \infty)$. $\mathbb{N}$ is the set of positive integers; $\mathbb{C}_- := \{ z \in \mathbb{C} \mid \mathrm{Re} z < 0 \}$; $\|x\| := \sqrt{x^\top x}$ is the Euclidean norm of $x \in \mathbb{R}^n$; $\mathbf{Gl}_n(\mathbb{R})$ is the set of invertible matrices $A \in \mathbb{R}^{n\times n}$; for $A \in \mathbf{Gl}_n(\mathbb{R})$ we write $A > 0$ ($A < 0$) if A is positive (negative) definite; $\sigma(A) \subseteq \mathbb{C}$ is the spectrum of a matrix $A \in \mathbb{R}^{n\times n}$; $\mathcal{L}^\infty(I;\mathbb{R}^p)$ is the Lebesgue space of measurable and essentially bounded functions $f : I \to \mathbb{R}^p$ with norm $\|f\|_\infty := \operatorname{ess\,sup}_{t\in I} \|f(t)\|$; $\mathcal{W}^{k,\infty}(I;\mathbb{R}^p)$ is the Sobolev space of k-times weakly differentiable functions $f : I \to \mathbb{R}^p$ such that $f, \dots, f^{(k)} \in \mathcal{L}^\infty(I;\mathbb{R}^p)$; $\mathcal{C}^k(I;\mathbb{R}^p)$ is the set of k-times continuously differentiable functions $f : I \to \mathbb{R}^p$, $\mathcal{C}(I;\mathbb{R}^p) = \mathcal{C}^0(I;\mathbb{R}^p)$; $f|_J$ is the restriction of $f : I \to \mathbb{R}^n$ to $J \subseteq I$.

1.2 System class

We consider linear systems of the form

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t), \quad x(0) = x^0 \in \mathbb{R}^n, \\ y(t) &= Cx(t), \end{aligned} \tag{1}$$

where $A \in \mathbb{R}^{n\times n}$ and $B, C^\top \in \mathbb{R}^{n\times m}$; in particular, the dimensions of the input $u(t)$ and the output $y(t)$ coincide. We assume that the system has strict relative degree $r \in \mathbb{N}$, i.e., $CA^kB = 0$ for all $k = 0, \dots, r-2$, and $\Gamma := CA^{r-1}B \in \mathbf{Gl}_m(\mathbb{R})$. Then, a straightforward generalization of (Ilchmann and Wirth, 2013, Thm. 3) yields that there exist $R_i \in \mathbb{R}^{m\times m}$, $S, P^\top \in \mathbb{R}^{m\times(n-rm)}$ and $Q \in \mathbb{R}^{(n-rm)\times(n-rm)}$ such that system (1) is equivalent to

$$\begin{aligned} y^{(r)}(t) &= \sum_{i=1}^{r} R_i y^{(i-1)}(t) + S\eta(t) + \Gamma u(t), \\ \dot{\eta}(t) &= Q\eta(t) + Py(t) \end{aligned} \tag{2}$$

with initial conditions

$$\begin{aligned} (y(0), \dots, y^{(r-1)}(0)) &= (y^0_0, \dots, y^0_{r-1}) \in \mathbb{R}^{rm}, \\ \eta(0) &= \eta^0 \in \mathbb{R}^{n-rm}. \end{aligned}$$

We introduce the system class under consideration.

Definition 1. For $r, m \in \mathbb{N}$ a system (2) belongs to the system class $\Sigma_{r,m}$, if

(i) the high-gain matrix $\Gamma \in \mathbf{Gl}_m(\mathbb{R})$ is sign definite [1]; w.l.o.g. we assume $\Gamma + \Gamma^\top > 0$,
(ii) the system is minimum phase, i.e., $\sigma(Q) \subseteq \mathbb{C}_-$.

We write $(A, B, C) \in \Sigma_{r,m}$.

We record the following, the proof of which is straightforward.

Lemma 2. For $L \in \mathbb{R}^{p\times p}$ with $\sigma(L) \subseteq \mathbb{C}_-$ there exists $0 < K = K^\top$ such that $KL + L^\top K = -I_p$, and

$$\forall\, t \geq 0 : \ \|e^{Lt}\| \leq \sqrt{\|K^{-1}\|\|K\|}\, e^{-\frac{1}{2\|K\|}t}.$$

In virtue of Lemma 2, for Q from (2) let

$$M := \sqrt{\|K^{-1}\|\|K\|}, \ \mu := \frac{1}{2\|K\|}, \tag{3}$$

where $KQ + Q^\top K = -I_{n-rm}$. If $n - rm = 0$, then we set $M := 0$ and $\mu := 1$.

[1] That is, for any $v \in \mathbb{R}^m$ we have $v^\top \Gamma v = 0$ if, and only if, $v = 0$.

Since we consider situations where the output measurement signal may be lost for some time, we propose assumptions relating the maximal duration of measurement losses and minimal time of measurement availability. The package dropouts in the system and the accompanying lost information of the measurements $y(t)$ are not assumed to happen in *a priori* known time intervals. We only assume that it is possible to determine, at every time instant t, whether the measurement of $y(t)$ is available or not; if the availability is not certain, then it should be rendered "unavailable" (this also encompasses the situation that, after a dropout, the availability of the measurement is only determined with some delay). Based on this we define an "availability function"

$$a(t) = \begin{cases} 1, & \text{measurement of } y(t) \text{ available,} \\ 0, & \text{measurement of } y(t) \text{ not available.} \end{cases} \tag{4}$$

Let (t_k^-), (t_k^+) be sequences with $t_k^\pm \nearrow \infty$ and $t_k^- < t_k^+ < t_{k+1}^- < t_{k+1}^+$ such that

$$\begin{aligned} \{\, t \geq 0 \mid a(t) = 1 \,\} &= \bigcup_{k\in\mathbb{N}} (t_k^+, t_{k+1}^-], \\ \{\, t \geq 0 \mid a(t) = 0 \,\} &= \bigcup_{k\in\mathbb{N}} (t_k^-, t_k^+], \end{aligned} \tag{5}$$

that is, on the interval $(t_k^+, t_{k+1}^-]$ the signal is available, and on the interval $(t_k^-, t_k^+]$ the signal is not available. Note, that it is also possible that both sequences contain only finitely many points, then either $a(t) = 1$ for $t \geq t_N^+$ or $a(t) = 0$ for $t \geq t_N^-$ for some $N \in \mathbb{N}$. Now, we assume the following on the maximal duration of measurement losses and the minimal time of measurement availability.

Assumption 1. Let $p := \|P\|$, $s := \|S\|$ and $\beta := 1 + \frac{spM}{\mu} + \sum_{i=1}^r \|R_i\|$ be given by the system parameters, M, μ from (3) and q, A_r be the constants introduced in Section 1.3. The signal is lost for at most $\Delta > 0$, i.e., for $t_k^\pm$ as in (5) we have $|t_k^- - t_k^+| \leq \Delta$ for all $k \in \mathbb{N}$, such that for some $\kappa \geq 2$ and $\theta > s$ we have that Δ satisfies

$$spM\Delta^2 e^{\beta\Delta} \leq 1, \tag{Δ_1}$$

$$pM^2\Delta e^{\beta\Delta} \leq \frac{q}{A_r} \cdot \frac{\mu(\kappa-1)}{2\kappa\theta}. \tag{Δ_2}$$

Assumption 2. The signal is available for at least $\delta > 0$, i.e., for $t_k^\pm$ as in (5) we have $|t_k^+ - t_{k+1}^-| \geq \delta$ for all $k \in \mathbb{N}$, such that for Δ, β, κ, θ from Assumption 1 and M, μ from (3) we have that δ satisfies

$$e^{\mu\delta} \geq 2\kappa M\big(M + p\Delta e^{\beta\Delta}(1 + sM^2\Delta)\big), \tag{δ_1}$$

$$e^{\mu\delta} \geq 2\frac{\kappa}{\theta}(1 + sM^2). \tag{δ_2}$$

Remark 3. For systems with trivial internal dynamics (the second equation in (2) is not present) Assumptions 1 & 2 are much weaker. In this case we have $p = 0$, $s = 0$ and $M = 0$ with which the inequalities (Δ_1), (Δ_2) and (δ_1), (δ_2) are always satisfied (for $\theta = 2\kappa$). Hence, arbitrary $\Delta > 0$ and $\delta > 0$ are possible so that $|t_k^- - t_k^+| \leq \Delta$ and $|t_k^+ - t_{k+1}^-| \geq \delta$ for all $k \in \mathbb{N}$. So the only (implicit) requirement is that the sequence $(|t_k^- - t_k^+|)$ is bounded.

1.3 Control objective, design parameters and feedback law

Control objective We aim to find a control scheme which achieves tracking of a given reference trajectory

with prescribed transient behavior of the error, where the measurement output is subject to dropouts. To be more precise, for a system (2) with $(A, B, C) \in \Sigma_{r,m}$ and a given reference signal $y_{\mathrm{ref}} \in \mathcal{W}^{r,\infty}(\mathbb{R}_{\geq 0}; \mathbb{R}^m)$ the output y tracks the reference in the sense that the error $e(\cdot) := y(\cdot) - y_{\mathrm{ref}}(\cdot)$, whenever the measurement of y is available to the controller, evolves within a prescribed *performance funnel*

$$\mathcal{F}_\varphi := \{\, (t, e) \in \mathbb{R}_{\geq 0} \times \mathbb{R}^m \mid \varphi(t)\|e\| < 1 \,\},$$

where φ belongs to the set Φ of monotonically increasing functions introduced below.

$$\Phi := \left\{ \phi \in \mathcal{C}^1(\mathbb{R}_{\geq 0}; \mathbb{R}) \;\middle|\; \begin{array}{l} \forall\, t_2 \geq t_1 \geq 0 : \\ 0 < \phi(t_1) \leq \phi(t_2), \\ \exists\, d > 0\ \forall\, t \geq 0 : \\ |\dot{\phi}(t)| \leq d(1 + \phi(t)) \end{array} \right\}.$$

The performance funnel $\mathcal{F}_\varphi$ joins the two objectives of $e(t)$ approaching zero with prescribed transient behavior and asymptotic accuracy. Its boundary is given by the reciprocal of φ. We stress that φ may be unbounded and in this case (and if no measurement losses occur for $t \geq T$ for some $T > 0$) asymptotic tracking may be achieved, i.e., $\lim_{t\to\infty} e(t) = 0$.

Design parameters In order to formulate the control law, which achieves the control objective, we introduce the following design parameters. *Step 1.* Choose $q \in (0, 1)$ and define the bijection $\alpha : [0, 1) \to [1, \infty)$ via $\alpha(s) = 1/(1-s)$. For $k \geq 0$ define the function

$$A_k(s) = \sum_{j=0}^{k} s^j,$$

and set

$$A_r := A_r(\alpha(q^2)).$$

Step 2. For $\Delta, \delta, p, s, \beta, \kappa, \theta$ from Assumptions 1 & 2, respectively, $x_{\mathrm{ref}}(\cdot) := (y_{\mathrm{ref}}(\cdot), \dot{y}_{\mathrm{ref}}(\cdot), \ldots, y_{\mathrm{ref}}^{(r-1)}(\cdot))$, and M, μ from (3) choose $\eta^* > 0$ with

$$\eta^* \geq \max \left\{ \begin{array}{l} \frac{p}{\mu}\|y_{\mathrm{ref}}\|_\infty e^{\mu\delta}, \|x_{\mathrm{ref}}\|_\infty e^{\mu\delta}, \\ \dfrac{\|x_{\mathrm{ref}}\|_\infty (1 + e^{\beta\Delta}) e^{\mu\delta - \beta\Delta}}{\Delta} \end{array} \right\}, \tag{6}$$

and set

$$E := \theta\Delta e^{\beta\Delta}\eta^* > 0.$$

Step 3. Let $\varphi_0 \in \Phi$ such that

$$\varphi_{0,\min} := \tfrac{2\kappa p M^2}{\mu(\kappa-1)\eta^*} \leq \varphi_0(0) \leq \tfrac{q}{A_r E} =: \varphi_{0,\max}, \tag{ϕ_1}$$

which is possible by (Δ_2).

Step 4. Now, we choose some additional constants which are necessary to exploit (Berger et al., 2021c, Cor. 1.10). Let $\hat{\alpha}^\dagger(z) = z/(1+z)$, and define $\tilde{\alpha}(s) := 2s\alpha'(s) + \alpha(s) = (1+s)/(1-s)^2$. Further, let $\mu_0 := \operatorname{ess\,sup}_{t\geq 0}(|\dot{\varphi}_0(t)|/\varphi_0(t))$ which by properties of Φ satisfies $\mu_0 \leq \frac{d(1+\varphi_0(0))}{\varphi_0(0)}$ for some $d > 0$. Then, in virtue of (Berger et al., 2021c, Eq. (12)), for $k = 1, \ldots, r-1$ we recursively define the constants $c_0 = 0$ and

$$\begin{aligned} e_1^0 &:= \varphi_0(0)e(0), \\ c_1 &:= \max\{\|e_1^0\|^2, \hat{\alpha}^\dagger(1+\mu_0), q^2\}^{1/2} < 1, \\ \mu_k &:= 1 + \mu_0\big(1 + c_{k-1}\alpha(c_{k-1}^2)\big) \\ &\quad + \tilde{\alpha}(c_{k-1}^2)\big(\mu_{k-1} + c_{k-1}\alpha(c_{k-1}^2)\big), \\ e_k^0 &:= \varphi_0(0)e^{(k-1)}(0) + \alpha(\|e_{k-1}^0\|^2)e_{k-1}^0, \\ c_k &:= \max\{\|e_k^0\|^2, \hat{\alpha}^\dagger(\mu_k), q^2\}^{1/2} < 1, \end{aligned}$$

where $e^{(i)}(0) = y_i^0 - y_{\mathrm{ref}}^{(i)}(0)$ for $i = 0, \ldots, r-1$, and set

$$C := \textstyle\sum_{i=1}^{r-1} c_i + c_{i-1}\alpha(c_{i-1}^2) + (1 + c_{r-1}\alpha(c_{r-1}^2)).$$

Step 5. We refine the function $\varphi_0 \in \Phi$ satisfying (ϕ_1) such that for an intermediate $\rho \in (0, \delta)$

$$\varphi_0(\rho) \geq \max\left\{ \tfrac{Ce^{\mu\delta}}{\eta^*}, \tfrac{C\,e^{\mu\delta}}{\Delta\eta^*} \right\}. \tag{ϕ_2}$$

Remark 4. We note that the purpose of the constant q chosen in *Step 1* of the design procedure is to determine the initial width of the performance funnel, described by the upper bound for $\varphi_0(0)$ in (ϕ_1). Then again, condition (ϕ_2) ensures that its width (and hence the tracking error) is not too large before the signal possibly vanishes the next time.

Feedback law The idea for the controller design is to choose a funnel function $\varphi_0 \in \Phi$ (as in the previous subsection) which is reset whenever $a(t) = 0$. Then, as soon as $a(t^*) = 1$ for some $t^* \geq 0$ and the measurement is available again, the funnel controller from Berger et al. (2021c) is restarted with $\varphi(t) = \varphi_0(t - t^*)$ so that $\varphi(t^*) > 0$ and the performance funnel is sufficiently large at t^* to ensure applicability of (Berger et al., 2021c, Thm. 1.9). For feasibility we assume that the availability function $a(\cdot)$ from (4) is left-continuous and has only finitely many jumps in each compact interval. With this, and recalling $\alpha(s) = 1/(1-s)$, we introduce the following control law for systems (2) under possible output measurement losses:

$$\begin{aligned} \tau(t) &= \begin{cases} t, & a(t) = 0, \\ \tau(t-), & a(t) = 1, \end{cases} \\ \varphi(t) &= \begin{cases} 0, & a(t) = 0, \\ \varphi_0(t - \tau(t)), & a(t) = 1, \end{cases} \\ e_1(t) &= \varphi(t)e(t) = \varphi(t)\big(y(t) - y_{\mathrm{ref}}(t)\big), \\ e_{i+1}(t) &= \varphi(t)e^{(i)}(t) + \alpha(\|e_i(t)\|^2)e_i(t), i = 1, \ldots, r-1, \\ u(t) &= -a(t)\alpha(\|e_r(t)\|^2)e_r(t). \end{aligned} \tag{7}$$

Note that if $\Gamma + \Gamma^\top < 0$ the proposed control would read $u(t) = a(t)\alpha(\|e_r(t)\|^2)e_r(t)$.

If the output measurement is always available, i.e., $a(t) = 1$ for all $t \geq 0$, then the controller (7) coincides with that proposed in Berger et al. (2021c) and the existence of a global solution of the closed-loop system follows from the results presented there. Since it is not known *a priori* when output measurement losses occur, the funnel function φ cannot be globally defined in advance. Therefore, φ is defined online as part of the control law (7); it is equal to a shifted version of the reference funnel function φ_0 whenever measurements are available, and zero otherwise. Note that the loss of the system's output signal possibly introduces a discontinuity in the control signal.

2. MAIN RESULT

We show that the application of the funnel controller (7) to a system (2) under possible output measurement losses leads to a closed-loop initial-value problem which has a global solution. By a solution of (2), (7) on $[0, \omega)$ we mean a function $(y, \eta) \in \mathcal{C}^{r-1}([0,\omega), \mathbb{R}^m) \times \mathcal{C}([0,\omega), \mathbb{R}^{n-rm})$ with $\omega \in (0, \infty]$, which satisfies $(y(0), \dots, y^{(r-1)}(0)) = (y_0^0, \dots, y_{r-1}^0)$, $\eta(0) = \eta^0$ and $(y^{(r-1)}, \eta)|_{[0,\omega)}$ is locally absolutely continuous and satisfies (2) with u defined by (7) for almost all $t \in [0, \omega)$; (y, η) is called maximal, if it has no right extension that is also a solution.

Theorem 5. Consider a system (2) with $(A, B, C) \in \Sigma_{r,m}$ and initial values $(y_0^0, \dots, y_{r-1}^0) \in \mathbb{R}^{rm}$ and $\eta^0 \in \mathbb{R}^{n-rm}$. Let $y_{\text{ref}} \in \mathcal{W}^{r,\infty}(\mathbb{R}_{\geq 0}; \mathbb{R}^m)$, $a(\cdot)$ be as in (4) and choose design parameters η^* as in (6), and $\varphi_0 \in \Phi$ satisfying (ϕ_1),(ϕ_2). If the initial conditions

$$\forall\, i = 1, \dots, r \,:\, \|e_i(0)\| < 1, \quad \|\eta^0\| \leq \eta^*$$

are satisfied, then the control scheme (7) applied to system (2) yields an initial value problem which has a solution, every solution can be extended to a maximal solution and every maximal solution $(y, \eta) : [0, \omega) \to \mathbb{R}^m \times \mathbb{R}^{n-rm}$ has the following properties:

(i) the solution is global, i.e., $\omega = \infty$,
(ii) the tracking error $e(t) = y(t) - y_{\text{ref}}(t)$ evolves within the funnel boundaries, i.e., for all $t \geq 0$ we have $\varphi(t)\|e(t)\| < 1$,
(iii) the input control signal is globally bounded, i.e., $u \in \mathcal{L}^\infty(\mathbb{R}_{\geq 0}; \mathbb{R}^m)$, and $y \in \mathcal{W}^{r,\infty}(\mathbb{R}_{\geq 0}; \mathbb{R}^m)$.

Least squares moment matching for linear and nonlinear systems

Alberto Padoan *

* *Automatic Control Laboratory, ETH Zürich, Zürich, Switzerland (e-mail:apadoan@ethz.ch).*

Abstract: The model reduction problem by least squares moment matching is studied. A recent time-domain characterization of least squares moment matching for linear systems is used to define a notion of least squares moment matching for nonlinear systems. Models achieving least squares moment matching are shown to minimize an *a priori* error bound on the worst case r.m.s. gain of an error system with respect to a given family of signals, thus providing new insights on the linear theory.

Keywords: Model reduction, nonlinear systems, least squares, moment matching.

1. INTRODUCTION

Model reduction is art of approximating of a system while retaining its most essential properties (Antoulas, 2005). A classical solution to this problem relies on the notion of moment matching (Antoulas, 2005). For linear systems, the main idea is to use rational interpolation theory to ensure that the coefficients of the Laurent series expansion of the transfer functions of the original system and of its approximant coincide at given points of the complex plane up to a given order. Following the seminal contributions (Grimme, 1997; Gallivan et al., 2004, 2006), moment matching extended to nonlinear systems using invariance equations and steady-state responses (Astolfi, 2010). This, in turn, has led to the development of new model reduction methods for several classes of systems, including time-delay systems (Scarciotti and Astolfi, 2016) and systems with singularities (Padoan and Astolfi, 2019).

A significant limitation of methods based on moment matching is that the interpolation conditions are required to hold exactly, which, for some purposes, is an unnecessarily stringent assumption. Furthermore, methods based on moment matching do not provide *a priori* guarantees on the quality of approximation in general. Least squares moment matching provides a particularly interesting solution to both issues (Aguirre, 1992; Smith and Lucas, 1995; Gugercin and Antoulas, 2006), requiring that the interpolation conditions imposed by moment matching are satisfied only in a least squares sense. Least squares moment matching thus overcomes the issues mentioned above by minimizing an optimization criterion, which directly yields *a priori* error bounds and, under certain assumptions, guaranteed stability properties (Gugercin and Antoulas, 2006). For linear systems, there is a vast literature on least squares moment matching (Aguirre, 1992; Smith and Lucas, 1995; Gugercin and Antoulas, 2006; Mayo and Antoulas, 2007; Nakatsukasa et al., 2018), with deep connections to Padé approximation (Aguirre, 1992) and Prony's method for filter design (Gugercin and Antoulas, 2006). Yet, the notion of least squares moment matching does not have a nonlinear counterpart to date.

Goal of this work is to present a unifying notion of least squares moment matching for linear and nonlinear systems. The main ingredient of our approach is the formalism introduced in (Astolfi, 2010), where moments of nonlinear systems have been defined and characterized using tools from output regulation theory (Isidori, 1995). The starting point of our discussion is a new time-domain characterization of least squares moment matching for linear systems first presented in (Padoan, 2021), which relies on the solution of a constrained optimization problem involving a Sylvester equation. In close analogy with the results obtained in (Padoan, 2021) for linear systems, models achieving least squares moment matching are defined in terms of a constrained optimization problem involving an invariance equation and shown to minimize an *a priori* error bound on the worst case r.m.s. gain of an error system with respect to a given family of signals.

The remainder of this work is organized as follows. Section 2 is dedicated to the model reduction problem by least squares moment matching for linear systems. Section 3 provides a unifying notion of least squares moment matching and a direct nonlinear counterpart of the linear theory. Section 4 concludes this work with a summary and an outlook to future research directions.

Notation: $\mathbb{Z}_+$, $\mathbb{R}$ and $\mathbb{C}$ denote the set of non-negative integers, of real numbers, and of complex numbers, respectively. $\mathbb{C}_-$ denotes the set of complex numbers with negative real part. e_k denotes the vector with the k-th entry equal to one and all other entries equal to zero. I denotes the identity matrix. J_0 denotes the matrix with ones on the superdiagonal and zeros elsewhere. $J_{s^\star}$ denotes the Jordan block associated with the eigenvalue $s^\star \in \mathbb{C}$, *i.e.* $J_{s^\star} = s^\star I + J_0$. $\sigma(A)$ denotes the spectrum of the matrix $A \in \mathbb{R}^{n\times n}$. M^T denotes the transpose of the matrix $M \in \mathbb{R}^{p\times m}$. $\|\cdot\|_2$ and $\|\cdot\|_{2*}$ denote the Euclidean 2-norm on $\mathbb{R}^n$ and the corresponding dual norm (Boyd and Vandenberghe, 2004, p.637), respectively. Finally, $f^{(k)}(\cdot)$ denotes the derivative of order $k \in \mathbb{Z}_+$ of the function $f(\cdot)$, provided it exists, with $f^{(0)}(\cdot) = f(\cdot)$ by convention.

2. LINEAR SYSTEMS

Consider a system described by the equations

$$\dot{x} = Ax + Bu, \quad y = Cx, \tag{1}$$

in which $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$ and $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times 1}$ and $C \in \mathbb{R}^{1\times n}$ are constant matrices, with transfer function defined as

$$W(s) = C(sI - A)^{-1}B.$$

The system (1) is assumed to be minimal, *i.e.* controllable and observable.

Definition 1. (Antoulas, 2005, p.345) The *moment of order* $k \in \mathbb{Z}_+$ of system (1) at $s^\star \in \mathbb{C}$, with $s^\star \notin \sigma(A)$, is defined as the complex number

$$\eta_k(s^\star) = \frac{(-1)^k}{k!} W^{(k)}(s^\star).$$

Given distinct *interpolation points* $\{s_i\}_{i=1}^N$, with $s_i \in \mathbb{C}$ and $s_i \notin \sigma(A)$, and the corresponding *orders of interpolation* $\{k_i\}_{i=1}^N$, with $k_i \in \mathbb{Z}_+$, model reduction by moment matching consists in finding a system

$$\dot{\xi} = F\xi + Gv, \quad \psi = H\xi, \tag{2}$$

where $\xi(t) \in \mathbb{R}^r$, $v(t) \in \mathbb{R}$, $\psi(t) \in \mathbb{R}$ and $F \in \mathbb{R}^{r\times r}$, $G \in \mathbb{R}^{r\times 1}$ and $H \in \mathbb{R}^{1\times r}$ are constant matrices, the transfer function of which

$$\hat{W}(s) = H(sI - F)^{-1}G$$

satisfies the *interpolation conditions*

$$\eta_j(s_i) = \hat{\eta}_j(s_i), \quad j \in \{0, \dots, k_i\},\ i \in \{1, \dots, N\}, \tag{3}$$

where $\eta_j(s_i)$ and $\hat{\eta}_j(s_i)$ denote the moments of order j of the systems (1) and (2) at s_i, respectively. The system (2) is referred to as a *model (of system* (1)*)* and is said to *achieve moment matching (at* $\{s_i\}_{i=1}^N$*)* if the interpolation conditions (3) hold (Antoulas, 2005, Chapter 11). Furthermore, if $r < n$, then (2) is said to be a *reduced order model (of system* (1)*)*.

We are interested in the following problem. Suppose that the number of interpolation conditions

$$\nu = \sum_{i=1}^{N} (k_i + 1)$$

is larger than the number of moments that can be matched, i.e. $\nu > 2r$ (Antoulas, 2005, Chapter 11). In this case, the interpolation conditions (3) give rise to an overdetermined system of equations which can be solved in a least squares sense, leading directly to the *model reduction problem by least squares moment matching*.

Problem 1. Consider system (1). Let $\{s_i\}_{i=1}^N$ be a set of distinct interpolation points, with $s_i \in \mathbb{C}$ and $s_i \notin \sigma(A)$, and let $\{k_i\}_{i=1}^N$ be the corresponding orders of interpolation, with $k_i \in \mathbb{Z}_+$. Let $\nu = \sum_{i=1}^N (k_i + 1)$ and $r \in \mathbb{Z}_+$, with $2r < \nu$. Find, if possible, a model (2) of order r which minimizes the index

$$\mathcal{J} = \sum_{i=1}^{N} \sum_{j=0}^{k_i} \left| \eta_j(s_i) - \hat{\eta}_j(s_i) \right|^2. \tag{4}$$

The model (2) is said to *achieve least squares moment matching (at* $\{s_i\}_{i=1}^N$*)* if it minimizes the index (4).

2.1 Least squares moment matching for linear systems

Following (Padoan, 2021), we begin our analysis with a characterization of least squares moment matching in terms of the solutions of the optimization problem

$$\begin{aligned} \text{minimize} \quad & \|(C\Pi - HP)T\|_{2*}^2 \\ \text{subject to} \quad & A\Pi + BL = \Pi S, \\ & FP + GL = PS, \\ & \sigma(F) \cap \sigma(S) = \emptyset, \end{aligned} \tag{5}$$

for a given non-singular matrix $T \in \mathbb{R}^{\nu\times\nu}$, where $F \in \mathbb{R}^{r\times r}$, $G \in \mathbb{R}^{r\times 1}$, $H \in \mathbb{R}^{1\times r}$ and $P \in \mathbb{R}^{r\times\nu}$ are the optimization variables, and $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times 1}$, $C \in \mathbb{R}^{1\times n}$, $S \in \mathbb{R}^{\nu\times\nu}$ and $L \in \mathbb{R}^{1\times\nu}$ are problem data. To this end, we first introduce some basic assumptions.

(A1) The matrix $S \in \mathbb{R}^{\nu\times\nu}$ is non-derogatory [1] and has characteristic polynomial

$$\chi_S(s) = \prod_{i=1}^{N} (s - s_i)^{k_i+1}. \tag{6}$$

(A2) The matrix $L \in \mathbb{R}^{1\times\nu}$ is such that the pair (S, L) is observable.

(A3) The matrix $T \in \mathbb{R}^{\nu\times\nu}$ is non-singular and such that

$$ST = TJ, \quad LT = \Lambda, \tag{7}$$

with $J = \operatorname{diag}(J_{s_1}, \dots, J_{s_N})$ and $\Lambda = [\, e_1^\mathsf{T} \ \cdots \ e_1^\mathsf{T} \,]$.

Theorem 2. Consider system (1) and the model (2). Suppose Assumptions (A1)-(A3) hold. Assume $\sigma(A) \cap \sigma(S) = \emptyset$. Then the model (2) achieves least squares moment matching at $\sigma(S)$ if and only if there exists a matrix $P \in \mathbb{R}^{r\times\nu}$ such that (F, G, H, P) is a solution of the optimization problem (5).

Least squares moment matching admits a nice interpretation in terms of the steady-state behavior of the error system

$$\dot{x} = Ax + Bu, \quad \dot{\xi} = F\xi + Gu, \quad e = Cx - H\xi, \tag{8}$$

in which $x(t) \in \mathbb{R}^n$, $\xi(t) \in \mathbb{R}^r$, $u(t) \in \mathbb{R}$, and $e(t) \in \mathbb{R}$. Specifically, suppose that both the system (1) and the model (2) are driven by a signal generator described by the equations

$$\dot{\omega} = S\omega, \quad \theta = L\omega, \tag{9}$$

with $\omega(t) \in \mathbb{R}^\nu$ and $\theta(t) \in \mathbb{R}$. Furthermore, suppose that all solutions of the signal generator (9) are periodic and that the steady-state output response [2] e_{ss} of the interconnected system (9)-(8), with $u = \theta$, is well-defined. Then achieving least squares moment matching corresponds to minimizing an upper bound of the *worst case r.m.s. gain* of the error system (8) with respect to the family of signals produced by the signal generator (9), defined as (Boyd and Barratt, 1991, p.98)

$$\gamma_{rms} = \sup_{\omega(\cdot)\in\mathcal{W}} \frac{\|e_{ss}\|_{rms}}{\|\omega\|_{rms}} \tag{10}$$

where $\|\omega\|_{rms}$ is the *r.m.s. value* of the signal $\omega(t) \in \mathbb{R}^\nu$, defined as (Boyd and Barratt, 1991, p.86)

$$\|\omega\|_{rms} = \left(\lim_{\tau\to\infty} \frac{1}{\tau} \int_0^\tau \|\omega(t)\|_2^2 \, dt \right)^{1/2}, \tag{11}$$

[1] A matrix is non-derogatory if its characteristic polynomials and its minimal polynomial coincide (Horn and Johnson, 1994, p.178).
[2] See (Isidori, 1995, Chapter 8).

provided the limit exists, while $\mathcal{W}$ is the family of signals produced by (9) with non-zero r.m.s. value.

Theorem 3. Consider system (1), the model (2) and the signal generator (9). Suppose Assumptions (A1)-(A3) hold. Assume that $\sigma(A) \cup \sigma(F) \subset \mathbb{C}_-$, $S + S^\mathsf{T} = 0$ and $(S, \omega(0))$ is controllable. Then the following statements hold.

(i) The steady-state output response of the interconnected system (9)-(8), with $u = \theta$, is well-defined and uniquely determined by the moments of the error system (8) at $\sigma(S)$.

(ii) The worst case r.m.s. gain of the error system (8) with respect to the family of signals produced by the signal generator (9) is well-defined and such that

$$\gamma_{rms} \leq \|C\Pi - HP\|_{2*}, \tag{12}$$

with $\Pi \in \mathbb{R}^{n\times\nu}$ and $P \in \mathbb{R}^{r\times\nu}$ the (unique) solutions of the Sylvester equations

$$A\Pi + BL = \Pi S. \tag{13}$$

and

$$FP + GL = PS, \tag{14}$$

respectively.

(iii) The error bound (12) is minimized if the model (2) achieves least squares moment matching at $\sigma(S)$ and if the matrix $T \in \mathbb{R}^{\nu\times\nu}$ is orthogonal [3].

3. NONLINEAR SYSTEMS

Consider a system described by the equations [4]

$$\dot{x} = f(x, u), \quad y = h(x), \tag{15}$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$, and $f : \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$, $g : \mathbb{R}^n \to \mathbb{R}^n$ and $h : \mathbb{R}^n \to \mathbb{R}$ such that $f(0, 0) = 0$ and $h(0) = 0$, and a signal generator described by the equations

$$\dot{\omega} = s(\omega), \quad \theta = l(\omega), \tag{16}$$

in which $\omega(t) \in \Omega$ and $\theta(t) \in \mathbb{R}$, with $\Omega \subset \mathbb{R}^\nu$ a sufficiently small [5] open, connected, invariant set containing the origin, while the mappings $s : \Omega \to \Omega$ and $h : \Omega \to \mathbb{R}$ are such that $s(0) = 0$ and $l(0) = 0$, respectively. The system (15) is assumed to be minimal, *i.e.* (locally) accessible and observable [6] at the origin.

We begin by recalling the definition of moment of a nonlinear system from (Astolfi, 2010). To this end, we first introduce some basic assumptions.

(A1)* The matrix $S = \frac{\partial s}{\partial \omega}(0)$ is non-derogatory.

(A2)* The system (16) is (locally) observable at the origin.

(A3)* The partial differential equation

$$f(\pi(\omega), l(\omega)) = \frac{\partial \pi}{\partial \omega}(\omega) s(\omega), \tag{17}$$

admits a unique solution $\pi(\cdot)$, locally defined in the neighbourhood Ω of the origin, such that $\pi(0) = 0$.

Definition 4. (Astolfi, 2010) Consider system (15) and the signal generator (16). Suppose Assumptions (A1)*-(A3)* hold. The *moment of system* (15) *at* (s, l) is defined as the mapping $\mu(\cdot) = h(\pi(\cdot))$, where $\pi(\cdot)$ is the unique solution of the partial differential equation (17).

[3] A matrix $T \in \mathbb{R}^{n\times n}$ is orthogonal if $TT^\mathsf{T} = I$ (Horn and Johnson, 1994, p.84).

[4] All mappings are assumed to be smooth, *i.e.* infinitely many times differentiable, if not otherwise stated.

[5] All statements are local, although global versions can be given.

[6] See (Nijmeijer and Van der Schaft, 1990) for the notion of local accessibility and observability.

Remark 5. Assumptions (A1)*-(A3)* ensure that the moment of system (15) at (s, l) is (locally) well-defined. Note that the partial differential equation (17) admits a unique formal (power series) solution if and only if the following non-resonance condition holds (Huang, 2004, Lemma 4.13)

$$\sigma(A) \cap \sigma_k(S) = \emptyset, \quad k = 1, 2, \ldots, \tag{18}$$

in which $A = \frac{\partial f}{\partial x}(0, 0)$ and $S = \frac{\partial s}{\partial \omega}(0)$, and

$$\sigma_k(S) = \left\{ \lambda \in \mathbb{C} \,:\, \lambda = \sum_{i=1}^{\nu} \lambda_i k_i,\ k = \sum_{i=1}^{\nu} k_i \right\}, \tag{19}$$

where $\lambda_i \in \sigma(S)$ and $k_i \in \{0, 1, \ldots, k\}$. In particular, Assumption (A3)* holds if the equilibrium $x = 0$ of the system $\dot{x} = f(x, 0)$ is (locally) exponentially stable and if the signal generator (16) is periodic.

Definition 6. (Astolfi, 2010) The system

$$\dot{\xi} = \phi(\xi, v), \quad \psi = \kappa(\xi), \tag{20}$$

with $\xi(t) \in \mathbb{R}^r$, $v(t) \in \mathbb{R}$, $\psi(t) \in \mathbb{R}$, and $\phi : \mathbb{R}^r \times \mathbb{R} \to \mathbb{R}^n$, $\kappa : \mathbb{R}^r \to \mathbb{R}$ such that $\phi(0, 0) = 0$ and $\kappa(0) = 0$, is a *model of system* (15) *at* (s, l) if its moment at (s, l) is (locally) well-defined and coincides with that of system (15), *i.e.* if the partial differential equation

$$\phi(p(\omega), l(\omega)) = \frac{\partial p}{\partial \omega}(\omega) s(\omega) \tag{21}$$

possesses a unique solution $p(\cdot)$, locally defined in the neighbourhood Ω of the origin, such that $p(0) = 0$ and

$$h(\pi(\omega)) = \kappa(p(\omega)), \tag{22}$$

where $\pi(\cdot)$ is the (unique) solution of the partial differential equation (17). In this case, system (20) is said to *match the moment of system* (15) *(or to achieve moment matching) at* (s, l). Furthermore, system (20) is a *reduced order model (of system* (15)*) at* (s, l) if $r < n$.

3.1 Least squares moment matching for nonlinear systems

We are now in a position to introduce a nonlinear enhancement of the notion of least squares moment matching.

Definition 7. Consider system (15) and the signal generator (16). Let $\tau : \Omega \to \Omega$ be a diffeomorphism such that $\tau(0) = 0$. Suppose Assumptions (A1)*-(A3)* hold. The model (20) *achieves least squares moment matching at* (s, l) if the triple (ϕ, κ, p) is a formal (power series) solution of the constrained the optimization problem

$$\begin{aligned} \text{minimize} \quad & \sup_{\omega\in\Omega} \left\| \left(\frac{\partial \mu}{\partial \omega}(\tau(\omega)) - \frac{\partial \hat{\mu}}{\partial \omega}(\tau(\omega)) \right) \frac{\partial \tau}{\partial \omega}(\omega) \right\|_{2*} \\ \text{subject to} \quad & \phi(p(\omega), l(\omega)) = \frac{\partial p}{\partial \omega}(\omega) s(\omega),\ \omega \in \Omega, \\ & \sigma(F) \cap \sigma_k(S) = \emptyset,\ k = 1, 2, \ldots, \end{aligned} \tag{23}$$

in which $\mu(\cdot) = h(\pi(\cdot))$, $\hat{\mu}(\cdot) = \kappa(p(\cdot))$, $F = \frac{\partial \phi}{\partial \xi}(0,0)$ and $S = \frac{\partial s}{\partial \omega}(0)$, where $\phi(\cdot, \cdot)$, $\kappa(\cdot)$ and $p(\cdot)$ are the optimization variables, while system (15) and the signal generator (16) (and, thus, the solution $\pi(\cdot)$ of the partial differential equation (17)) are problem data.

The *model reduction problem by least squares moment matching* for nonlinear systems can be thus posed as follows.

Problem 2. Consider system (15) and the signal generator (16). Let $\tau : \Omega \to \Omega$ be a diffeomorphism such that

$\tau(0) = 0$. Suppose Assumptions (A1)*-(A3)* hold. Let $r \in \mathbb{Z}_+$, with $2r < \nu$. Find, if possible, a model (20) of order r achieves least squares moment matching at (s, l).

We now characterize least squares moment matching in terms of the steady-state behavior of the error system

$$\dot{x} = f(x, u), \quad \dot{\xi} = \phi(\xi, u), \quad e = h(x) - \kappa(\xi), \tag{24}$$

in which $x(t) \in \mathbb{R}^n$, $\xi(t) \in \mathbb{R}^r$, $u(t) \in \mathbb{R}$, and $e(t) \in \mathbb{R}$. Generalizing Theorem 3, one may show that if the steady-state output response e_{ss} of the interconnected system (16)-(24), with $u = \theta$, is (locally) well-defined and if all solutions of the signal generator (9) are periodic, then achieving least squares moment matching corresponds to minimizing an upper bound of the *worst case r.m.s. gain* of the error system (24) with respect to the family of signals produced by the signal generator (9), defined as [7]

$$\gamma_{rms} = \sup_{\omega(\cdot) \in \mathcal{W}} \frac{\|e_{ss}\|_{rms}}{\|\omega\|_{rms}}, \tag{25}$$

where $\mathcal{W}$ is the family of signals produced by (16) with non-zero r.m.s. value.

Theorem 8. Consider system (15), the signal generator (16) and the model (20). Let $\tau : \Omega \to \Omega$ be a diffeomorphism such that $\tau(0) = 0$. Suppose Assumptions (A1)*-(A3)* hold. Assume that the zero equilibrium of the system $\dot{x} = f(x, 0)$, $\dot{\xi} = \phi(\xi, 0)$ is locally exponentially stable, that all solutions of system (16) are periodic, and that the pair $(s, \omega(0))$ is exciting [8]. Then the following statements hold.

(i) The steady-state output response of the interconnected system (16)-(24), with $u = \theta$, is (locally) well-defined and uniquely determined by the moment of the error system (24) at (s, l).

(ii) The worst case r.m.s. gain of the error system (24) with respect to the family of signals produced by the signal generator (9) is well-defined and such that

$$\gamma_{rms} \leq \sup_{\omega \in \Omega} \left\| \frac{\partial \mu}{\partial \omega}(\omega) - \frac{\partial \hat{\mu}}{\partial \omega}(\omega) \right\|_{2*}, \tag{26}$$

where $\mu(\cdot)$ and $\hat{\mu}(\cdot)$ are the moments of systems (15) and (20) at (s, l), respectively.

(iii) The error bound (26) is minimized if the model (20) achieves least squares moment matching at (s, l) and if the mapping $\tau(\cdot)$ is an isometry [9] (on Ω).

4. CONCLUSION

The model reduction problem by least squares moment matching has been studied. A recent time-domain characterization of least squares moment matching has been used to define a notion of least squares moment matching for nonlinear systems. The results presented in this work can be used to obtain new families of models achieving least squares moment matching both for linear and nonlinear systems. The natural geometric and system-theoretic interpretations of such families will be discussed in detail in a future publication.

(e-mail: junyu.mao18@imperial.ac.uk, g.scarciotti@imperial.ac.uk)

Abstract: In this extended abstract, we present a time-domain data-driven technique for model reduction by moment matching of linear systems. We propose an algorithm, based on the so-called swapped interconnection, that (asymptotically) approximates an arbitrary number of moments of the system from a single time-domain sample. A family of reduced-order models that match the estimated moments is derived. Finally, the use of the proposed algorithm is demonstrated on the problem of model reduction of an atmospheric storm track model.

Keywords: Model reduction, system identification, moment matching, data-driven, time-domain.

1. INTRODUCTION

In a wide range of modern engineering problems, where large-scale systems are under consideration, high-order mathematical models are commonly constructed to describe the dynamics of those systems for the model-based analysis, control and prediction. However, in practice, the high dimensionality of these models poses a considerable challenge to nowadays computational power, in spite of its rapid advancement. To ease this computational burden, the problem of *model reduction* aims at reducing the complexity (*e.g.* dimensionality) of dynamical models. Informally, model reduction can be considered as the problem of approximating the important behaviours (*i.e.* input-output mapping) of a certain model by a simplified description, *e.g.*, a lower-order model. For linear systems, model reduction techniques have been extensively studied for decades, see, *e.g.*, Adamjan et al. (1971); Moore (1981); Meyer (1990). A popular family of methods is based on the interpolation framework and Krylov projection theory, see, *e.g.*, Kimura (1986); Georgiou (1999); Byrnes et al. (2001). This class is also commonly referred to as *moment matching* methods since the resulting reduced-order models match exactly the "moments" of the original system at specific frequencies.

Recently, to largely obviate the conventional need of a state-space model of the system to be reduced, some data-driven model reduction methods have been proposed in the interpolation-based moment matching framework. Among these works, we mention the seminal work of Mayo and Antoulas (2007) which introduced the so-called Loewner framework, which leverages frequency-domain samples for model reduction by moment matching. This extended abstract is based on a different framework introduced by (*e.g.* Scarciotti and Astolfi (2017)) which focuses on time-domain measurements to construct families of reduced-order models which asymptotically match the moments over time, for both linear and nonlinear systems. The experimental formulation of that approach is based on output measurements of an interconnection where the signal generator drives the system to be reduced, which we refer to as the "*direct*" interconnection in the rest of this paper.

In this work, we study a direct counterpart of Scarciotti and Astolfi (2017) based on a "*swapped*" interconnection – the system output drives a (generalized) signal generator. We show that the method proposed in this paper has some surprising advantages over Scarciotti and Astolfi (2017) in terms of sample efficiency. Also, we note that the results of this paper provide a necessary preliminary step for the development of data-driven model reduction techniques for nonlinear systems.

The remainder of this paper is organized as follows. In Section 2.1 we recall the theory of moment matching. Section 2.2 presents a data-driven approach that estimates the moments asymptotically, together with the associated reduced-order models. Finally, in Section 2.3, the proposed approach is demonstrated by a storm track model.

Notation $\mathbb{R}$ and $\mathbb{C}$ denote the sets of real numbers and complex numbers respectively. $\mathbb{R}_{\geq 0}$ ($\mathbb{R}_{>0}$) denotes the set of non-negative (positive) real numbers. $\mathbb{C}_0$ ($\mathbb{C}_{<0}$) denotes the set of complex numbers with zero (negative) real part. The set of non-negative integers is denoted by $\mathbb{Z}_{\geq 0}$. The identity matrix is denoted by the symbol I, and $\sigma(A)$ denotes the spectrum of a square matrix A. The symbol $\otimes$ represents the Kronecker product. The operator $\mathrm{vec}(A)$ indicates the vectorization of a matrix $A \in \mathbb{R}^{n\times m}$. $A^\top$ denotes the transpose of any matrix A. ι denotes the imaginary unit.

2. DATA-DRIVEN MOMENT MATCHING BY SWAPPED INTERCONNECTION

2.1 Moment Matching via System Interconnections – Recalled

In this section we recall the notion of moment for linear systems and its relation to the steady-state of certain interconnections. First consider a linear, single-input, single-output (SISO) [1],

[1] The results can be easily extended to systems with multiple inputs and multiple outputs.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

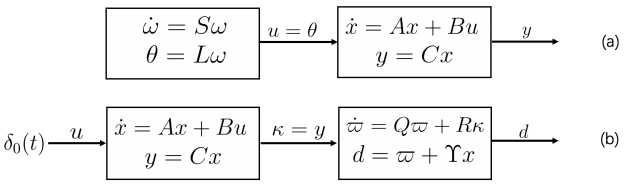

Fig. 1. Diagrammatic illustrations of the *direct* interconnection (a) and the *swapped* interconnection (b).

continuous-time system, described by equations of the form

$$\dot x = Ax + Bu, \qquad y = Cx, \tag{1}$$

with state $x(t) \in \mathbb{R}^n$, input $u(t) \in \mathbb{R}$, output $y(t) \in \mathbb{R}$, $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times 1}$ and $C \in \mathbb{R}^{1\times n}$. The associated transfer function is $W(s) = C(sI - A)^{-1}B$. Assume system (1) is minimal, *i.e.*, both controllable and observable. In the following we define the moments of system (1).

Definition 1. *The 0-moment of system (1) at $s_i \in \mathbb{C}\backslash\sigma(A)$ is the complex number $\eta_0(s_i) = W(s_i)$. The k-moment of system (1) at s_i is the complex number $\eta_k(s_i) = \frac{(-1)^k}{k!}\left[\frac{d^k}{ds^k}W(s)\right]_{s=s_i}$, where $k \geq 1$ is an integer.*

Definition 1 is a direct characterization of moments based on the transfer function and consequently it can only be used for linear, time-invariant systems. To obviate this restriction, Astolfi (2010a) noted that the moments are in a one-to-one relation with the (well-defined) steady-state responses of interconnections between the system and some "signal generators". Consider the signal generator

$$\dot\omega = S\omega, \qquad \theta = L\omega, \tag{2}$$

with $\omega(t) \in \mathbb{R}^\nu$, $u(t) \in \mathbb{R}$, $S \in \mathbb{R}^{\nu\times\nu}$ and $L \in \mathbb{R}^{1\times\nu}$, and the interconnection between this generator and system (1), namely

$$\dot\omega = S\omega, \qquad \dot x = Ax + BL\omega, \qquad y = Cx. \tag{3}$$

This interconnection is schematically represented in Fig. 1(a) and is called *direct* interconnection. Likewise, consider the signal generator

$$\dot\varpi = Q\varpi + R\kappa, \qquad d = \varpi + \Upsilon x, \tag{4}$$

with $\varpi(t) \in \mathbb{R}^\nu$, $\kappa(t) \in \mathbb{R}$, $d(t) \in \mathbb{R}^\nu$, $Q \in \mathbb{R}^{\nu\times\nu}$, $R \in \mathbb{R}^{\nu\times 1}$ and $\Upsilon \in \mathbb{R}^{\nu\times\nu}$, and the interconnection between this generator and system (1), namely

$$\dot x = Ax + Bu, \qquad \dot\varpi = Q\varpi + RCx, \qquad d = \varpi + \Upsilon x. \tag{5}$$

This interconnection is schematically represented in Fig. 1(b) with $u = \delta_0$, where δ_0 indicates the Dirac-delta, and is called *swapped* interconnection.

To streamline the presentation, we now introduce a series of assumptions.

Assumption 1. *For the signal generator (2), the pair (S, L) is observable. For the signal generator (4), the pair (Q, R) is controllable.*

Assumption 2. *System (1) is asymptotically stable, i.e., $\sigma(A) \subset \mathbb{C}_{<0}$. The matrix S has simple eigenvalues with $\sigma(S) \subset \mathbb{C}_0$. The pair (S, ω_0) is excitable (see Padoan et al. (2016)).*

Assumption 3. *System (1) is asymptotically stable. The matrix Q has simple eigenvalues with $\sigma(Q) \subset \mathbb{C}_0$. The initial condition $x(0)$ is 0.*

Note that under the asymptotic stability of system (1), the assumption that the initial condition of the system is zero is without loss of generality.

We now recall a result that connects moments with the steady states of interconnections (3) and (5).

Theorem 1 (see Astolfi (2010b))**.** *Let $s_i \in \mathbb{C} \setminus \sigma(A)$, for $i = 1, \dots, \rho$. Consider system (1) and assume that for the signal generators (2) and (4), the matrices S and Q are non-derogatory* [2] *with characteristic polynomial $p(s) = \prod_{i=1}^{\rho}(s - s_i)^{k_i}$, and $\nu = \sum_{i=1}^{\rho} k_i$. Then, the moments of system (1), namely $\eta_0(s_1), \dots, \eta_{k_1-1}(s_1), \dots, \eta_0(s_\rho), \dots, \eta_{k_\rho-1}(s_\rho)$, are in a one-to-one relation to*

- *the matrix $C\Pi$, in which $\Pi \in \mathbb{R}^{n\times\nu}$ is the unique solution of the Sylvester equation*
$$\Pi S = A\Pi + BL, \tag{6}$$
provided Assumption 1 holds.
- *the steady state of the output $y(t)$ of the interconnection (3), provided that Assumptions 1 and 2 hold.*
- *the matrix ΥB, in which $\Upsilon \in \mathbb{R}^{\nu\times n}$ is the unique solution of the Sylvester equation*
$$Q\Upsilon = \Upsilon A + RC, \tag{7}$$
provided Assumption 1 holds.
- *the steady state of the output $d(t)$ of the interconnection (5), provided that $u = \delta_0$ and Assumptions 1 and 3 hold.*

Given a set of moments, Theorem 1 provides four alternative characterizations of those moments. In particular, the fact that moments are in one-to-one relation with certain steady states opens the possibility of computing them from time-domain measurements of these signals.

Throughout this paper, we focus on the swapped interconnection. We conclude this section, by recalling a family of reduced-order models that achieve moment matching at (Q, R), *i.e.*, the reduced-order models have the same moments at the frequencies $s_i \in \sigma(Q)$. This family is described by the equations

$$\dot\xi = (Q - RH)\xi + \Upsilon Bu, \qquad \psi = H\xi, \tag{8}$$

for any $H \in \mathbb{R}^{1\times\nu}$ such that $\sigma(Q - RH) \cap \sigma(Q) = \emptyset$. This family contains all the ν-order models which achieve moment matching at $\sigma(Q)$. In this paper we do not need the family of reduced-order models associated to (S, L), hence, it is omitted.

2.2 On-Line Moment Matching from Experimental Data

In this section we develop a data-driven approach for (asymptotically) estimating the moments (more precisely ΥB) of the system, purely based on the measurements of the state $\varpi(t)$ of the user-defined signal generator. We first state an instrumental observation about the signal $d(t)$.

Remark 1. *Let Υ be the unique solution of equation (7). Note that the signal $d(t)$ can be expressed as the output of the system described by*

$$\dot d = Qd + \Upsilon Bu, \qquad \chi = d. \tag{9}$$

This follows from interconnection (5) and equation (7), namely

$$\begin{aligned}\dot d &= \dot{\varpi} + \Upsilon\dot x = Q\varpi + Ry + \Upsilon\left(Ax + Bu\right)\\ &= Q\varpi + \underbrace{(RC + \Upsilon A)}_{Q\Upsilon}x + \Upsilon Bu = Q(\varpi + \Upsilon x) + \Upsilon Bu\\ &= Qd + \Upsilon Bu.\end{aligned}$$

We are now ready to explicitly describe the dynamics of the signal $d(t)$ for the interconnection (5).

[2] A matrix is non-derogatory if its characteristic and minimal polynomial coincide.

Proposition 1. *Consider the interconnection (5) with $\varpi(0) = 0$ and $u = \delta_0$. Suppose Assumption 3 holds. Then, for all $t \in \mathbb{R}_{\geq 0}$, the response of system (9) is*

$$d(t) = e^{Qt}\Upsilon B. \tag{10}$$

Proof. Under the assumption that $x(0) = 0$ and $\varpi(0) = 0$, we have that $d(0) = 0$. The result follows trivally by computing the impulse response of the system (9). □

Exploiting Proposition 1, we can characterize the relation between the state of system (1) and the state of the signal generator (4), through the matrix Υ, namely

$$\varpi(t) + \Upsilon x(t) = d(t) = e^{Qt}\Upsilon B, \tag{11}$$

which underpins the following theorem.

Theorem 2. *Consider the interconnection (5) with $\varpi(0) = 0$ and $u = \delta_0$. Suppose Assumptions 1 and 3 hold. Then, ΥB characterizes the steady state $\varpi_{ss}(t)$ of $\varpi(t)$*

$$\varpi_{ss}(t) = e^{Qt}\Upsilon B. \tag{12}$$

Proof. As system (1) is asymptotically stable (by Assumption 3), the impulse response of $x(t)$ will exponentially decay to zero as the time goes to infinity, *i.e.*, $\lim_{t\to+\infty} x(t) = 0$. By Assumption 3, Q has simple eigenvalues with $\sigma(Q) \in \mathbb{C}_0$. Consequently, $\varpi_{ss}(t)$ is well defined for all times and e^{Qt} is a signal that is persistent in time. Thus, equation (11) at steady state reduces to (12).

□

We are ready to present the estimation in the following theorem.

Theorem 3. *Consider the interconnection (5) with $\varpi(0) = 0$ and $u = \delta_0$. Suppose Assumptions 1 and 3 hold. Then,*

$$\widetilde{\Upsilon B}_k := e^{-Qt_k}\varpi(t_k) \tag{13}$$

is an online estimate of ΥB with the following asymptotic property: there exist a sequence $\{t_k\}$ such that

$$\lim_{k\to+\infty} \widetilde{\Upsilon B}_k = \Upsilon B. \tag{14}$$

Proof. Multiplying e^{-Qt} to both sides of equation (11), evaluated at t_k, yields $\widetilde{\Upsilon B}_k + \epsilon(t_k) = \Upsilon B$, in which $\epsilon(t_k) = e^{-Qt_k}\Upsilon x(t_k) = e^{-Qt_k}\Upsilon e^{At_k}B$ is an exponentially decaying error signal. It follows by Theorem 2 that

$$\lim_{k\to+\infty}\left(\widetilde{\Upsilon B}_k - \Upsilon B\right) = \lim_{t_k\to+\infty} \epsilon(t_k) = 0, \tag{15}$$

as long as the time sequence $\{t_k\}$ indexed by k grows unbounded to $+\infty$. □

We summarize the above results in Algorithm 1.

Remark 2. *In the original model-based method proposed in Astolfi (2010b), the computation of the matrix Υ involves solving the Sylvester equation (7), which has a computational complexity*[3] *of order $\mathcal{O}(n^3)$. In comparison, Algorithm 1 only involves a matrix exponential and a matrix multiplication of order ν, hence both have a computational complexity of roughly $\mathcal{O}(\nu^3)$ (Al-Mohy and Higham (2010)). Thus, the proposed method is computationally efficient than the original method as $\nu \ll n$.*

Algorithm 1 On-Line Approximation of ΥB.

Input: a *sufficiently* small tolerance $\eta_{\Upsilon B} > 0$, $k = 0$
while 1 **do**
  Obtain data $\varpi(t_k)$ and record time instant t_k
  Compute $\widetilde{\Upsilon B}_k$

$$\widetilde{\Upsilon B}_k = e^{-Qt_k}\varpi(t_k)$$

  if $\left\|\widetilde{\Upsilon B}_k - \widetilde{\Upsilon B}_{k-1}\right\| \leq \frac{\eta_{\Upsilon B}}{t_k - t_{k-1}}$ **then**
    Break
  end if
  $k = k + 1$
end while
Return: $\widetilde{\Upsilon B}_k$

Remark 3. *A surprising advantage of the proposed approach based on the swapped interconnection is the sample efficiency, i.e., the number of samples required to properly estimate the moments. In Scarciotti and Astolfi (2017), the method, which is based on a direct interconnection, requires data from at least ν time instants to estimate ν moments. In contrast, within Algorithm 1, data from only one time instant suffices to fully estimate an arbitrarily large number of moments.*

More importantly, the data-driven approach under the swapped interconnection plays a core role in paving the path for developing a data-driven framework for the two-sided moment matching (Ionescu (2015)).

With the estimation of moments from Algorithm 1, we are able to construct the associated reduced-order models by replacing the moments ΥB with its online estimate $\widetilde{\Upsilon B}_k$. For all $t_k > 0$, the family of reduced-order models for system (1) at the pair $(\sigma(Q), t_k)$ is defined as

$$\dot{\xi} = (Q - RH_k)\xi + \widetilde{\Upsilon B}_k u, \qquad \psi = H_k\xi, \tag{16}$$

where $H_k \in \mathbb{R}^{1\times\nu}$ is a free parametrization as long as $\sigma(Q - RH_k) \cap \sigma(Q) = \emptyset$. Furthermore, Astolfi (2010a) shows that the free matrix H_k can be chosen to enforce additional properties of the reduced-order models, *e.g.*, stability, passivity, prescribed relative degree, spectrum and zeros.

2.3 Numerical Example

In this section we illustrate the use of Algorithm 1 with the *Eady Example*[4], *i.e.*, an atmospheric storm track model which is a widely-used benchmark (Antoulas et al. (2000)) for a variety of model reduction techniques, see *e.g.*, Antoulas (2005). In this work, we use the interpolation points $\pm 0.1\iota, \pm 0.58\iota, \pm 0.8\iota, \pm 0.9\iota, \pm 1.08\iota, \pm 1.26\iota, \pm 2.5\iota, \pm 7.0\iota$, which are mostly the major peaks of the bode plot of the storm track system. This selection results in a reduced order of 16. The determination of the free parametrization H_k is based on assigning the eigenvalues of F_k (see Astolfi (2010a)).

Fig. 2 shows the bode plots of the full order system (solid/blue line) and the reduced-order model (dashed/red line) constructed using the estimated moments $\widetilde{\Upsilon B}_k$ obtained at the end of an online experiment of 18 seconds. It shows that the moments between the two systems are matched at those interpolated frequencies (green circles). In addition, the time history of

[3] This is the computational cost for general dense A and B, *e.g.,* using the classic Bartels–Stewart algorithm. If A and B are very sparse, the computational cost can be further reduced to $\mathcal{O}(n^2 r)$ or $\mathcal{O}(nr^2)$ by ADI method (Benner et al. (2009)), where r is the dimension of the low-rank factor.

[4] The data can be downloaded at `http://slicot.org/20-site/126-benchmark-examples-for-model-reduction`.

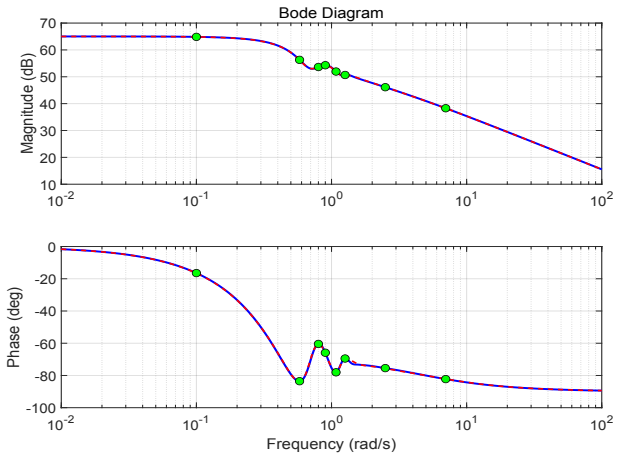

Fig. 2. Bode plots of the storm track model (solid/blue line) and of the data-driven reduced-order model (dashed/red line) constructed with the approximation $\widehat{\Upsilon B}_k$ for $t_k = 18$ s. The circles represent the set of interpolation points.

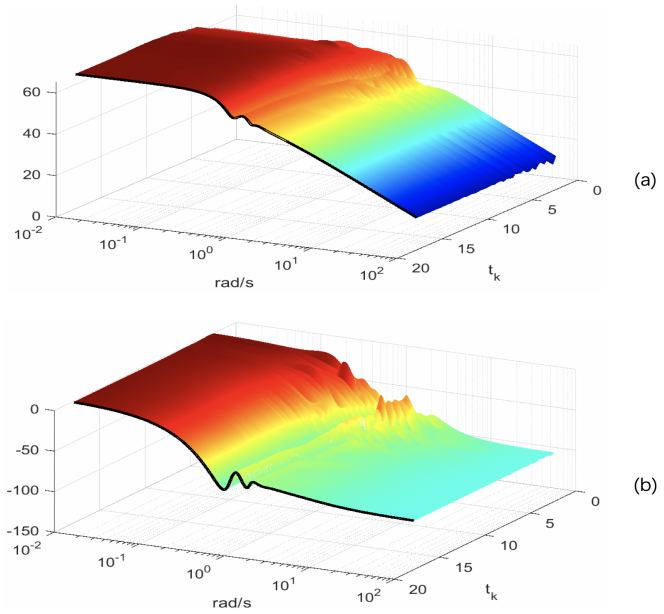

Fig. 3. The surface represents the magnitude (a) and phase (b) of the transfer function of the reduced-order model as a function of t_k, with $2.44 \leq t_k \leq 18$ s. The solid/black line indicates the transfer function of the reduced-order model constructed using the exact moments ΥB.

the bode plot of the reduced-order models obtained within an experimental time interval $\mathcal{T} = \{t_k \in \mathbb{R} : 2.44 \leq t_k \leq 18\}$ (of unit *second*) is shown in Fig. 3. The solid/black line represents the model obtained with the exact ΥB. The plots illustrate the evolution of the data-driven reduced-order model over time, demonstrating that it converges to the exact moment-matching reduced-order model as the time goes to infinity.

3. CONCLUSIONS

We have presented a theoretical framework and a time-domain data-driven method to solve the model reduction problem by moment matching, without knowing the state-space model of the linear system to be reduced. Firstly, an algorithm under the swapped interconnection has been proposed to asymptotically approximate the moments of an unknown system. Then, by exploiting the obtained approximations, a family of (parametrized) reduced-order models has been given. Finally, we have illustrated the performances of the proposed algorithm by means of a widely-used benchmark.

Abstract: Recent work has demonstrated the potential of applying supervised learning to train neural networks which approximate optimal feedback laws. In this talk, we show that some neural networks with good test accuracy can fail to even locally stabilize the dynamics. To address this challenge, we propose some novel neural network architectures which guarantee local asymptotic stability while still closely approximating optimal feedback laws on large domains.

Keywords: Large-scale optimal control problems, numerical methods for optimal control, learning for control, machine learning, stability of nonlinear systems.

1. INTRODUCTION

Designing optimal feedback controllers for high-dimensional nonlinear systems remains an outstanding challenge. Even when the system dynamics are known, one needs to solve a Hamilton-Jacobi-Bellman (HJB) partial differential equation (PDE) in as many variables as there are states, leading to the well-known curse of dimensionality.

Recent work has demonstrated the promise of supervised learning with neural networks (NNs) as one potential approach for handling challenging, high-dimensional problems. The main idea is to fit a model to data generated by solving many open loop optimal control problems (OCPs), thus obtaining an approximate optimal feedback controller. Further details can be found in e.g. Kang and Wilcox (2017), Izzo and Öztürk (2021), Nakamura-Zimmerer et al. (2021a,b), and Azmi et al. (2021).

Despite progress in the methodology, much less work has been done to study and improve the stability and reliability of these NN controllers. To see why this is needed, if we train a set of NNs to control a Burgers'-type PDE (12), a surprisingly large number of these fail to stabilize the system despite having good test accuracy. Figure 1 shows a simulation with one such NN controller.

Tailor and Izzo (2019) have also pointed out that test accuracy incompletely characterizes the performance of NN controllers, and suggest some more practical evaluations of optimality and stability. Izzo et al. (2021) study linear stability near a desired equilibrium, linear time delay stability, and stability around a nominal trajectory.

The purpose of this talk is to bring attention to stability issues with NN-controlled systems and to discuss recent work by Nakamura-Zimmerer et al. (2021b, 2022a,b) exploring NN architectures which can potentially mitigate these challenges. Some of these architectures can guarantee, at a minimum, local asymptotic stability (LAS) of the system. At the same time, these NNs can still learn the optimal feedback law and thus provide semi-global stability and optimality. We compare the new architectures to standard NNs by means of several practical closed loop stability and optimality tests. As a testbed we use the Burgers'-type PDE system (12), which is nonlinear, open loop unstable, and high-dimensional.

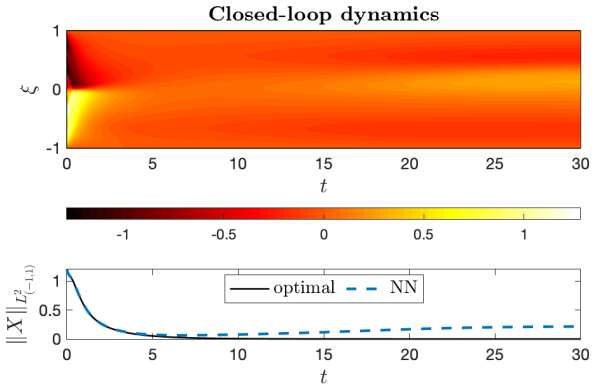

Fig. 1. Closed loop simulation of the Burgers'-type PDE (12) showing instability. Feedback control is based on an NN approximation of the solution of the HJB PDE; see Nakamura-Zimmerer et al. (2021a). The top plot shows the state $X(t, \xi)$, where ξ is the spatial variable.

2. PROBLEM SETTING

We focus on infinite horizon nonlinear OCPs of the form

$$\begin{cases} \underset{\boldsymbol{u}(\cdot)\in\mathbb{U}}{\text{minimize}} \;\; J\left[\boldsymbol{u}(\cdot)\right] = \int_0^\infty \mathcal{L}(\boldsymbol{x},\boldsymbol{u})dt, \\ \text{subject to } \dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}), \\ \qquad\qquad \boldsymbol{x}(0) = \boldsymbol{x}_0. \end{cases} \tag{1}$$

⋆ This work was supported with funding from the Air Force Office of Scientific Research (AFOSR) under grant FA9550-21-1-0113, the National Science Foundation (NSF) under grant no. 2134235, and the University of California, Santa Cruz, Baskin School of Engineering Dissertiation Year Fellowship.

Here $\boldsymbol{x} : [0,\infty) \to \mathbb{R}^n$ is the state, $\boldsymbol{u} : [0,\infty) \to \mathbb{U}$ is the control with box constraints $\mathbb{U} \subseteq \mathbb{R}^m$, and $\boldsymbol{f} : \mathbb{R}^n \times \mathbb{U} \to \mathbb{R}^n$ is a continuously differentiable ($\mathcal{C}^1$) vector field. We consider running costs $\mathcal{L} : \mathbb{R}^n \times \mathbb{U} \to [0,\infty)$ of the form

$$\mathcal{L}(\boldsymbol{x},\boldsymbol{u}) = q\left(\boldsymbol{x}-\boldsymbol{x}_f\right) + \left(\boldsymbol{u}-\boldsymbol{u}_f\right)^T \boldsymbol{R}\left(\boldsymbol{u}-\boldsymbol{u}_f\right), \qquad (2)$$

where $(\boldsymbol{x}_f,\boldsymbol{u}_f) \in \mathbb{R}^n \times \mathbb{U}$ is a (possibly unstable) equilibrium, $\boldsymbol{R} \in \mathbb{R}^{m\times m}$ is a positive definite matrix, and $q : \mathbb{R}^n \to [0,\infty)$ is a smooth, positive semi-definite function which is zero at $\boldsymbol{x}_f$. This standard cost function is a natural choice for regularization or set-point tracking problems. We make the standard assumptions that $\boldsymbol{u}_f$ is contained in an open subset of $\mathbb{U}$ and that the OCP (1) is well-posed, i.e. that an optimal control $\boldsymbol{u}^*(t)$ exists such that $J\left[\boldsymbol{u}^*(\cdot)\right] < \infty$ and $\lim_{t\to\infty} \mathcal{L}\left(\boldsymbol{x}^*(t),\boldsymbol{u}^*(t)\right) = 0$.

Due to real-time application requirements, we would like to design a closed loop feedback controller, $\boldsymbol{u} = \boldsymbol{u}^*(\boldsymbol{x})$, which can be evaluated online given any measurement of $\boldsymbol{x}$. The mathematical framework for designing such an optimal feedback policy is the HJB equation.

Define the *value function* $V : \mathbb{R}^n \to \mathbb{R}$ as the optimal cost-to-go of (1) starting at the point $\boldsymbol{x}(0) = \boldsymbol{x}$, i.e. $V(\boldsymbol{x}) \coloneqq J\left[\boldsymbol{u}^*(\cdot)\right]$. Under appropriate conditions, the value function is the solution of the steady state HJB PDE,

$$\min_{\boldsymbol{u}\in\mathbb{U}} \mathcal{H}\left(\boldsymbol{x}, V_{\boldsymbol{x}}, \boldsymbol{u}\right) = 0, \qquad V\left(\boldsymbol{x}_f\right) = 0, \qquad (3)$$

where $V_{\boldsymbol{x}} \coloneqq \left[\partial V/\partial \boldsymbol{x}\right]^T$ and we define the Hamiltonian

$$\mathcal{H}(\boldsymbol{x},\boldsymbol{\lambda},\boldsymbol{u}) \coloneqq \mathcal{L}(\boldsymbol{x},\boldsymbol{u}) + \boldsymbol{\lambda}^T \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}). \qquad (4)$$

If (3) can be solved (in the viscosity sense), then it provides both necessary and sufficient conditions for optimality. Furthermore, the optimal feedback control is then obtained from the the Hamiltonian minimization condition,

$$\boldsymbol{u}^*(\boldsymbol{x}) = \boldsymbol{u}^*\left(\boldsymbol{x}; V_{\boldsymbol{x}}(\boldsymbol{x})\right) = \arg\min_{\boldsymbol{u}\in\mathbb{U}} \mathcal{H}\left(\boldsymbol{x}, V_{\boldsymbol{x}}, \boldsymbol{u}\right). \qquad (5)$$

To circumvent the challenge of directly solving the HJB equation (3), we can leverage the necessary conditions for optimality, well-known in optimal control as Pontryagin's Minimum Principle (PMP):

$$\lim_{t_f\to\infty} \begin{cases} \dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}^*(\boldsymbol{x};\boldsymbol{\lambda})), & \boldsymbol{x}(0) = \boldsymbol{x}_0, \\ \dot{\boldsymbol{\lambda}}(t) = -\mathcal{H}_{\boldsymbol{x}}(\boldsymbol{x},\boldsymbol{\lambda},\boldsymbol{u}^*(\boldsymbol{x};\boldsymbol{\lambda})), & \boldsymbol{\lambda}(t_f) = \boldsymbol{0}. \end{cases} \qquad (6)$$

Here $\boldsymbol{\lambda} : [0,\infty) \to \mathbb{R}^n$ is called the *costate*. If we assume that the solution of (6) is optimal, then along the trajectory $\boldsymbol{x} = \boldsymbol{x}^*(t;\boldsymbol{x}_0)$ we have

$$\begin{cases} V(\boldsymbol{x}) = \int_t^\infty \mathcal{L}\left(\boldsymbol{x}(s),\boldsymbol{u}^*(s)\right) ds, \\ V_{\boldsymbol{x}}(\boldsymbol{x}) = \boldsymbol{\lambda}(t), \quad \boldsymbol{u}^*(\boldsymbol{x}) = \boldsymbol{u}^*(t). \end{cases} \qquad (7)$$

In supervised learning, the BVP (6) is solved for different initial conditions in the domain of interest. This yields a data set of optimal value function, gradient, and control values which can be used to train feedback controllers.

3. STABILITY-ENHANCING ARCHITECTURES FOR OPTIMAL FEEDBACK DESIGN

Our goal is to learn a feedback policy which approximates the optimal control, i.e. $\widehat{\boldsymbol{u}}(\boldsymbol{x}) \approx \boldsymbol{u}^*(\boldsymbol{x})$. Due to the complex and sometimes unpredictable behavior of NNs, there is a clear need for designing feedback controllers with *built-in* stability properties.

Previously, Nakamura-Zimmerer et al. (2021b, 2022a) proposed V-*QRnet* (originally just called *QRnet*), λ-*QRnet*, and u-*QRnet*. These controllers combine a linear quadratic regulator (LQR) with NNs. The LQR terms are good approximations of the optimal control near $\boldsymbol{x}_f$, and empirically improve stability. Meanwhile, the NNs are intended to capture nonlinearities and thereby learn the nonlinear optimal feedback over a large domain.

However, none of these architectures can *guarantee* LAS, motivating the pursuit of alternative designs. In this talk we describe one of the novel NN architectures introduced in recent work by Nakamura-Zimmerer et al. (2022b). This architecture, called, u_{Jac}-*QRnet*, guarantee LAS of $\boldsymbol{x}_f$ while retaining the ability to approximate the nonlinear optimal control semi-globally.

3.1 Novel "Jacobian" QRnet *controller*

Here we describe the stability-enhancing architectures, u-*QRnet* and u_{Jac}-*QRnet*, which combine NNs with local LQR approximations. LQR is a linear state feedback law which is computed by linearizing the nonlinear OCP (1) about $(\boldsymbol{x}_f,\boldsymbol{u}_f)$ to obtain

$$\boldsymbol{u}^{\text{LQR}}(\boldsymbol{x}) = \boldsymbol{u}_f - \boldsymbol{K}(\boldsymbol{x}-\boldsymbol{x}_f). \qquad (8)$$

Here $\boldsymbol{K} \in \mathbb{R}^{m\times n}$ is the LQR gain matrix and is computed by solving a continuous algebraic Riccati equation. We note that LQR is in fact a first order approximation of the optimal control, i.e. $\left[\partial \boldsymbol{u}^*/\partial \boldsymbol{x}\right](\boldsymbol{x}_f) = -\boldsymbol{K}$.

Let us first review u-*QRnet* from Nakamura-Zimmerer et al. (2022a). This models the full nonlinear optimal control by combining (8) with an NN, $\boldsymbol{\mathcal{N}} : \mathbb{R}^n \to \mathbb{R}^m$:

$$\widehat{\boldsymbol{u}}(\boldsymbol{x}) = \boldsymbol{u}^{\text{LQR}}(\boldsymbol{x}) + \boldsymbol{\mathcal{N}}(\boldsymbol{x}) - \boldsymbol{\mathcal{N}}(\boldsymbol{x}_f). \qquad (9)$$

To construct u_{Jac}-*QRnet*, we cancel out the linear contribution of the NN:

$$\widehat{\boldsymbol{u}}(\boldsymbol{x}) = \boldsymbol{u}^{\text{LQR}}(\boldsymbol{x}) - \left[\tfrac{\partial \boldsymbol{\mathcal{N}}}{\partial \boldsymbol{x}}(\boldsymbol{x}_f)\right](\boldsymbol{x}-\boldsymbol{x}_f) + \boldsymbol{\mathcal{N}}(\boldsymbol{x}) - \boldsymbol{\mathcal{N}}(\boldsymbol{x}_f). \qquad (10)$$

The Jacobian term is key to guaranteeing LAS by construction. Note that (9) and (10) are shown without saturation constraints, but it is easy to smoothly incorporate these directly into the model; see Nakamura-Zimmerer et al. (2022b) for details. Nakamura-Zimmerer et al. (2022b) also propose a number of other models which are not covered here.

A drawback of (10) is that the Jacobian $\left[\partial \boldsymbol{\mathcal{N}}/\partial \boldsymbol{x}\right](\boldsymbol{x}_f)$ must be evaluated during each forward pass during training. This makes training the model more expensive than u-*QRnet* which does not include this term. *After training, however, we can store the Jacobian matrix in memory so that it does not have to be recomputed online.* Therefore online evaluation is just as fast as u-*QRnet*.

3.2 Local stability guarantees and approximation capacity

Like u-*QRnet* (9), the new u_{Jac}-*QRnet* (10) automatically makes the goal state $\boldsymbol{x}_f$ an equilibrium [1]. Moreover, if we linearize the feedback control $\widehat{\boldsymbol{u}}(\cdot)$ at $\boldsymbol{x}_f$ then we recover the LQR control gain (8). This property is desirable because LQR locally asymptotically stabilizes $\boldsymbol{x}_f$, and hence the proposed controllers provide LAS by construction. This is stated formally in Proposition 1, whose proof is straightforward.

[1] Note that V-*QRnet* does *not* always make $\boldsymbol{x}_f$ an equilibrium.

Proposition 1. (LAS guarantee). Suppose $\widehat{\boldsymbol{u}}(\cdot)$ is a feedback policy specified by (10). Then $[\partial\widehat{\boldsymbol{u}}/\partial\boldsymbol{x}](\boldsymbol{x}_f) = -\boldsymbol{K}$ and $\boldsymbol{x}_f$ is an LAS equilibrium of the NN-controlled system, $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \widehat{\boldsymbol{u}}(\boldsymbol{x}))$.

LAS is a critical but bare minimum requirement. To achieve the ultimate goal of semi-global stability and optimality through NN training, (10) must also be able to approximate $\boldsymbol{u}^*(\cdot)$ with sufficient accuracy. Because $\boldsymbol{u}^*(\cdot)$ is in general not everywhere analytic, we cannot directly use the Taylor series-like structure of (10) to show this is possible. Nevertheless, for OCPs like (1) we expect $\boldsymbol{u}^*(\cdot)$ to be at least continuous and locally $\mathcal{C}^1$. Then we can apply Theorem 2 below, which shows that NNs of the form (10) are universal approximators for such functions.

Theorem 2. (Universal approximation). Let $\boldsymbol{x}_f = \boldsymbol{0}$ be an interior point of the compact set $\mathbb{X} \subset \mathbb{R}^n$. Suppose $\boldsymbol{u} \in \mathcal{C}(\mathbb{X} \to \mathbb{R}^m)$, $\boldsymbol{u}(\boldsymbol{0}) = \boldsymbol{0}$, and $\boldsymbol{u}(\cdot)$ is $\mathcal{C}^1$ in a neighborhood of $\boldsymbol{0}$. Then for all $\varepsilon > 0$, there exists a feedforward NN with $\mathcal{C}^1$ bounded, non-constant activation functions, $\boldsymbol{\mathcal{N}} \in \mathcal{C}^1(\mathbb{X} \to \mathbb{R}^m)$, such that for all $\boldsymbol{x} \in \mathbb{X}$,

$$\left\| \boldsymbol{u}(\boldsymbol{x}) - \left(\left[\frac{\partial \boldsymbol{u}}{\partial \boldsymbol{x}}(\boldsymbol{0}) - \frac{\partial \boldsymbol{\mathcal{N}}}{\partial \boldsymbol{x}}(\boldsymbol{0}) \right] \boldsymbol{x} + \boldsymbol{\mathcal{N}}(\boldsymbol{x}) - \boldsymbol{\mathcal{N}}(\boldsymbol{0}) \right) \right\|_1 < \varepsilon. \tag{11}$$

The proof applies the Stone-Weierstrass theorem and a universal approximation theorem from Hornik (1991). Details are given in Nakamura-Zimmerer et al. (2022b).

4. NUMERICAL RESULTS

Here we compare the proposed controllers to standard feedforward NNs trained to approximate the value function, its gradient, and the optimal control. We refer to these as V-NN, λ-NN, and u-NN, respectively. We also compare to *V-QRnet*, *λ-QRnet*, and *u-QRnet*. The results indicate that the new architectures are indeed able to accurately learn the optimal feedback control while guaranteeing local stability.

As a testbed we revisit the Burgers' stabilization OCP from Nakamura-Zimmerer et al. (2021b). This is a high-dimensional nonlinear OCP formulated by pseudospectral discretization of an unstable version of a Burgers' PDE. Briefly, the problem can be summarized as

$$\begin{cases} \min\limits_{\boldsymbol{u}(\cdot)} \; J[\boldsymbol{u}(\cdot)] = \int_0^\infty \left(\boldsymbol{x}^T \boldsymbol{Q} \boldsymbol{x} + \boldsymbol{u}^T \boldsymbol{R} \boldsymbol{u} \right) dt, \\ \text{s.t.} \;\; \dot{\boldsymbol{x}} = -\frac{1}{2} \boldsymbol{D}\boldsymbol{x} \circ \boldsymbol{x} + \nu \boldsymbol{D}^2 \boldsymbol{x} + \boldsymbol{\alpha} \circ \boldsymbol{x} \circ e^{-\beta \boldsymbol{x}} + \boldsymbol{B}\boldsymbol{u}. \end{cases} \tag{12}$$

Here $\boldsymbol{x} : [0, \infty) \to \mathbb{R}^n$ represents the PDE state $X(t, \xi)$ collocated at spatial coordinates $\xi_j = \cos(j\pi/n)$, $j = 1, \ldots, n$, $\boldsymbol{u} : [0, \infty) \to \mathbb{R}^m$ is the control, $\boldsymbol{D} \in \mathbb{R}^{n \times n}$ is the Chebyshev differentiation matrix, $\boldsymbol{Q} \in \mathbb{R}^{n \times n}$, $\boldsymbol{R} \in \mathbb{R}^{m \times m}$ are diagonal positive definite matrices, and "$\circ$" denotes elementwise multiplication. The parameters $\nu, \beta > 0, \boldsymbol{\alpha} \in \mathbb{R}^n$, and $\boldsymbol{B} \in \mathbb{R}^{n \times m}$ are defined in Nakamura-Zimmerer et al. (2021b), and we take $n = 64$ and $m = 2$.

We train the NNs using supervised learning, which consists of three steps: data generation, optimization, and evaluation against test data. For details we refer the reader to Nakamura-Zimmerer et al. (2021b, 2022b).

We generate data by solving the BVP (6) for randomly sampled initial conditions. To get models with varying approximation accuracy, we generate training data sets with different numbers of trajectories. To account for statistical variation, for each different data set size we conduct ten trials with different randomly generated training trajectories and NN weight initializations. We use an independent test data set containing 500 trajectories.

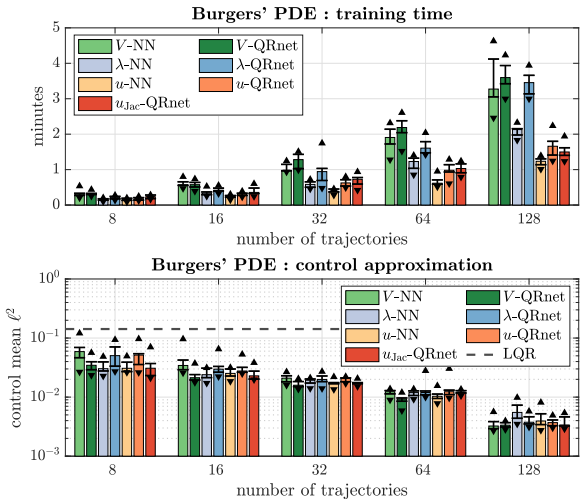

Fig. 2. Training time and test approximation error, depending on the amount of training data. Bar heights show the medians over ten trials, error bars show the 25th and 75th percentiles, and triangles are minimum and maximum values.

All NNs use five hidden layers with 32 neurons each. Figure 2 shows training times and test accuracies of the NNs. We see that, somewhat surprisingly, *u_{Jac}-QRnet* is just as fast to train as *u-NN* and *u-QRnet*[2]. We also find that *u_{Jac}-QRnet* has similar test accuracy statistics to the standard NNs, confirming that they can learn complicated nonlinear functions in practice.

Remark 3. Figures 3 to 5 show results for u-NN, *u-QRnet*, and *u_{Jac}-QRnet*. Results for other models are similar so we restrict the figures to these for clarity.

4.1 Local stability verification

As a first step we assess the local stability of each NN-controlled system. Let $\bar{\boldsymbol{x}} \in \mathbb{R}^n$ be an equilibrium[3] of the closed loop system. The dynamics near $\bar{\boldsymbol{x}}$ can be approximated by $\dot{\boldsymbol{x}} \approx \boldsymbol{A}_{\text{cl}}(\boldsymbol{x} - \bar{\boldsymbol{x}})$, where

$$\boldsymbol{A}_{\text{cl}} := \left.\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{x}}\right|_{\bar{\boldsymbol{x}}, \widehat{\boldsymbol{u}}(\bar{\boldsymbol{x}})} + \left.\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{u}}\right|_{\bar{\boldsymbol{x}}, \widehat{\boldsymbol{u}}(\bar{\boldsymbol{x}})} \left.\frac{\partial \widehat{\boldsymbol{u}}}{\partial \boldsymbol{x}}\right|_{\bar{\boldsymbol{x}}} \tag{13}$$

is the closed loop Jacobian. Thus, after synthesizing a feedback controller we can easily check for local stability by seeing if $\boldsymbol{A}_{\text{cl}}$ is Hurwitz.

Figure 3 shows the real part of the most positive eigenvalue of $\boldsymbol{A}_{\text{cl}}$ for each NN. We find that standard NNs must be trained to a high level of accuracy before they are even locally stabilizing, which necessitates a large data set and

[2] Some other novel architectures proposed by Nakamura-Zimmerer et al. (2022b), for example *λ_{Jac}-QRnet* which approximates the value gradient, do take significantly longer to train than standard NNs. However, even for these the training time is still very reasonable.

[3] In general $\bar{\boldsymbol{x}} \neq \boldsymbol{x}_f$. An equilibrium $\bar{\boldsymbol{x}}$ near $\boldsymbol{x}_f$, if it exists, can be obtained with a root-finding algorithm.

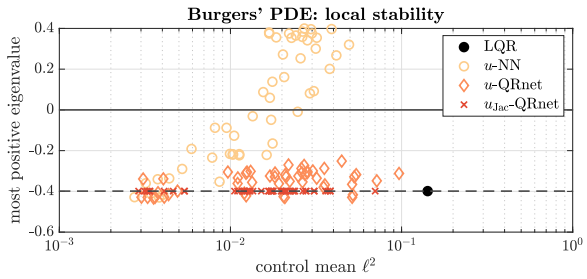

Fig. 3. Most positive real part of closed loop Jacobian eigenvalue. Each marker represents a single model.

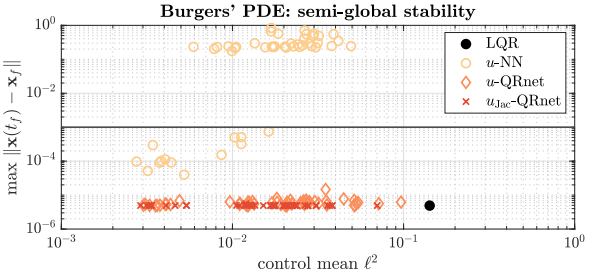

Fig. 4. Worst-case failure of final state over $N_{\text{MC}} = 100$ simulations. Each marker represents a single model.

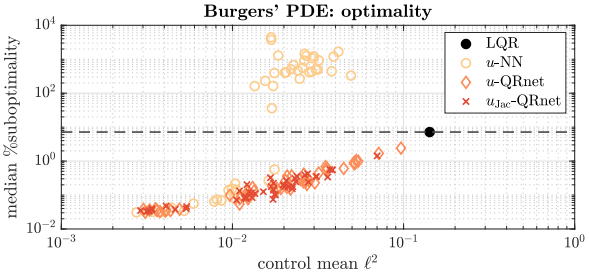

Fig. 5. Percent extra cost vs. BVP data over $N_{\text{MC}} = 100$ simulations. Each marker represents a single model.

long training time. On the other hand, *u-QRnet* and u_{Jac}-*QRnet* yield LAS even when trained on small data sets (recall Proposition 1 guarantees this for u_{Jac}-*QRnet*).

4.2 Monte Carlo nonlinear stability analysis

Here and in Section 4.3 we conduct Monte Carlo (MC) simulations to analyze nonlinear closed loop stability and performance. $N_{\text{MC}} = 100$ initial conditions $\boldsymbol{x}_0^{(i)}$ are randomly selected with $\left\|\boldsymbol{x}_0^{(i)}\right\| = 1.2 \approx \max_{\boldsymbol{x}^{(j)} \in \mathcal{D}_{\text{train}}} \left\|\boldsymbol{x}^{(j)}\right\|$, placing them at the edge of the training domain where the NNs may be less accurate.

We stop each simulation when the system reaches a steady state or exceeds a large final time. If the *worst case failure*, $\max_{\boldsymbol{x}_0^{(i)}} \left\|\boldsymbol{x}\left(t_f; \boldsymbol{x}_0^{(i)}\right)\right\|$, is sufficiently small then the nonlinear system is likely semi-globally stable. Conversely, if the controller fails to stabilize even one trajectory then we cannot rely on it.

Figure 4 shows the worst-case failures for each NN. Notably, only the most accurate *u*-NNs successfully stabilize the system. Furthermore, although stability on average improves with test accuracy, some highly accurate *u*-NNs fail to stabilize all trajectories. In contrast, *all u-QRnets* and u_{Jac}-*QRnet* stabilize all MC trajectories. These empirical results suggest that the proposed architectures make the control design more reliable, consistently yielding a stabilizing control law even with small data sets.

4.3 Monte Carlo optimality analysis

In this talk we are interested in both stability and optimality. For a given $\widehat{\boldsymbol{u}}(\cdot)$, optimality can be quantified by the accumulated cost compared to the optimal costs, $V\left(\boldsymbol{x}_0^{(i)}\right)$. Figure 5 shows the results of this analysis for the same set of MC simulations conducted in Section 4.2. We see a clear correlation between higher test accuracy and better performance. All the NN controllers (if stable) follow this trend, and moreover, their average performance is better than LQR alone. It follows that the proposed architectures improve stability without sacrificing optimality.

Ultimately, these results support the argument that while machine learning can serve as an effective computational tool, it is crucial to integrate control theory at each step of the model design, training, and evaluation process.

(e-mail: zeinab.badreddine@imj-prg.fr; helene.frankowska@imj-prg.fr)

Abstract: In some applied models (as for instance of flocking or of the crowd control) it is more natural to deal with elements of a metric space (as for instance a family of subsets of a vector space endowed with the Hausdorff metric) rather than with vectors of a normed vector space. We consider a generalized control system on a metric space and investigate necessary and sufficient conditions for viability and invariance of proper subsets, describing state constraints. As examples of application we study controlled continuity equations on the metric space of probability measures, endowed with the Wasserstein distance, and controlled morphological systems on the space of nonempty compact subsets of the Euclidean space endowed with the Hausdorff metric. We also provide sufficient conditions for the existence and uniqueness of contingent solutions to the Hamilton-Jacobi-Bellman equation on a proper metric space.

Keywords: mutational control system; viability and invariance; optimal control; Wasserstein space; Hamilton-Jacobi inequalities.
MSC 2020: 34A06, 49L12, 49Q22.

Dynamical systems *under state constraints* are ubiquitous in the literature since a long while. Indeed, in many applied fields, as economics, finance, demography, medical sciences, aerospace, sustainable development, robotics, etc., the models do involve pointwise constraints on trajectories. Viability theory is an area of mathematics that studies evolutions of trajectories of dynamical systems under state constraints and many related questions. This theory is also a helpful tool for investigation of some classical questions arising in control. Indeed, various problems of control theory can be linked to viability and invariance properties of appropriately chosen sets, as for instance the optimal synthesis problem can be related to the *viability retroaction map* on the epigraph of the value function arising in optimal control [10], solutions of Hamilton-Jacobi-Bellman equations – to functions having viable/invariant epigraph/hypograph under extended control systems [11], optimal trajectories – to viable trajectories on the epigraph of the value function for an extended control system [11], stabilising controls – to the viability retroaction map on the epigraph of a Lyapunov function [12]. Viability theory is well investigated in the finite dimensional framework and Hilbert spaces, see for instance [4, 5, 8] and the bibliographies contained therein.

In the recent years, there is an increasing interest in control problems stated on metric spaces, cf. [2, 9, 13, 14]. The main goal of the present paper is to extend the viability and invariance theorems to the framework of proper subsets of a metric space on which a subset of transitions is fixed.

⋆ This material is based upon work supported by the Air Force Office of Scientific Research under award number FA9550-18-1-0254.

As an application, we discuss the Hamilton-Jacobi inequalities on a proper metric space. We show that under some technical assumptions the value function of the mutational Mayer optimal control problem is the unique contingent solution satisfying a prescribed final time condition. Two examples of applications are provided as well.

1. PRELIMINARIES AND BASIC DEFINITIONS

Let (E,d) be a metric space (with the metric d) and denote by $B(x,r)$ the closed ball centered at $x\in E$ with radius $r\geq 0$. Recall that a subset $K\subset E$ is called proper if $K\cap B(x,r)$ is compact for any $(x,r)\in K\times\mathbb{R}_+$. The distance between two nonempty subsets K, M of E is defined by $\mathrm{dist}(K,M):=\inf_{k\in K,\,m\in M} d(k,m)$. Note that $\mathrm{dist}(K,M)$ measures the proximity of sets and it is not a distance function on subsets of E. Obviously, it is smaller than the Hausdorff distance.

We first recall some definitions and notations from [3, 15].

A map $\mathcal{V}:[0,1]\times E\to E$ is called transition on (E,d) if:

- $\forall\, x\in E,\ \mathcal{V}(0,x)=x$;
- $\forall\, x\in E,\ \forall\, t,\ h\in[0,1[\ \text{ with }\ t+h\leq 1,$ $\mathcal{V}(t+h,x)=\mathcal{V}(h,\ \mathcal{V}(t,x))$;
- $\alpha(\mathcal{V}):=\sup\limits_{x,y\in E;x\neq y}\ \limsup\limits_{h\to 0+}\dfrac{d(\mathcal{V}(h,x),\mathcal{V}(h,y))-d(x,y)}{h\,d(x,y)}$ $<+\infty$;
- $\beta(\mathcal{V}):=\sup\limits_{x\in E}\limsup\limits_{h\to 0+}\dfrac{d(x,\ \mathcal{V}(h,x))}{h}<+\infty$.

For any transitions $\mathcal{V}_1$, $\mathcal{V}_2$ on (E,d), define the pseudo distance

$$d_\Lambda(\mathcal{V}_1,\mathcal{V}_2):=\sup_{x\in E}\limsup_{h\to 0+}\frac{1}{h}\,d(\mathcal{V}_1(h,x),\ \mathcal{V}_2(h,x)).$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Let $\Theta(E)$ be a fixed nonempty set of transitions, $T > 0$ and $x(\cdot) : [0, T] \to E$. For $t \in [0, T[$, the set

$$\overset{\circ}{x}(t) := \{\mathcal{V} \in \Theta(E) \,|\, \lim_{h\to 0+} \frac{1}{h}\, d\Big(\mathcal{V}(h, x(t)), x(t+h)\Big) = 0\}$$

is called mutation of $x(\cdot)$ at time t (relative to $\Theta(E)$).

A mapping $x(\cdot) : [0, T] \to E$ is called primitive of $\mathcal{V} : [0, T] \to \Theta(E)$ if it is Lipschitz and $\overset{\circ}{x}(t) \ni \mathcal{V}(t)$ for a.e. $t \in [0, T]$. The reverse sign $\ni$ reflects the fact that $\overset{\circ}{x}(t)$ may be multivalued, while $\mathcal{V}(t)$ is single-valued.

For a nonempty subset K of E and $x \in K$, the set

$$\overset{\circ}{T}_K(x) := \{\mathcal{V} \in \Theta(E) \,|\, \liminf_{h\to 0+} \frac{1}{h}\mathrm{dist}(\mathcal{V}(h, x), K) = 0\}$$

is called the contingent transition set to K at x.

Let $T > 0$, $W : [0, T] \times E \to \mathbb{R} \cup \{+\infty\}$ and (t, x) be in the domain of W with $t < T$. Below, $\mathbf{0} : [0, 1] \times \mathbb{R} \to \mathbb{R}$ and $\mathbf{1} : [0, 1] \times \mathbb{R} \to \mathbb{R}$ denote the transitions on $\mathbb{R}$ defined by $\mathbf{0}(h, t) = t$, $\mathbf{1}(h, t) = t + h$, for all $h \in [0, 1]$, $t \in \mathbb{R}$. For any transition $\mathcal{V} \in \Theta(E)$, the contingent directional derivative of W at (t, x) in the direction $(\mathbf{1}, \mathcal{V})$ is defined by

$$\overset{\circ}{D}_{\uparrow} W(t, x)(\mathbf{1}, \mathcal{V}) = \lim_{\varepsilon\to 0+} \inf_{\substack{h\in]0,\varepsilon] \\ y\in B(\mathcal{V}(h,x),\varepsilon h)}} \frac{W(t + h, y) - W(t, x)}{h}$$

As in [6], it is not difficult to link directional derivatives to the contingent transition set to the epigraph of W at (t, x).

Let (U, d_U) be a complete separable metric space of control parameters and define the set of admissible controls by

$$\mathcal{U} := \{u(\cdot) : [0, \infty) \to U \,|\, u(\cdot) \text{ is Lebesgue measurable}\}.$$

2. WEAK INVARIANCE, VIABILITY AND INVARIANCE

Consider a map $f : E \times U \to \Theta(E)$. f is called continuous if for any $(x_0, u_0) \in E \times U$ and $\varepsilon > 0$, there exists some $\delta > 0$ such that for all $(x, u) \in E \times U$,

$$d(x, x_0) + d_U(u, u_0) < \delta \implies d_\Lambda(f(x, u), f(x_0, u_0)) < \varepsilon.$$

$f(\cdot, u)$ is said to be uniformly Lipschitz in u, if there is a constant $L > 0$ such that

$$d_\Lambda(f(x, u),\ f(y, u)) \le L\, d(x, y), \quad \forall\, x, y \in E,\ \forall\, u \in U.$$

For any $x_0 \in E$ consider the mutational control system

$$[S] \quad \overset{\circ}{x}(s) \ni f(x(s),\ u(s)) \ \text{ a.e.},\ x(0) = x_0,\ u(\cdot) \in \mathcal{U}.$$

A Lipschitz mapping $x(\cdot) : [0, T] \to E$ is said to be a solution to [S] on $[0, T]$ for some $T > 0$, if there exists a control $u(\cdot) \in \mathcal{U}$ such that $\overset{\circ}{x}(t) \ni f(x(t), u(t))$ a.e. in $[0, T]$ and $x(0) = x_0$. If $f(\cdot, u)$ is uniformly Lipschitz in u, then, by [15, Proposition 21, p. 41] and the Gronwall lemma, to every control $u(\cdot) \in \mathcal{U}$ corresponds at most one solution of [S]. Below we always assume that f is continuous and that

$$\sup_{x\in E, u\in U} \alpha(f(x, u)) < +\infty; \quad \sup_{x\in E, u\in U} \beta(f(x, u)) < +\infty.$$

We also assume that for each $x_0 \in E$ and $\bar{u} \in U$ there exists a solution to $\overset{\circ}{x} \ni f(x, \bar{u})$, $x(0) = x_0$ defined on $[0, 1]$. By [15, Theorem 20, p.40] it is always the case when E is proper. For more general metric spaces such existence depends on the choice of $\Theta(E)$ and f.

For any $x_0 \in E$ and $t \ge 0$, denote by $\mathcal{S}_t(x_0)$ the set of all solutions to the mutational control system $[S]$ defined on $[0, t]$ and by $R(t; x_0) := \{x(t) \in E \,|\, x(\cdot) \in \mathcal{S}_t(x_0)\}$, the reachable set from x_0 at time t.

Consider the controlled mutational equation

$$\overset{\circ}{x}(s) \ni f(x(s),\ u(s)) \text{ a.e. } s \ge 0,\ u(\cdot) \in \mathcal{U} \qquad (1)$$

and let $K \subset E$ be a proper nonempty set. K is called weakly invariant under (1) if for every $x_0 \in K$ we have $R(t; x_0) \cap K \neq \emptyset$ for any $t \ge 0$, see [17].

K is called viable under (1) if for any $x_0 \in K$, there exists a solution $x(\cdot)$ of (1) with $x(0) = x_0$ satisfying $x(t) \in K$ for all $t \ge 0$.

K is called invariant under (1) if every solution $x(\cdot)$ of (1) with $x(0) \in K$ satisfies $x(t) \in K$ for all $t \ge 0$.

Clearly any viable set is weakly invariant. To illustrate that weak invariance does not yield viability, consider the two dimensional control system $x' = u(t)$ in $\mathbb{R}^2$ with $U = \{0\} \times \{-1, 1\}$ and the set K equal to the unit sphere in $\mathbb{R}^2$. Then every trajectory of this system staring in K leaves it immediately. At the same time $x_0 \in R(t; x_0)$ for any $x_0 \in K$ and $t \ge 0$. Therefore K is weakly invariant.

Proposition 1. (Necessary condition for weak invariance). Assume that (U, d_U) is compact and $K \subset E$ is weakly invariant. If $x \in K$ is so that for a sequence $h_i \to 0+$

$$\sup_{y\in R(h_i;x)} \inf_{u\in U}\ d\Big(y, f(x, u)(h_i, x)\Big) = o(h_i), \qquad (2)$$

then there exists $u \in U$ satisfying $f(x, u) \in \overset{\circ}{T}_K(x)$. In particular, if for every $x \in K$ we can find $h_i \to 0+$ satisfying (2), then $f(x, U) \cap \overset{\circ}{T}_K(x) \neq \emptyset$ for every $x \in K$.

Theorem 2. (Sufficient condition for weak invariance). Assume that $f(\cdot, u)$ uniformly Lipschitz in u, that $R(t; x_0)$ compact for all $x_0 \in K$ and $t > 0$ and that for any $x \in K$, $f(x, U) \cap \overset{\circ}{T}_K(x) \neq \emptyset$. Then K is weakly invariant under (1).

Theorem 3. (Sufficient condition for viability). Under the assumptions of Theorem 2 suppose that for each $x_0 \in K$ and $t > 0$, the set $\mathcal{S}_t(x_0)$ is closed in the metric of uniform convergence. Then K is viable under (1).

Under the assumptions of Theorem 2, it can be shown, using the Ascoli-Arzelà Theorem 47.1 from [16], that every sequence $\{x_n(\cdot)\}_n \subset \mathcal{S}_T(x_0)$ has a subsequence converging uniformly to a Lipschitz function $x : [0, T] \to E$. Clearly, $x(t) \in R(t; x_0)$ for all $t \in [0, T]$. This does not yield however that $x(\cdot) \in \mathcal{S}_T(x_0)$. When E is a locally compact, complete metric space, using a more sophisticated construction as in [17, Theorem of Barbashin], it is even possible to get a Lipschitz mapping $x : [0, T] \to E$ satisfying $x(t_2) \in R(t_2; t_1, x(t_1))$ for all $0 \le t_1 < t_2 \le T$. Still this does not imply that $x(\cdot) \in \mathcal{S}_T(x_0)$. To illustrate that the assumptions in the above two theorems are not equivalent, consider a compact subset $U \subset \mathbb{R}^n$ and the control system $x' = u(t) \in U$, $x(0) = x_0$. It is well known that its reachable sets are compact, while, in general, $\mathcal{S}_T(x_0)$ is not closed in the metric of uniform convergence.

Theorem 4. (Mutational invariance). Suppose that $f(\cdot, u)$ is uniformly Lipschitz in u. Then K is invariant under (1) if and only if $f(x, U) \subset \overset{\circ}{T}_K(x)$ for each $x \in K$.

3. HAMILTON-JACOBI INEQUALITIES

In this section, (E,d) is a proper metric space. Given an extended lower semicontinuous cost function $g : E \to \mathbb{R} \cup \{+\infty\}$ and $x_0 \in E$, we associate to it the Mayer optimal control problem

$[P]$ minimize $g(x(1))$

over all the solutions of the mutational control system [S] defined on $[0,1]$.

Consider the mutational equation

$$\overset{\circ}{z}(\cdot) \ni f(z(\cdot), u(\cdot)), \quad u(\cdot) \in \mathcal{U} \tag{3}$$

and define the value function $V : [0,1] \times E \to \mathbb{R} \cup \{+\infty\}$ by : for all $t \in [0,1]$ and $x \in E$, $V(t,x) := \inf\{g(z(1)) \,|\, z(\cdot)$ is a solution to (3) on $[t,1]$, $z(t) = x\} \in \mathbb{R} \cup \{\pm\infty\}$.

Theorem 5. Assume that for any $x \in E$, the set $\mathcal{S}_1(x)$ is closed in the metric of uniform convergence. Then for any $t_0 \in [0,1]$ and $x \in E$ there exist a control $u(\cdot) \in \mathcal{U}$ and a solution z to (3) with $z(t_0) = x$ defined on $[t_0,1]$ and satisfying $V(t_0,x) = g(z(1))$.

Theorem 6. Assume that $f(\cdot,u)$ is uniformly Lipschitz in u and that for any $x \in E$, there exist $h_i \to 0+$ satisfying (2). Then, the value function V verifies the boundary condition $V(1,\cdot) = g(\cdot)$ and the following contingent inequalities:

- for any (t,x) in the domain of V with $t < 1$, $\sup_{u \in U} \overset{\circ}{D}_{\uparrow}(-V)(t,x)(\mathbf{1}, f(x,u)) \le 0$.
- for any (t,x) in the domain of V with $t < 1$, $\overset{\circ}{D}_{\uparrow} V(t,x)(\mathbf{1}, f(x,u)) \le 0$ for some $u \in U$.

A continuous map $w : [0,1] \times E \to \mathbb{R}$ is called a contingent solution to the mutational Hamilton-Jacobi equation (associated with $[P]$, $[S]$) if it satisfies the boundary condition $w(1,\cdot) = g(\cdot)$ and the above two contingent inequalities with V replaced by w.

Theorem 7. Assume that $f(\cdot,u)$ is uniformly Lipschitz in u. If g is continuous, then V is continuous. Furthermore, if g is locally Lipschitz, then V is locally Lipschitz.

Theorem 8. Let $g : E \to \mathbb{R}$ be continuous and $f(\cdot,u)$ be uniformly Lipschitz in u. Assume that for any $x \in E$, the set $\mathcal{S}_1(x)$ is closed in the metric of uniform convergence and there exist $h_i \to 0+$ satisfying (2). Then V is the unique continuous contingent solution to the mutational Hamilton-Jacobi equation.

4. EXAMPLES

In this section we discuss two examples where the general results of previous sections do apply. We endow the space $Lip(\mathbb{R}^N, \mathbb{R}^N)$ of all bounded Lipschitz continuous functions $F : \mathbb{R}^N \to \mathbb{R}^N$ with the topology of local uniform convergence. For any $F \in Lip(\mathbb{R}^N, \mathbb{R}^N)$, denote by $Lip\, F$ the smallest Lipschitz constant of F and set $||F||_\infty := \sup_{x \in \mathbb{R}^N} |F(x)|$. For $F : \mathbb{R}^N \to \mathbb{R}^N$ and $K \subset \mathbb{R}^N$ define $(Id + F)(K) := \{x + F(x) \mid x \in K\}$.

4.1 Morphological control problem

Consider the metric space $\mathcal{K}(\mathbb{R}^N)$ of nonempty compact subsets of $\mathbb{R}^N$ supplied with the Pompeiu-Hausdorff distance: for all $K_1, K_2 \in \mathcal{K}(\mathbb{R}^N)$

$$d_H(K_1,K_2) := \max\left\{ \max_{x \in K_1} \operatorname{dist}(x,K_2),\ \max_{x \in K_2} \operatorname{dist}(x,K_1) \right\}.$$

Then $(\mathcal{K}(\mathbb{R}^N),\ d_H)$ is a proper metric space, see for instance [15, Proposition 47, p.57].

For any $F : [0,\infty) \to Lip(\mathbb{R}^N, \mathbb{R}^N)$, $t \ge 0$ and $K_0 \in \mathcal{K}(\mathbb{R}^N)$, the set $\mathcal{V}_{F(\cdot)}(t,K_0) := \{x(t) \,|\, x(\cdot) \in W^{1,1}\big([0,t],\mathbb{R}^N\big),\ x'(s) = F(s)(x(s))$ a.e., $x(0) \in K_0\}$ is called the reachable set at time t of the system governed by $F(\cdot)(\cdot)$ from the initial condition K_0. The subset of transitions is given by

$$\Theta(\mathcal{K}(\mathbb{R}^N)) = \{\mathcal{V}_F \,|\, F \in Lip(\mathbb{R}^N, \mathbb{R}^N)\}.$$

Let $f : \mathcal{K}(\mathbb{R}^N) \times U \to Lip(\mathbb{R}^N, \mathbb{R}^N)$ be continuous with

$$\sup_{u \in U,\, K \in \mathcal{K}(\mathbb{R}^N)} \Big(Lip\ f(K,u) + ||f(K,u)||_\infty \Big) < +\infty\ . \tag{4}$$

Consider the morphological control system

$$[M] \qquad \overset{\circ}{K}(\cdot) \ni \mathcal{V}_{f(K(\cdot),u(\cdot))},\ u(\cdot) \in \mathcal{U}.$$

A map $K(\cdot) : [0,T] \to \mathcal{K}(\mathbb{R}^N)$, where $T > 0$, is called a solution to [M] if $K(\cdot)$ is Lipschitz continuous with respect to d_H and for some $u(\cdot) \in \mathcal{U}$ and for a.e. $t \in [0,T]$

$$\lim_{h \to 0+} \frac{1}{h} \cdot d_H\Big(\mathcal{V}_{f(K(t),u(t))}(h, K(t)), K(t+h) \Big) = 0.$$

Setting $F(t) := f(K(t),u(t))$, it follows that $K(\cdot)$ is the mutational primitive of $\mathcal{V}_{F(\cdot)}$ on $[0,T]$. The results from [15, pp. 388, 113, 74 and 24] imply

Proposition 9. For any $K_0 \in \mathcal{K}(\mathbb{R}^N)$, $T > 0$ and $u(\cdot) \in \mathcal{U}$, there exists a solution $K(\cdot)$ to $[M]$ on $[0,T]$ with $K(0) = K_0$ and for every time $t \in [0,T]$, $K(t)$ coincides with the reachable set of the differential equation

$$x'(\tau) = f\big(K(\tau), u(\tau)\big)\big(x(\tau)\big), \quad x(0) \in K_0.$$

Moreover, if $f(\cdot,u)$ is uniformly Lipschitz in u w.r.t. the metric on $Lip(\mathbb{R}^N, \mathbb{R}^N)$ generated by $\|\cdot\|_\infty$, then the solution to [M] with the initial condition K_0 is unique.

We shall need the following assumptions:

$$(\mathbf{H1}) \quad \begin{cases} (4) \text{ holds and } (U, d_U) \text{ is a compact metric space;} \\ f(\cdot,u) \text{ is uniformly Lipschitz in } u \text{ w.r.t. } \|\cdot\|_\infty; \\ f(K,U) \text{ is convex for every } K \in \mathcal{K}(\mathbb{R}^N). \end{cases}$$

Theorem 10. Assume **(H1)** and consider a closed nonempty subset $\Omega \subset \mathcal{K}(\mathbb{R}^N)$. Then Ω is viable under [M] if and only if for each $K \in \Omega$, there exists some $u \in U$ satisfying

$$\liminf_{h \to 0+} \frac{1}{h} \operatorname{dist}((Id + hf(K,u))(K), \Omega) = 0.$$

Furthermore, Ω is invariant under [M] if and only if the above equality holds true for each $K \in \Omega$ and any $u \in U$.

4.2 Control system in a Wasserstein space

Denote by $\mathcal{P}(\mathbb{R}^N)$ the family of all Borel probability measures on $\mathbb{R}^N$ endowed with the narrow topology.
For any $\emptyset \ne K \subseteq \mathbb{R}^N$, denote by $\mathcal{P}(K) \subseteq \mathcal{P}(\mathbb{R}^N)$ the set of all Borel probability measures with the support contained in K and by $\mathcal{P}_c(\mathbb{R}^N)$ the subset of all Borel probability measures with a compact support.

We first recall some notions in $\mathcal{P}(\mathbb{R}^N)$, see for instance [1].

For any $\mu \in \mathcal{P}(\mathbb{R}^N)$ and a Borel map $T : \mathbb{R}^N \to \mathbb{R}^N$, let $T_{\#}\mu \in \mathcal{P}(\mathbb{R}^N)$ denote the pushforward of μ through T:

$$T_{\#}\mu(B) := \mu(T^{-1}(B)) \text{ for any Borel set } B \subset \mathbb{R}^N.$$

Denote $\mathcal{P}_2(\mathbb{R}^N) := \{\mu \in \mathcal{P}(\mathbb{R}^N) \,|\, \int_{\mathbb{R}^N} |x|^2 \, \mathrm{d}\mu(x) < +\infty\}$ and by W_2 the Wasserstein distance on $\mathcal{P}_2(\mathbb{R}^N)$, see [1]. The space $(\mathcal{P}_2(\mathbb{R}^N), W_2)$ is called the Wasserstein space of order 2. It is well known that $(\mathcal{P}_2(\mathbb{R}^N), W_2)$ is complete and separable. Furthermore, for any nonempty compact $K \subset \mathbb{R}^N$, the set $\mathcal{P}(K)$ is compact in $(\mathcal{P}_2(\mathbb{R}^N), W_2)$.

Consider a continuous map $f : \mathcal{P}_2(\mathbb{R}^N) \times U \to Lip(\mathbb{R}^N, \mathbb{R}^N)$ such that $f(\cdot, u)$ is uniformly Lipschitz in u w.r.t. the metric on $Lip(\mathbb{R}^N, \mathbb{R}^N)$ generated by $\|\cdot\|_\infty$ and the controlled continuity equation

$$[C] \qquad \partial_t \mu(t) + \nabla(f(\mu(t), u(t)) \cdot \mu(t)) = 0, \quad u(\cdot) \in \mathcal{U}.$$

Given $T > 0$, an absolutely continuous map $\mu(\cdot) : [0, T] \to \mathcal{P}_2(\mathbb{R}^N)$ is a solution to [C] on $[0, T]$ if for some $u(\cdot) \in \mathcal{U}$ it solves

$$\partial_t \mu(t) + \nabla(f(\mu(t), u(t)) \cdot \mu(t)) = 0 \tag{5}$$

on $[0, T]$ in the sense of distributions.

The existence and the representation of solutions of the non-local continuity equation (5) for every initial condition in $\mathcal{P}_c(\mathbb{R}^N)$ were investigated in [7]. We shall assume:

$$(\mathbf{H2}) \quad \begin{cases} A_2 := \sup_{u \in U,\, \mu \in \mathcal{P}_2(\mathbb{R}^N)} Lip\, f(\mu, u) < \infty; \\ \rho_2 := \sup_{u \in U,\, \mu \in \mathcal{P}_2(\mathbb{R}^N)} ||f(\mu, u)||_\infty < +\infty; \\ (U, d_U) \text{ is a compact metric space;} \\ f(\mu, U) \text{ is convex } \forall\, \mu \in \mathcal{P}_2(\mathbb{R}^N). \end{cases}$$

Under assumptions (H2), $\mathcal{P}_c(\mathbb{R}^N)$ is invariant by solutions of [C], see [7].

Let $g \in Lip(\mathbb{R}^N, \mathbb{R}^N)$ and for any $\mu_0 \in \mathcal{P}_c(\mathbb{R}^N)$ and $h \in [0, 1]$, define $\mathcal{V}_g(h, \mu_0) := \mu(h)$, where $\mu(\cdot) : [0, 1] \to \mathcal{P}_2(\mathbb{R}^N)$ is the distributional solution to the continuity equation

$$\partial_t \mu(t) + \nabla(g \cdot \mu(t)) = 0, \quad \mu(0) = \mu_0. \tag{6}$$

Then $\mathcal{V}_g : [0, 1] \times \mathcal{P}_c(\mathbb{R}^N) \to \mathcal{P}_c(\mathbb{R}^N)$ is a transition on $(\mathcal{P}_c(\mathbb{R}^N), W_2)$. For any $t > 0$ and $\mu_0 \in \mathcal{P}_c(\mathbb{R}^N)$, consider the sets $\mathcal{S}_t^C(\mu_0)$ of solutions to [C] on $[0, t]$ with $\mu(0) = \mu_0\}$ and

$$R^C(t, \mu_0) := \{\mu(t) \,|\, \mu \in \mathcal{S}_t^C(\mu_0)\}.$$

It follows from [7] that assumption **(H2)** implies that for any $T > 0$ and $\mu_0 \in \mathcal{P}_c(\mathbb{R}^N)$ the set $\mathcal{S}_T^C(\mu_0)$ is compact in the metric of uniform convergence.

Proposition 11. Assume **(H2)**. Then, there exists $k > 0$ such that for any $\mu_0 \in \mathcal{P}_c(\mathbb{R}^N)$, any $h_n \to 0+$ and any $\mu(h_n) \in R^C(h_n, \mu_0)$ we can find $u_n \in U$ satisfying

$$W_2\Big(\mu(h_n), \mathcal{V}_{f(\mu_0, u_n)}(h_n, \mu_0)\Big) \le k h_n^2$$

and $W_2\Big((Id + f(\mu_0, u_n))_{\#}\mu_0, \mathcal{V}_{f(\mu_0, u_n)}(h_n, \mu_0)\Big) \le A_2 \rho_2 h_n^2$.

The above results together with those from Section 3 allow to deduce the following viability and invariance theorem.

Theorem 12. Assume **(H2)** and let $\Omega \subset \mathcal{P}_c(\mathbb{R}^N)$ be nonempty and proper. Then Ω is viable under [C] if and only if for each $\mu \in \Omega$, there exists some $u \in U$ satisfying

$$\liminf_{h \to 0+} \frac{1}{h} \operatorname{dist}((Id + h f(\mu, u))_{\#}\mu, \Omega) = 0.$$

Furthermore, Ω is invariant under [C] if and only if the above equality holds true for each $\mu \in \Omega$ and any $u \in U$.

Abstract: In this study, we explore the relationship between the complexity of neural networks and the internal compositional structure of the function to be approximated. The results shed light on the reason why using neural network approximation helps to avoid the curse of dimensionality.

Keywords: Non-linear control systems, deep learning, optimal control, power systems

1. INTRODUCTION

In this study, we explore the relationship between the complexity of neural networks and the internal compositional structure of the function to be approximated. The results shed light on the reason why using neural network approximation helps to avoid the curse of dimensionality (COD). In Section 2, we discuss the challenge of COD in feedback control. In Section 3, we introduce four compositional features that determine the complexity and error upper bound of neural network approximation for dynamical and control systems. In Section 4, several examples are given to illustrate the widely observed phenomenon in science and engineering that complicated functions are formed by the composition of simple ones.

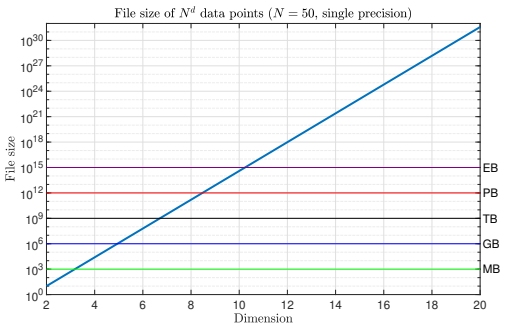

Fig. 1. The size of data file that grows exponentially with the space dimension. In each dimension, $N = 50$. The total number of data points is N^d.

2. THE CURSE OF DIMENSIONALITY

The COD is a bottleneck in many applications of dynamical systems and nonlinear control. It is a phenomenon in which the complexity of an approximate solution grows fast, such as exponentially, with the state space dimension. For instance, consider a feedback control law

$$u = u(\mathbf{x}),\ \mathbf{x} \in \mathbb{R}^d,\ u \in \mathbb{R}. \tag{1}$$

for a system of dimension d. If d is large and if an analytic representation cannot be found for $u(\mathbf{x})$, a numerical approximation has to be applied to store the control law in a digital format. If $u(\mathbf{x})$ is approximated using interpolation based on its value at grid points, the size of the dataset increases exponentially. Specifically, suppose we use N grid points in each dimension. Then the total number of grid points in a d dimensional domain is N^d. The value of $u(\mathbf{x})$ over the grid forms a huge dataset even for moderate dimensions such as $d = 7$ or 8. Figure 1 shows an example in which $N = 50$. If $d = 7$, the memory needed to store the value of $u(\mathbf{x})$ over the grid using single precision is about 1TB. This number is 1PB for $d = 9$ and 1EB for $d = 10$. Due to the limitations on processor's primary storage, bus speed and computation speed, the interpolation of datasets that have such large sizes is practically intractable, not to mention that the computation has to be carried out in real-time for feedback control.

3. COMPOSITIONAL FEATURES AND THE COMPLEXITY OF NEURAL NETWORKS

For the last few years, a new trend of overcoming the COD in nonlinear dynamics and control using deep learning has been developed rapidly. Many examples of successfully applying deep learning to high dimensional differential equations and optimal control were published in which the dimensions range from six to several hundred, well beyond what conventional computational methods can deal with (Han et al. (2018); Izzo et al. (2019); Nakamura-Zimmerer et al. (2021); Kang et al. (2021a); Sirignano and Spiliopoulos (2018); Raissi et al. (2019); B. Azmi (2020)). These empirical successes of deep learning in overcoming the COD inspire us to study the underlying reason why neural networks are capable of solving so many high dimensional problems. The philosophy in our study is based on a widely

⋆ This work was supported in part by U.S. Naval Research Laboratory - Monterey, CA and National Science Foundation

observed fact in science and engineering: complicated functions are formed by the composition of relatively simple functions. In Kang and Gong (2022), a set of key features of compositional functions is defined. It can be mathematically proved that these features determine the upper bounds of neural network complexity and approximation error. These upper bounds do not suffer from the COD.

To exemplify the compositional structure of nonlinear systems, consider the swing equations of a power system with N_g generators

$$\begin{aligned}\frac{d\omega_i}{dt} &= \frac{\omega_0}{2H_i}\left(P_m - D\frac{\omega_i-\omega_0}{\omega_0} - E_i^2 G_{ii} \cdots \right.\\ &\left. - \sum_{j=1,j\neq i}^{10} E_i E_j [B_{ij}\sin(\delta_i-\delta_j) + G_{ij}\cos(\delta_i-\delta_j)]\right)\\ \frac{d\delta_i}{dt} &= \omega_i - \omega_0,\end{aligned} \tag{2}$$

where $i = 1, ..., N_g$. For the ith generator, the two state variables are δ_i, the rotor angle in radian, and ω_i, the rotor speed in radian per second. Other parameters include H_i (the inertial constant of the generator), $\omega_0 = 2\pi \times f_0$ (the synchronous angular frequency in radian per second for an ac power system with frequency f_0), D (the damping coefficient), P_m (the mechanical power input from the turbine), E_i (the electromotive force or internal voltage of the generator). In addition, $G_{ij} + jB_{ij}$, the mutual admittance between E_i and E_j, is the i^{th} row j^{th} column element of the admittance matrix among all electromotive forces, and G_{ii} is the conductance representing the local load seen from E_i. Details about the model and its parameters refer to Athay et al. (1979).

A power system may have tens or hundreds of generators. This complicated system model, however, is a composition of functions that have low input dimensions. The compositional structure can be represented using a layered directed acyclic graph (DAG). For example, Figure 2 is a DAG of the function in (2). Each colored node in the DAG represents a nonlinear function. They are all sine and cosine functions with a single input. Although some linear nodes (white color) have high input dimensions, such as the node in the output layer, it is proved in Kang and Gong (2022) that linear nodes do not increase the complexity, or the number of neurons, of the neural network. The

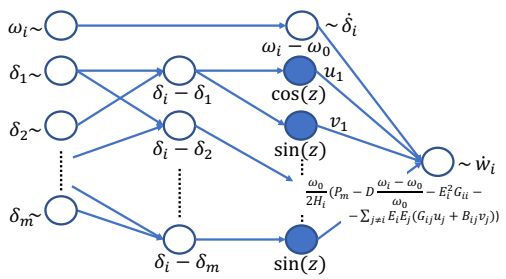

Fig. 2. The layered DAG of the function in (2) as a compositional function.

question we would like to answer is: how does a layered DAG help in the effort of using deep learning to find the trajectory or the optimal control of a system? Our study shows that some compositional features are critical to the required complexity of neural networks used in deep learning. These features are briefly introduced as follows.

- $|\mathcal{V}|$ (complexity feature): The total number of nonlinear nodes in the layered DAG, where $\mathcal{V}$ is the set of nonlinear nodes of the compositional function.
- r_{max} (dimension feature): The largest ratio, d/m, for all nodes in $\mathcal{V}$, where d is the input dimension of the node and m is the smoothness of the node.
- Λ (volume feature): Each nonlinear node, denote the function by f, has a domain. Assume that the domain is a square of edge length R. The volume feature is defined to be the largest value in
$$\{\max\{R,1\}||f||;\ f \in \mathcal{V}\}, \tag{3}$$
where $||\cdot||$ is the Sobolev norm
$$||f|| = ||f||_{L^\infty} + \sum \left\| \frac{\partial f}{\partial x_i} \right\|_{L^\infty}. \tag{4}$$
- $L_{\max}$ (Lipschitz constant feature): The largest Lipschitz constants associated with nonlinear nodes. Note that this Lipschitz constant is defined based on the layered structure of the DAG. For more details, the readers are referred to Kang and Gong (2022).

Consider a general dynamical system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}),\ \mathbf{x} \in \mathbb{R}^d \tag{5}$$

in which $\mathbf{f}(\mathbf{x}) \in \mathbb{R}^d$ has a layered compositional structure. Let $\boldsymbol{\phi}(t, \mathbf{x})$ represents the solution of (5) in which $\mathbf{x}$ is the initiate state, $\boldsymbol{\phi}(0, \mathbf{x}) = \mathbf{x}$.

Theorem 1. (Kang and Gong (2022)) Suppose that all nodes in $\mathbf{f}$ are C^1. Let $D \subset \mathbb{R}^d$ be a closed set and $R > 0$ be a constant. Suppose $\boldsymbol{\phi}(t, \mathbf{x}) \in [-R, R]^d$ for $t \in [0, T]$ and $\mathbf{x} \in D$. Then, there always exists a deep feedforward neural network, denoted by $\boldsymbol{\phi}^{NN}(\mathbf{x})$, in which activation functions are C^∞. Furthermore, the network satisfies

$$\left\|\boldsymbol{\phi}^{NN}(\mathbf{x}) - \boldsymbol{\phi}(T, \mathbf{x})\right\|_2 < (C_1 L_{max} \Lambda\, |\mathcal{V}| + C_2) n^{-1/r_{max}} \tag{6}$$

where n is an integer that determines an upper bound of the total number of neurons in $\boldsymbol{\phi}^{NN}(\mathbf{x})$, i.e., the complexity of the neural network,

$$\#\text{ of neurons in } \boldsymbol{\phi}^{NN} \leq \left(n^{1/r_{max}} + 1\right) n\, |\mathcal{V}| \tag{7}$$

The constants, C_1 and C_2, in (6) are determined by $\|\mathbf{f}\|_2$, $\left\|\frac{\partial \mathbf{f}}{\partial \mathbf{x}}\right\|_2$, T and the input dimensions of the nodes in $\mathcal{V}$.

It is worth to note that the error upper bound (6) depends on Λ, L_{max} and $|\mathcal{V}|$ as a polynomial function, rather than an exponential function. The value of r_{max} depends on the input dimensions of individual notes of $\mathbf{f}$, not directly on the overall dimension, d. Therefore, if r_{max} is bounded and if Λ, L_{max} and $|\mathcal{V}|$ do not increase exponentially with d, the neural network approximation of $\boldsymbol{\phi}(T, \mathbf{x})$ is free from the COD. A similar result holds true for optimal control. Consider a control system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}),\ \mathbf{x} \in D \subset \mathbb{R}^d,\ \mathbf{u} \in \mathbb{R}^q,\ t \in [0, T] \tag{8}$$

A zero-order hold control, $U = [\,\mathbf{u}_1\ \mathbf{u}_2\ \cdots\ \mathbf{u}_{N_t}\,]$ in which $\mathbf{u}_k$ is the constant control for $t \in [t_{k-1}, t_k]$. The goal of an optimal control problem is to find U that minimizes the cost function

$$J(\mathbf{x}, U) = \Psi \circ \boldsymbol{\phi}(\Delta t; \mathbf{u}_{N_t}, \cdot) \cdot \boldsymbol{\phi}(\Delta t; \mathbf{u}_{N_t-1}, \cdot) \circ \cdots \circ \boldsymbol{\phi}(\Delta t; \mathbf{u}_1, \mathbf{x}) \tag{9}$$

where $\Psi : \mathbb{R}^d \to \mathbb{R}$ is a function.

Theorem 2. Suppose that $\mathbf{f}$ and Ψ are compositional functions in which all nodes are C^2. Let $D \subset \mathbb{R}^d$ be a bounded closed set. Assume that the Hession of $J(\mathbf{x}, U)$ with respect to U is positive definite. Let $U^*(\mathbf{x})$ represents the optimal feedback control. Then, for any $\epsilon > 0$, there exists a deep neural network, U^{*NN}, that approximates the optimal control. The estimation error is

$$\left\| U^{*NN}(\mathbf{x}) - U^*(\mathbf{x}) \right\|_2 \leq 3\epsilon, \ \mathbf{x} \in D \tag{10}$$

The complexity of U^{*NN} is bounded by

$$n \leq C\epsilon^{-(4r_{max}+1+4r_{max}/r^{\mathbf{f}}_{max})} \tag{11}$$

where $r^{\mathbf{f}}_{max}$ is the dimension feature of $\mathbf{f}$ and r_{max} is the largest dimension feature of $\mathbf{f}$ and Ψ, C is a polynomial of q and other compositional features of $\mathbf{f}$ and Ψ.

4. SOME EXAMPLES OF COMPOSITIONAL FEATURES

According to Theorems 1 and 2, if the compositional features of a family of systems do not increase exponentially with d, the approximation of a trajectory or an optimal control has a polynomial error upper bound; the complexity of the neural network increases at a polynomial rate. In the following, we use three examples to demonstrate that this kind of polynomial relationship is not unusual.

4.1 Compositional features of power systems

The first example is the power system model in (2). Its layered DAG is shown in Figure 2. Its compositional features are summarized as follows.

$$r_{max} = 1, \ \ \Lambda = 4\pi, \ \ |\mathcal{V}| = 2(N_g - 1)N_g,$$
$$L_{max} = \max_{1 \leq i,j \leq N_g, i \neq j} \left\{ \frac{\omega_0}{2H_i} E_i E_j G_{ij}, \frac{\omega_0}{2H_i} E_i E_j B_{ij} \right\}. \tag{12}$$

The dimension feature is $r_{max} = 1$ because all nonlinear nodes ($\sin(z)$ and $\cos(z)$) have a single input. Here we treat the nodes as functions in C^1 although they are also in C^∞. This simplifies the formula in the derivation. The value of Λ depends on the radius of the domain of nonlinear nodes and their Sobolev norm (4). For each nonlinear node, the domain of its input is bounded by 2π. Furthermore, $\sin(z)$, $\cos(z)$ and their derivatives are all bounded by 1. Then it is straightforward to derive the volume feature $\Lambda = 4\pi$. Following the definition in Kang and Gong (2022), the Lipschitz constant associated with a node is the Lipschitz constant of $\mathbf{f}$ (not the node) with respect to the node when the node is treated as a free variable. For example, the nonlinear nodes in Figure 2 are $\cos(z)$ and $\sin(z)$. If one of them, for instance the first $\cos(z)$ connecting to $\delta_i - \delta_1$, is treated as a variable, the Lipschitz constant of the function associated with this node equals

$$\frac{\omega_0}{2H_i} E_i E_1 G_{i1}. \tag{13}$$

This computation is for the first nonlinear node ($j = 1$) in the ith generator. The value of L_{max} in (19) is the largest one among the numbers computed similarly for all the N_g generators and all nonlinear nodes. For the ith generator, $1 \leq i \leq N_g$, there are $2(N_g - 1)$ nonlinear nodes. Therefore, the total number of nonlinear nodes is $|\mathcal{V}| = 2(N_g - 1)N_g$. We would like to emphasize that the compositional features in (12) are either constants or polynomial functions of N_g. As such, they do not increase exponentially with N_g. From Theorem 1, there exists a deep neural network approximation of the power system that avoids the COD. In fact, a similar conclusion can be extended to the Lyapunov function of the power system, which is proved in Kang et al. (2021b).

Theorem 3. Consider a power system (2) that has N_g generators. Let $\mathcal{R} \subset \mathbb{R}^{2N_g}$ be a bounded set. Then, there exists a solution, $V(\mathbf{x})$, to Zubov's equation (a special Lyapunov function that characterizes the domain of attraction) and a neural network, $V^{NN}(\mathbf{x})$, that has n^{NN} hyperbolic tangent neurons. They satisfy

$$\left| V^{NN}(\mathbf{x}) - V(\mathbf{x}) \right| < (C_1 N_g^2 + C_2) \frac{N_g}{\sqrt{n^{NN}}} \tag{14}$$

for $\mathbf{x} \in \mathcal{R}$, where C_1 and C_2 are constants independent of N_g.

4.2 Lorenz-96 model

Consider a system of ODEs

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) \tag{15}$$

in which $\mathbf{f} : [-R, R]^d \subset \mathbb{R}^d \to \mathbb{R}^d$ is the vector field that defines the Loranz-96 model in Lorenz (1996),

$$\mathbf{f} = \begin{bmatrix} x_0(x_2 - x_{-1}) - x_1 + F \\ x_1(x_3 - x_0) - x_2 + F \\ \vdots \\ x_{i-1}(x_{i+1} - x_{i-2}) - x_i + F \\ \vdots \\ x_{d-1}(x_{d+1} - x_{d-2}) - x_d + F \end{bmatrix}, \tag{16}$$

where $x_{-1} = x_{d-1}$, $x_0 = x_d$, $x_{d+1} = x_1$ and F is a constant. Let's treat $\mathbf{f}$ as a compositional function. An example of its layered DAG when $d = 4$ is shown in Figure 3. All nonlinear nodes in Figure 3 are located in the second

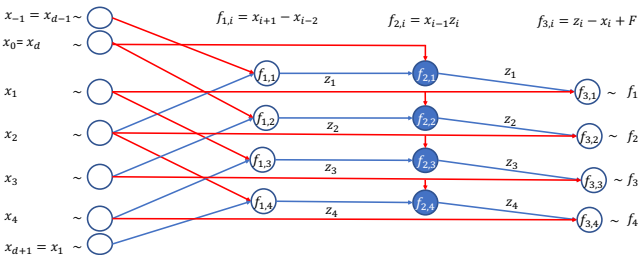

Fig. 3. DAG structure of the function (16) for $d = 4$. For a clear illustration, edges pointing to the first, the second, and the third layer are shown in red, blue and green respectively.

layer. They are defined by

$$f_{2,j}(x_{j-1}, z_j) = x_{j-1} z_j, \ \ j = 1, \cdots, d. \tag{17}$$

All nonlinear nodes have the dimension $d_{2,j} = 2$ and the domain $[-2R, 2R]^2$. Since $f_{2,j}$ is C^∞, we can set the smoothness to be any integer $m \geq 2$. As an example, we set $m = 1$. Then the dimension feature is $r_{max} = 2$. The Sobolev norm of $f_{2,j}$ is straightforward to compute, which

determines Λ, the volume feature. To compute the Lipchitz constant associated with the node, $f_{2,j}$, we construct the truncation of $\mathbf{f}$ along the second layer, which is given by

$$\bar{\mathbf{f}}(z_1, \cdots, z_{2d}) = \begin{bmatrix} z_1 - z_{d+1} + F \\ z_2 - z_{d+2} + F \\ \vdots \\ z_d - z_{2d} + F \end{bmatrix}, \tag{18}$$

where x_i, $1 \le i \le d$, are represented by the dummy inputs z_j, $j = d+1, \cdots, 2d$. The Lipschitz constant of $\bar{\mathbf{f}}$ with respect to z_j is $L_{2,j} = 1$, for $j = 1, \cdots, d$. The total number of nonlinear nodes in the system equals the dimension, d, because each equation in (16) has a single nonlinear node. To summarize, the compositional features of the Lorenz-96 model are

$$\begin{aligned} r_{max} &= 2,\ \Lambda = \max\{(2R), 1\}(2R + 4R^2), \\ L_{max} &= 1,\ |\mathcal{V}| = d. \end{aligned} \tag{19}$$

There is no exponential growth in the features. They are either constants or a linear function of d.

4.3 Burgers' Equation

Consider the following discretized Burgers's equation

$$\begin{aligned} \dot{u}_1 &= -u_1 \frac{u_2 - u_0}{2\Delta x} + \kappa \frac{u_2 + u_0 - 2u_1}{\Delta x^2} \\ \dot{u}_2 &= -u_2 \frac{u_3 - u_1}{2\Delta x} + \kappa \frac{u_3 + u_1 - 2u_2}{\Delta x^2} \\ &\vdots \\ \dot{u}_{N-1} &= -u_{N-1} \frac{u_N - u_{N-2}}{2\Delta x} + \kappa \frac{u_N + u_{N-2} - 2u_{N-1}}{\Delta x^2} \end{aligned} \tag{20}$$

The discretization is based on central different in which $\Delta x = L/N$ is the parameter that represents the step size of the state variable $x \in [0, L]$. The boundary condition is $u_0 = u_N = 0$. The dimension of the state space is N. The layered DAG of the function in (20) is shown in Figure 4. Due to the viscosity term in the equation, the solutions are stable. For initial conditions in a bounded set, we can assume that the state variables are bounded in $[-R, R]^N$ for some $R > 0$. The compositional features are summarized in (21). They are either constants or linear functions of N. None of them grows exponentially.

$$r^{\mathbf{f}}_{max} = 1, \Lambda^{\mathbf{f}} = \frac{1}{2}R^2 + R, L^{\mathbf{f}}_{max} = \frac{N}{L}, \left|\mathcal{V}^{\mathbf{f}}_G\right| = 2N. \tag{21}$$

5. CONCLUSION

The relationship revealed in this study between the complexity of neural networks and the compositional features in system models illustrates the reason why deep learning is an effective tool of overcoming the COD. The study raises more questions than answers. Many interesting problems are still widely open about the role of compositional structure in neural network design, as well as in the training and validation process.

Abstract: We consider stability analysis of constrained switching linear systems in which the dynamics is unknown and whose switching signal is constrained by an automaton. We propose a data-driven Lyapunov framework for providing probabilistic stability guarantees based on data harvested from observations of the system. By generalizing previous results on arbitrary switching linear systems, we show that, by sampling a finite number of observations, we are able to construct an approximate Lyapunov function for the underlying system. Moreover, we show that the entropy of the language accepted by the automaton allows to bound the number of samples needed in order to reach some pre-specified accuracy.

Keywords: Stability analysis, Constrained switching linear systems, Data-driven optimization, Scenario approach

1. INTRODUCTION

In this paper we address the problem of finding probabilistic guarantees for the stability of *constrained switching linear systems* whose dynamics is unknown.

Switching systems. We consider discrete-time *switching linear systems* (*SLS*) defined by a set $\mathcal{A} = \{A_i, \}_{i\in\{1,\dots,m\}}$ of m matrices. Their dynamics is given by the following equation:

$$x_{t+1} = A_{\sigma(t)}x_t \tag{1}$$

for any $t \in \mathbb{N}$, where $x_t \in \mathbb{R}^n$ and $\sigma(t) \in \{1, \dots, m\}$ are respectively the *state* and the *mode* at time t. The sequence $(\sigma(0), \sigma(1), \dots) \subseteq \{1, \dots, m\}^{\mathbb{N}}$ is the *switching sequence*.

Switching linear systems are an important family of hybrid systems which often arise in Cyber-Physical systems (see Tabuada (2009)). Indeed, the interaction between continuous and discrete dynamics causes hybrid behaviors which makes the stability analysis challenging. In recent years, many model-based stability analysis techniques have been proposed (see Lin and Antsaklis (2009) and references therein, or Jungers (2009)).

A *constrained switching linear system* (*CSLS*) is a switching linear system with logical rules on its switching signal. We represent these rules by an *automaton*. The stability of CSLS has also been studied extensively (see e.g. Dai (2011), Philippe et al. (2016) and Xu and Acikmese (2020)). In particular, we are interested in asymptotic stability of CSLS, whose definition is given as follows. A CSLS whose dynamics is given by (1) is said to be *asymptotically stable* (or *stable*, for short) if for all $x_0 \in \mathbb{R}^n$,

$$\lim_{t\to\infty} x_t = 0. \tag{2}$$

Data-driven approach. In many practical applications, the engineer cannot rely on having a model, but rather has to analyze stability in a *data-driven* fashion. Most classical data-driven methods (see e.g. Karimi and Kammer (2017), Hjalmarsson et al. (1998) and Campi et al. (2003)) are limited to linear systems and based on classical identification and frequency-domain approaches. These methods may not be well suited for complex systems such as constrained switching linear systems.

In order to tackle hybrid behaviors in switching systems, novel data-driven stability analysis methods have been recently developed based on *scenario optimization* (see Kenanian et al. (2019), Berger et al. (2021) and Rubbens et al. (2021)). In this paper we seek to take one more step towards complexity. To do that, we develop a data-driven method for providing probabilistic guarantees on the stability of noise-free constrained switching linear systems.

Outline. The rest of this paper is organized in two parts. We introduce the problem that we tackle in Section 2. All concepts needed to this end are introduced in Section 2.1, and the problem is formulated in Section 2.2. In Section 3, we propose a lifting result allowing us to reduce the computation of the *constrained joint spectral radius* to the *joint spectral radius* of a certain set of matrices. Moreover, we state the main theorem of this paper, which extends data-driven results from Berger et al. (2021) to constrained switching linear systems. Finally, we investigate further the obtained generalization. We show that the notion of *entropy* can be used to characterize the number of samples needed to reach a specified guarantee on the stability. We will show that, under some assumptions, a smaller entropy allows for a better probabilistic guarantee.

2. PROBLEM SETTING

2.1 Preliminaries

In this subsection, we introduce the notions necessary to formally present the problem that we solve in this paper.

Joint spectral radius. For arbitrary SLS, given a set of matrices $\mathcal{A} = \{A_1, \dots, A_m\} \subseteq \mathbb{R}^{n\times n}$, the quantity

$$\rho(\mathcal{A}) = \lim_{t\to\infty} \max_{\sigma(\cdot)\in\{1,\dots,m\}} \|A_{\sigma(t-1)} \dots A_{\sigma(0)}\|^{1/t} \quad (3)$$

is known as the *joint spectral radius* (*JSR*) of a switching linear system defined on $\mathcal{A}$. The JSR of an switching system rules the stability of the latter:

Proposition 1. (Jungers (2009), Corollary 1.1.). Given a set of matrices $\mathcal{A}$, the switching linear system defined by $\mathcal{A}$ is asymptotically stable if and only if $\rho(\mathcal{A}) < 1$.

It is a well known fact that for any stable arbitrary switching linear system, there is a norm acting as a *common Lyapunov function* (see Jungers (2009), Proposition 1.4.). The following proposition gives a sufficient condition for stability, by restricting the search to *common quadratic Lyapunov functions* (*CQLF*).

Proposition 2. (Jungers (2009), Proposition 2.8). Consider a finite set of matrices $\mathcal{A}$. If there exists $\gamma \geq 0$ and a symmetric matrix $P \succ 0$ such that $A^T P A \preceq \gamma^2 P$ holds for any matrix $A \in \mathcal{A}$, then $\rho(\mathcal{A}) \leq \gamma$.

Constrained joint spectral radius. First, we give the definition of an *automaton*. An automaton is a strongly connected, directed and labelled graph $\mathbf{G}(V, E)$ with V the set of nodes and E the set of edges. Note that we drop the explicit writing of V and E when it is clear from the context. The edge $(v, w, \sigma) \in E$ between two nodes $v, w \in V$ carries the *label* $\sigma \in \{1, \dots, m\}$, which maps to a mode of the switching system. A sequence of labels $(\sigma(0), \sigma(1), \dots)$ is a *word* in the language *accepted* by the automaton $\mathbf{G}$ if there is a path in $\mathbf{G}$ carrying the sequence as the succession of the labels on its edges. A CSLS defined on the set of matrices $\mathbf{\Sigma}$ and constrained by the automaton $\mathbf{G}$ is noted $S(\mathbf{G}, \mathbf{\Sigma})$. We define the set of all possible products of matrices in $\mathbf{\Sigma}$ of length l given an automaton $\mathbf{G}$ as

$$\begin{aligned}\mathbf{\Pi}_l = \{&A_{\sigma(l-1)} A_{\sigma(l-2)} \dots A_{\sigma(0)} : \\ &(\sigma(0), \sigma(1), \dots, \sigma(l-1)) \text{ is a word of } \mathbf{G}\}.\end{aligned} \quad (4)$$

The constrained joint spectral radius (*CJSR*), which is a generalization of the JSR to CSLS, was first introduced in Dai (2011). Given a set of matrices $\mathbf{\Sigma}$ and an automaton $\mathbf{G}$, the CJSR of the constrained switching linear system $S(\mathbf{G}, \mathbf{\Sigma})$ is defined as

$$\rho(\mathbf{G}, \mathbf{\Sigma}) = \lim_{t\to\infty} \max \left\{ \|\mathbf{A}\|^{1/t} \,:\, \mathbf{A} \in \mathbf{\Pi}_t \right\}. \quad (5)$$

In the same way, the stability of a constrained switching linear system is characterized by its CJSR:

Proposition 3. (Dai (2011), Corollary 2.8.). Given a set of matrices $\mathbf{\Sigma}$ and an automaton $\mathbf{G}$, the constrained switching linear system $S(\mathbf{G}, \mathbf{\Sigma})$ is asymptotically stable if and only if $\rho(\mathbf{G}, \mathbf{\Sigma}) < 1$.

2.2 Problem formulation

We will now formally present the problem that we solve in this paper.

Model-based setting. Consider a given constrained switching linear system $S(\mathbf{G}, \mathbf{\Sigma})$ with $\mathbf{\Sigma} \subseteq \mathbb{R}^{n\times n}$. Let $\Delta = \mathbb{S} \times \mathbf{\Pi}_l$ with $S \subseteq \mathbb{R}^n$ the unit sphere and $\mathbf{\Pi}_l$ the set of all admissible products of length l. We introduce the following optimization problem [1] (see Berger et al. (2021)):

$$\begin{aligned}\mathcal{P}(\Delta) : &\min_{\substack{P\in\mathbb{R}^{n\times n}\\ \gamma\geq 0}} (\gamma, ||P||_F^2) \\ &\text{s.t. } P \in \mathcal{X} := \left\{P : I \preceq P \preceq CI,\, P = P^T\right\}, \\ &\quad (\mathbf{A}x)^T P(\mathbf{A}x) \leq \gamma^{2l} x^T P x \quad \forall (x, \mathbf{A}) \in \Delta,\end{aligned} \quad (6)$$

for a large $C \in \mathbb{R}_{\geq 0}$, where $\|\cdot\|_F$ is the Frobenius norm. We denote $(\gamma^*(\Delta), P^*(\Delta))$ as the solution of optimization problem (6).

Following Proposition 2, Program (6) allows us to study stability in a model-based setting i.e., when Δ is known. Indeed if $\gamma < 1$, then the ellipsoidal norm $\|\cdot\|_{P^*(\Delta)}$ is a CQLF for the considered CSLS (Jungers, 2009). Observe that, in addition to the problem of Proposition 2, a tie-breaking rule is defined in Program (6). This tie-breaking rule allows for improving the probabilistic guarantees we obtain in Theorem 5 (see Kenanian et al. (2019) for details). A constraint $P \preceq CI$ is also added to ensure that the set of feasible P is compact, so that the existence of a solution is guaranteed [2].

Data-driven setting. In this work, we analyze the same problem in a data-driven framework: we assume that the system is not known (i.e., $\mathbf{A}$ is not known in Program (6)), but that we sample N trajectories of length l of a system $S(\mathbf{G}, \mathbf{\Sigma})$. The i-th trajectory is noted $(x_{i,0}, \dots, x_{i,l})$ for $i \in \{1, \dots, N\}$. The trajectories are assumed to be generated from initial states $x_{i,0}$ drawn randomly, uniformly and independently from $\mathbb{S}$, the unit sphere.

For each trajectory $i \in \{1, \dots, N\}$, the l matrices are generated from the automaton $\mathbf{G}(V, E)$ in the following way. An initial state u_0 is drawn randomly and uniformly from V. Then a random walk of length l is performed on $\mathbf{G}$, where, from $u_j \in V$, the next state u_{j+1} is drawn randomly, uniformly and independently from the set of its out-neighbours $\{u_{j+1} \in V : (u_j, u_{j+1}, \sigma_i(j) \in E\}$ where $\sigma_i(j)$ is the label corresponding to the edge linking u_j and u_{j+1}. The sequence of nodes $(u_0, \dots, u_j, u_{j+1}, \dots, u_l)$ form a switching sequence $\sigma_i(0), \dots, \sigma_i(l-1)$, which maps to the matrices $A_{\sigma_i(0)}, \dots, A_{\sigma_i(l-1)}$.

We define the set of N observations ω_N as

$$\omega_N = \{(x_{i,0}, \mathbf{A}_i), i = 1, \dots, N\} \quad (7)$$

where $\mathbf{A}_i = A_{\sigma_i(l-1)} \dots A_{\sigma_i(0)} \in \mathbf{\Pi}_l$. Note that the observations in ω_N are assumed to be noise-free.

[1] We note $\min(f(x), g(x))$ the multiobjective optimization problem where g(x) is used as a *tie-breaking rule*. That is, the objective is to minimize the function $f(x)$, and, in case there are several optimizers, the solution is the one which minimizes $g(x)$. Observe that the latter is unique because the problem is quasi-convex, and because $\|\cdot\|$ is a strongly convex function.

[2] For more details about these additions, see Berger et al. (2021).

We define $\mathbb{P} = \mathbb{P}_x \times \mathbb{P}_\sigma$ the probability measure on Δ with $\mathbb{P}_x$ the uniform distribution on $\mathbb{S}$ and $\mathbb{P}_\sigma$ the probability distribution describing the distribution of paths in $\mathbf{\Pi}_l$ as explained above. Note that $\mathbb{P}_\sigma$ is not necessarily a uniform measure.

Now, for a given set ω_N, let us define the *sampled optimization problem* $\mathcal{P}(\omega_N)$ associated to $\mathcal{P}$:

$$\begin{aligned}\mathcal{P}(\omega_N): \min_{\substack{P\in\mathbb{R}^{n\times n}\\ \gamma\geq 0}} \ & (\gamma, ||P||_F^2)\\ \text{s.t. } P\in\mathcal{X} &:= \left\{P : I \preceq P \preceq CI,\ P = P^T\right\},\\ (\mathbf{A}x)^T P(\mathbf{A}x) &\leq \gamma^{2l} x^T P x \quad \forall (x,\mathbf{A})\in\omega_N,\end{aligned} \tag{8}$$

We denote $(\gamma^*(\omega_N), P^*(\omega_N))$ as the solution of optimization problem (8), and $\text{Cost}(\omega_N)$ its optimal cost. The problem $\mathcal{P}(\omega_N)$ defined in Program (6) is the *data-driven* version of the optimization problem $\mathcal{P}(\Delta)$ defined in Program (8). The issue that we tackle in this paper is the inference of $\gamma^*(\Delta)$, the solution of optimization problem (6) from $(\gamma^*(\omega_N), P^*(\omega_N))$ with a certain user-defined level of confidence.

3. MAIN RESULTS

In this section, we present our main results. First, in Proposition 4 given an automaton $\mathbf{G}$ and a set of matrices $\mathbf{\Sigma}$, we show that the CJSR can be bounded by the classical JSR of the set of all admissible products of a given length $\mathbf{\Pi}_l$. Even though other reductions of the CJSR computation problems to a simpler JSR have already been proposed in the literature (see e.g. Dai (2011) and Philippe et al. (2016)), to the best of our knowledge, Proposition 4 is new, and will be useful for our purposes. Second, we use this result in order to derive a probabilistic guarantee allowing to relate the data-driven problem (8) to the model-based problem (6). This guarantee is given in Theorem 5.

Proposition 4. For all $l > 0$, given an automaton $\mathbf{G}$ and a set of matrices $\mathbf{\Sigma}$, the CJSR of $S(\mathbf{G}, \mathbf{\Sigma})$ and the JSR of the switching linear system defined by $\mathbf{\Pi}_l$ satisfy

$$\rho(\mathbf{G}, \mathbf{\Sigma}) \leq \rho(\mathbf{\Pi}_l)^{1/l}. \tag{9}$$

Moreover, the equality holds asymptotically i.e.,

$$\rho(\mathbf{G}, \mathbf{\Sigma}) = \lim_{l\to\infty} \rho(\mathbf{\Pi}_l)^{1/l}. \tag{10}$$

Proposition 4 allows us to reduce the problem of approximating the CJSR to the problem of approximating the JSR of another arbitrary switching linear system. Therefore we can generalize previous data-driven works on arbitrary systems. In particular, we draw our results on top of Berger et al. (2021) in order to obtain data-driven stability guarantees for constrained systems.

We remark that the data-driven problem (8) is a quasi-linear optimization problem, as defined in (Berger et al., 2021, Equation 1). Thus, a very similar analysis as in Berger et al. (2021), based on scenario-approach results Calafiore (2010), can be done. First, we recall the definition of a *Barabanov* matrix (see Berger et al. (2021), Defintion 7). A matrix $A \in \mathbb{R}^{n\times n}$ is said to be Barabanov if there exists a symmetric matrix $P \succ 0$ and $\gamma \geq 0$ such that $A^T P A = \gamma^2 P$.

Given Proposition 3, the following theorem generalizes Corollary 14 of Berger et al. (2021). It gives probabilistic guarantees for the stability of a constrained switching linear system. In the following theorem, $\Phi(\cdot, a, b)$ denotes the *regularized incomplete beta function* for the two parameters $a, b \in \mathbb{N}$ (see Kenanian et al. (2019), Definition 2).

Theorem 5. Consider an automaton $\mathbf{G}$, a set of matrices $\mathbf{\Sigma} \subseteq \mathbb{R}^{n\times n}$, samples $\omega_N \subset \Delta$ obtained as explained in Section 2.2, a fixed length $l > 0$ and $N \geq d := n(n+1)/2$. Suppose $\mathbf{\Pi}_l$ contains no Barabanov matrices. Consider problem $P(\omega_N)$ with solutions $\gamma^*(\omega_N)$ and $P^*(\omega_N)$. Then, for a given level of confidence $\beta \in (0,1)$,

$$\mathbb{P}\left(\left\{\omega_N \in \Delta^N : \rho(\mathbf{G}, \mathbf{\Sigma}) \leq \frac{\gamma^*(\omega_N)}{\sqrt[l]{\delta(\beta, \omega_N)}}\right\}\right) \geq \beta, \tag{11}$$

and the function $\delta(\beta, \omega_N)$ takes the form

$$\sqrt{1 - \Phi^{-1}(\varepsilon(\beta, N)\kappa(P^*(\omega_N))/p_{l,\min}, (n-1)/2, 1/2)}. \tag{12}$$

where $p_{l,\min}$ is the minimal probability of all matrices in $\mathbf{\Pi}_l$, $\kappa(P) = \sqrt{\det(P)/\lambda_{\min}(P)^n}$, and $\varepsilon(\beta, N)$ takes the closed form

$$\varepsilon(\beta, N) = 1 - \Phi(1-\beta, d+1, N-d). \tag{13}$$

Theorem 5 provides a general way of obtaining probabilistic stability guarantees. Indeed, for a given confidence level β, if one computes an upper bound (11) strictly less than 1, then following Proposition 3, stability holds with probability at least β.

We now show how one can use it in practice, by deriving a few corollaries. The following corollary holds if the distribution of drawing a product in $\mathbf{\Pi}_l$ is uniform.

Corollary 6. Suppose $\mathbb{P}_\sigma$ is a uniform measure. Then the function $\delta(\beta, \omega_N)$ in Theorem 5 can be written

$$\sqrt{1 - \Phi^{-1}(\varepsilon(\beta, N)|\mathbf{\Pi}_l|\kappa(P^*(\omega_N)), (n-1)/2, 1/2)}. \tag{14}$$

We now show that we can push further our analysis of the upper bound expressed in Corollary 6 by using the notion of *entropy* (Lind and Marcus, 1995, Definition 4.1.1). Let $|\mathcal{L}_{\mathbf{G},l}|$ be the language accepted by $\mathbf{G}$ restricted to length l. The entropy $h(\mathbf{G})$ of $\mathbf{G}$ is the growth rate of $|\mathcal{L}_{\mathbf{G},l}|$ i.e.,

$$h(\mathbf{G}) = \lim_{l\to\infty} \frac{\log_2 |\mathcal{L}_{\mathbf{G},l}|}{l}. \tag{15}$$

Since $|\mathbf{\Pi}_l| \leq |\mathcal{L}_{\mathbf{G},l}|$, the definition of the entropy gives the following corollary.

Corollary 7. For $l \to \infty$, the function $\delta(\beta, \omega_N)$ in Corollary 6 can be written

$$\lim_{l\to\infty} \sqrt{1 - \Phi^{-1}(\varepsilon(\beta, N)2^{lh(\mathbf{G})}\kappa(P^*(\omega_N)), (n-1)/2, 1/2)}. \tag{16}$$

Corollary 7 provides an asymptotic estimate of the probabilistic upper bound in Theorem 5, as a function of the entropy of the automaton $\mathbf{G}$. One can see that an automaton with small entropy allows for a better estimate of the CJSR, for a fixed number of samples. This is illustrated in Figure 1.

Now we show that we can also derive a practical bound for any finite $l > 0$, unlike Corollary 7 which holds

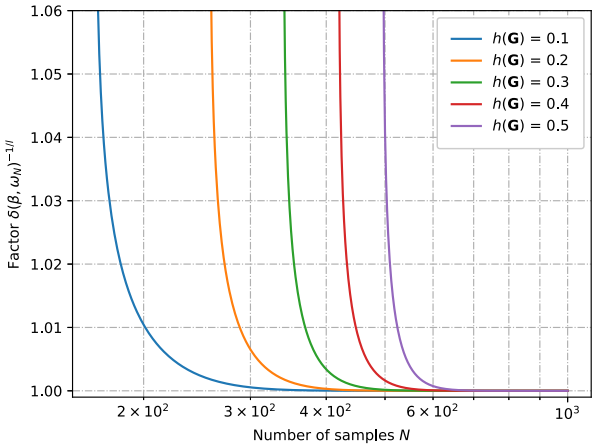

Fig. 1. Shape of the factor $1/\sqrt[l]{\delta(\beta, \omega_N)}$ in Theorem 5 with respect to the entropy, for a confidence level $\beta = 95\%$, a large l (here $l = 50$) and $n = 2$. One can see that this factor converges to 1 as N increases, and that a smaller entropy allows to converge faster.

asymptotically. For this we use classical results from graph theory.

Proposition 8. Let A be the adjacency matrix of some automaton $\mathbf{G}(V, E)$. Let $\lambda_1 \leq \cdots \leq \lambda_{|V|}$ be the eigenvalues of A. Assume A is diagonalizable. Then for any $l \geq 0$, $|\mathbf{\Pi}_l| \leq |V|\lambda_n^l$.

Proposition 8 directly gives the following corollary.

Corollary 9. Let A be the adjacency matrix of some automaton $\mathbf{G}(V, E)$ Let $\lambda_1 \leq \cdots \leq \lambda_{|V|}$ be the eigenvalues of A. Assume A is diagonalizable. Then for any $l > 0$, the function $\delta(\beta, \omega_N)$ in Corollary 6 can be written

$$\sqrt{1 - \Phi^{-1}(\varepsilon(\beta, N)|V|\lambda_n^l \kappa(P^*(\omega_N)), (n-1)/2, 1/2)}. \tag{17}$$

Corollary 9 provides a probabilistic upper bound in Theorem 5, as a function of the largest eigenvalue of the adjacency matrix of $\mathbf{G}$. One can see that an automaton with a small largest eigenvalue allows for a better estimate of the CJSR, for a fixed number of samples N and length l.

4. CONCLUSION

In this work, we extended the scope of data-driven stability analysis of hybrid systems by generalizing previous data-driven results to the constrained case. In particular we have built our results on the basis of Berger et al. (2021).

We proceeded as follows. We first proposed a lifting result allowing us to reduce the computation of the CJSR of a given CSLS to the computation of a simpler JSR. We then stated the main theorem of this paper, which provides probabilistic guarantees for the stability of a given noise-free CSLS. Finally, we claimed that in case of uniformity on the distribution of switching sequences, we can investigate further the obtained bound. We showed that a smaller entropy of the automaton allows for a better guarantee about the stability.

In further research, we plan to extend this type of method to noisy observations. We also plan to investigate different approaches. For example, getting rid of the lifting result would allow to reduce the conservativism introduced by the latter, i.e. the gap between the lifted JSR $\rho(\mathbf{\Pi}_l)^{1/l}$ and the true CJSR $\rho(\mathbf{G}, \mathbf{\Sigma})$ in (9). In this regard we plan to directly approximate *multiple Lyapunov functions* (Philippe and Jungers, 2015, Definition 2).

Abstract: In a seminal paper Foster (1924) showed that the impedances of lumped electrical circuits generated by inductances and capacitors are positive real odd functions ($\mathcal{PRO}$ for short). For multi-port electrical systems built from inductances and capacitors one obtains matrix-valued $\mathcal{PRO}$ functions, denoted $\mathcal{PRO}_m$ in the case of $m \times m$ matrix functions. Like $\mathcal{PRO}$, the class of matrix functions $\mathcal{PRO}_m$ is also a convex invertible cone, i.e., a convex cone closed under inversion (in the form of involution). Given a minimal, Weierstrass descriptor realization for a function in $\mathcal{PRO}_m$, we explicitly compute a minimal, Weierstrass descriptor realization for its involution, and through these formulas one can analyse the zero-pole structure of the function.

Keywords: Positive real odd matrix functions, convex invertible cones, descriptor systems, system inversion, transfer function zeros and poles.

1. INTRODUCTION

Positive real odd (rational) functions, often also referred to as positive real lossless functions, have been studied intensively in electrical engineering since it was observed by Foster (1924) that this class of functions, denoted $\mathcal{PRO}$, coincides with the impedances of lumped electrical circuits generated by inductances and capacitors. Foster also proved his famous canonical form for one-port reactance functions, namely, f is in $\mathcal{PRO}$ if and only if it has the form

$$f(z) = a_0 z + \sum_{k=1}^{s} \frac{a_k z}{z^2 + \omega_k^2}, \quad a_0 \geq 0,\ a_k, \omega_k \geq 0,\ 1 \leq k \leq s.$$

From this formula it is clear that all poles are simple, lie on in the imaginary axis $\mathrm{i}\mathbb{R}$ and have positive residue. Based on this formula, it is also possible to show that $\mathcal{PRO}$ is a convex invertible cone, cic for short, that is, a convex cone which is closed under inversion: For $f \in \mathcal{PRO}$, also $z \mapsto 1/f(z) \in \mathcal{PRO}$. See Cohen et al. (2007) for more on the cic-structure of $\mathcal{PRO}$. As a consequence of the fact that $\mathcal{PRO}$ is a cic, for any $0 \not\equiv f \in \mathcal{PRO}$, the poles of $1/f$ are also simple and on $\mathrm{i}\mathbb{R}$, so that both the poles and zeros of f are on $\mathrm{i}\mathbb{R}$ and they interlace.

Multi-port electrical systems build from inductances and capacitors correspond to positive real odd rational matrix functions, and they have also been studied intensively; cf., the classical monographs Newcomb (1966); Belevitch (1968); Anderson et al. (1973) as well as more recent work of Berger et al. (2014); Chu et al. (2008); Reis (2010), to name just a few. We write $\mathcal{PRO}_m$ for the class of positive real odd rational matrix functions of size $m \times m$, that is, an $m \times m$ rational matrix function F is in $\mathcal{PRO}_m$ in case

(i) $\mathrm{Re}(F(z)) \geq 0$ for all $\mathrm{Re}(z) > 0$;
(ii) $F(t) \in \mathbb{R}^{m \times m}$ for all $t \in \mathbb{R}$;
(iii) $-F(z) = F(-\overline{z})^*$ for z not a pole of F.

To the best of our knowledge, the cic structure of the class of matrix-valued $\mathcal{PRO}$ functions has not been studied in detail. It is straightforward to see that $\mathcal{PRO}_m$ is a convex cone, and also not difficult to prove that $\mathcal{PRO}_m$ is closed under inversion (in the form of involution). However, here we focus on explicit inversion formulas of functions in $\mathcal{PRO}_m$. In particular, we present two minimal realization formulas for functions F in $\mathcal{PRO}_m$, one of which is in Weierstrass descriptor form, and use these to explicitly compute minimal realization formulas of the same type for $F(z)^{-1}$. This gives another proof of the fact that $\mathcal{PRO}_m$ is a cic, but it also provides a way to analyse the zero and pole structure of functions in $\mathcal{PRO}_m$.

There is also an analogue of the foster canonical form for the matrix case. Any function $F \in \mathcal{PRO}_m$ can be written

$$F(z) = zQ + R + \sum_{j=1}^{s} \frac{1}{z^2 + \omega_j^2} (zQ_j + R_j), \qquad (1.1)$$

---

where $\omega_j \in \mathbb{R}_+$ and $Q, R, Q_j, R_j \in \mathbb{R}^{m\times m}$ matrices so that

$$Q,\, Q_j \geq 0, \quad R = -R^T,\, R_j = -R_j^T,\ j = 1, \dots s. \quad (1.2)$$

This canonical form has also been extensively studied in the classical literature including the question how $\mathcal{PRO}_m$ functions of the form (1.1) can be represented by a multi-port electrical system of inductances and capacitors; cf., Newcomb (1966) and Anderson et al. (1973) and references given there. However, not every rational matrix function F of the form (1.1), with $\omega_j \in \mathbb{R}_+$ and Q, R, Q_j, R_j matrices satisfying (1.2) are in $\mathcal{PRO}_m$. For instance, it is easy to verify that the function

$$F(z) = \frac{1}{z^2+\omega^2} R, \quad \text{with } \omega \in \mathbb{R}_+,\, R = -R^T \neq 0,$$

is not in $\mathcal{PRO}_m$. We are not aware of any earlier source where necessary and sufficient conditions for a function F of the form (1.1) to be in $\mathcal{PRO}_m$ are presented, apart from our own work in Ter Horst et al. (2021). In the next theorem we present such conditions.

Theorem 1.1. An $m \times m$ rational matrix function F is in $\mathcal{PRO}_m$ if and only if F is of the form

$$F(z) = zQ + R + \sum_{j=1}^{s} \frac{1}{z^2+\omega_j^2} \left(zQ_j + R_j\right),$$

where $\omega_j \in \mathbb{R}_+$, $Q, R, Q_j, R_j \in \mathbb{R}^{m\times m}$ with $Q, Q_j \geq 0$ and R, R_j skew-symmetric so that

$$-\omega_j Q_j \leq \mathrm{i}R_j \leq \omega_j Q_j, \quad j = 1, \dots, s. \quad (1.3)$$

Note that since Q_j and R_j are real, for (1.3) to hold it suffices to verify one of the inequalities; indeed, because the conjugate of a positive semidefinite matrix is also positive semidefinite, $\omega_j Q_j + \mathrm{i}R_j \geq 0$ implies $\omega_j Q_j - \mathrm{i}R_j \geq 0$, and conversely.

Furthermore, we briefly discuss the zero and pole structure of functions in $\mathcal{PRO}_m$, using the minimal, Weierstrass descriptor realization for a function in $\mathcal{PRO}_m$ and its involution.

The results presented here require rather technical and sometimes long proofs, which can be found in Ter Horst et al. (2021).

2. REALIZATION FORMULAS FOR $\mathcal{PRO}_M$

In this section we provide some realization formulas for functions in $\mathcal{PRO}_m$ and define what we mean by pole and zero multiplicity. The formulas are not so much novel, but are mainly required for the analysis later on.

2.1 Realization formulas

By compiling various results in Reis (2010), specifically Proposition 7 and Theorem 8, together with basic state space manipulations, the following transfer function representation of $\mathcal{PRO}_m$ functions transpires.

Theorem 2.1. A function F is in $\mathcal{PRO}_m$ if and only if it admits a realization of the form

$$F(z) = zM + D + B^T(zI_n - A)^{-1}B, \quad (2.1)$$

for some integer $n \geq 0$, $M, D \in \mathbb{R}^{m\times m}$, $B \in \mathbb{R}^{n\times m}$ and $A \in \mathbb{R}^{n\times n}$ where

$$\begin{aligned} &M \geq 0 \quad -A^T = A, \quad -D^T = D, \\ &\text{and the pair } (A, B) \text{ is controllable.} \end{aligned} \quad (2.2)$$

By a direct computation one can verify that Theorem 2.1 leads to the following descriptor realization characterization of $\mathcal{PRO}_m$ in Weierstrass form. See Dai (1989) and Kunkel et al. (2006) for more details on descriptor systems and the Weierstrass form.

Theorem 2.2. A function F is in $\mathcal{PRO}_m$ if and only if it admits a minimal descriptor realization of the form

$$F(z) = D^\circ + C^{\circ T}(zE^\circ - A^\circ)^{-1}B^\circ,$$

where we set $q = \operatorname{rank} M$ and factor $M = K^T K$ with $K \in \mathbb{R}^{q\times m}$, and where we set

$$A^\circ = \begin{bmatrix} A & 0 & 0 \\ 0 & I_q & 0 \\ 0 & 0 & I_q \end{bmatrix},\ E^\circ = \begin{bmatrix} I_n & 0 & 0 \\ 0 & 0 & I_q \\ 0 & 0 & 0 \end{bmatrix},\ B^\circ = \begin{bmatrix} B \\ 0 \\ -K \end{bmatrix},\ C^\circ = \begin{bmatrix} B \\ K \\ 0 \end{bmatrix}$$

and $D^\circ = D$, with $M, D \in \mathbb{R}^{m\times m}$, $B \in \mathbb{R}^{n\times m}$ and $A \in \mathbb{R}^{n\times n}$ matrices satisfying (2.2).

2.2 Poles and zeros

A number $z \in \mathbb{C} \cup \{\infty\}$ is a pole of $F \in \mathcal{PRO}_m$ simply when it is a pole of one of its entries. In the realization formulas of Theorems 2.1 and 2.2 the finite poles correspond to the eigenvalues of A. The multiplicity of a finite pole z of F is then defined as the dimension of the eigenspace of z as an eigenvalue of A, while the multiplicity of ∞ as a pole of F is defined as $\operatorname{rank} M$, provided $M \neq 0$. Since A is real and skew-symmetric, all poles are on $\mathrm{i}\mathbb{R}$ and the multiplicities of the finite poles add up to the McMillan degree of the proper part of F. Note that this definition of pole multiplicity is independent of the choice of the minimal realization.

Using the specific structure of the realizations obtained in Theorem 2.1 one can prove that the multiplicities cannot exceed the size of the matrix function.

Corollary 2.3. For $F \in \mathcal{PRO}_m$ every pole on $\mathrm{i}\mathbb{R}$, ∞ included, has a multiplicity of at most m.

In case $\det F(z) \not\equiv 0$ we say that F is invertible, with inverse given by the involution $F(z)^{-1}$, which is also in $\mathcal{PRO}_m$. In this case, we define the zeros of F to be the poles of $F(z)^{-1}$ and the zero-multiplicities of F are defined as the corresponding pole-multiplicities of $F(z)^{-1}$. The cic structure of $\mathcal{PRO}_m$ provides the following result.

Corollary 2.4. For $F \in \mathcal{PRO}_m$ every zero on $\mathrm{i}\mathbb{R}$, ∞ included, has a multiplicity of at most m.

3. INVERSION OF $\mathcal{PRO}_M$ FUNCTIONS

Let $F \in \mathcal{PRO}_m$ with $\det F(z) \not\equiv 0$. Then F is invertible, with inverse in $\mathcal{PRO}_m$ as well. In particular, the inverse of F has realization formulas as in Theorems 2.1 and 2.2. Throughout this section we assume $F \in \mathcal{PRO}_m$ is given in the state space realization form of Theorem 2.1. We express, in terms of the matrices in the realization (2.1)–(2.2), when $\det F(z) \not\equiv 0$, and in this case we present realization formulas of the types in Theorems 2.1 and 2.2 for the inverse of F.

3.1 Invertibility of $\mathcal{PRO}_m$ functions

By the inversion result for descriptor systems from Martins et al. (2007), together with a Schur complement computation, one obtains the following characterization for invertibility of F and of its inverse.

Proposition 3.1. Let $F \in \mathcal{PRO}_m$ be given by (2.1)-(2.2). Then for any $z \in \mathbb{C}$ we have

$$\det F(z) \not\equiv 0 \iff \det\left(\left[\begin{smallmatrix} zI_n & 0 \\ 0 & zM \end{smallmatrix}\right] - \left[\begin{smallmatrix} A & B \\ -B^T & -D \end{smallmatrix}\right]\right) \not\equiv 0.$$

Moreover, in that case we have

$$F(z)^{-1} = \left[\begin{smallmatrix} 0 & I_m \end{smallmatrix}\right]\left(\left[\begin{smallmatrix} zI_n & 0 \\ 0 & zM \end{smallmatrix}\right] - \left[\begin{smallmatrix} A & B \\ -B^T & -D \end{smallmatrix}\right]\right)^{-1}\left[\begin{smallmatrix} 0 \\ I_m \end{smallmatrix}\right].$$

Since $\left[\begin{smallmatrix} A & B \\ -B^T & -D \end{smallmatrix}\right]$ is also skew-symmetric, the invertibility criteria of Proposition 3.1 can be expressed in terms of a condition independent of the z variable.

Lemma 3.2. Let $F \in \mathcal{PRO}_m$ be given by (2.1)-(2.2). Then $\det F(z) \not\equiv 0$ if and only if $\operatorname{Ker}\left(\left[\begin{smallmatrix} B \\ D \end{smallmatrix}\right]|_{\operatorname{Ker} M}\right) = \{0\}$.

3.2 Minimal realizations of $F(z)^{-1}$

The realization in Proposition 3.1 will in general not be minimal, and hence some of the poles of the resolvent may not be poles of $F(z)^{-1}$, or the multiplicities may be inflated. To obtain a minimal realization, we decompose the matrices M, D and B with respect to the decomposition of $\mathbb{R}^m$ given by

$$\mathbb{R}^m = \mathcal{X}_1 \oplus \mathcal{X}_2 \oplus \mathcal{X}_3, \tag{3.1}$$

with

$$\begin{aligned} \mathcal{X}_1 &= \operatorname{Ker} M^{\perp}, \\ \mathcal{X}_2 &= \operatorname{Ker}(P_{\operatorname{Ker} M} D|_{\operatorname{Ker} M})^{\perp}, \\ \mathcal{X}_3 &= \operatorname{Ker}(P_{\operatorname{Ker} M} D|_{\operatorname{Ker} M}), \end{aligned}$$

which yields decompositions of the form

$$B^T = \begin{bmatrix} B_1^T \\ B_2^T \\ B_3^T \end{bmatrix},\ D = \begin{bmatrix} D_{11} & D_{12} & D_{13} \\ -D_{12}^T & D_{22} & 0 \\ -D_{13}^T & 0 & 0 \end{bmatrix},\ M = \begin{bmatrix} M_1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \tag{3.2}$$

with M_1 and D_{22} invertible. In particular, M_1 is positive definite and D_{22} is invertible and real, skew-symmetric, so that $\mathcal{X}_2$ must have even dimension. We set

$$m_1 = \dim \mathcal{X}_1, \quad m_2 = \dim \mathcal{X}_2, \quad m_3 = \dim \mathcal{X}_3,$$

so that $m = m_1 + m_2 + m_3$ and m_2 is even.

Furthermore, consider linear maps K_1 and Ξ so that

$$\begin{aligned} K_1 : \mathcal{X}_1 \to \mathbb{R}^{m_1}, \quad K_1^T K_1 = M_1, \\ \Xi : \mathcal{X}_3 \to \mathbb{R}^{m_3}, \quad \Xi^T \Xi = I_{\mathcal{X}_3}. \end{aligned} \tag{3.3}$$

Note that K_1 is invertible and Ξ orthogonal. Define

$$\begin{aligned} \widetilde{A} &= \begin{bmatrix} A - B_2 D_{22}^{-1} B_2^T & (B_1 + B_2 D_{22}^{-1} D_{12}^T) K_1^{-1} \\ K_1^{-T}(-B_1^T + D_{12} D_{22}^{-1} B_2^T) & -K_1^{-T}(D_{11} + D_{12} D_{22}^{-1} D_{12}^T) K_1^{-1} \end{bmatrix}, \\ \widetilde{B} &= \begin{bmatrix} B_3 \Xi^T \\ -K_1^{-T} D_{13} \Xi^T \end{bmatrix}. \end{aligned} \tag{3.4}$$

In terms of the decomposition (3.1), the condition for $\det F(z) \not\equiv 0$ is equivalent to $\operatorname{Ker}\left[\begin{smallmatrix} B_3 \\ D_{13} \end{smallmatrix}\right] = \{0\}$, or, equivalently, $\operatorname{Ker} \widetilde{B} = \{0\}$.

We are now ready to present the minimal Weierstrass realization for the inverse of F.

Theorem 3.3. Let $F \in \mathcal{PRO}_m$ be given by (2.1)-(2.2) and decompose B, D, M with respect to the decomposition (3.1) of $\mathbb{R}^m$ as in (3.2). Define $\widetilde{A}$ and $\widetilde{B}$ as in (3.4), with K_1 and Ξ as in (3.3), and assume $\operatorname{Ker} \widetilde{B} = \{0\}$ so that $\det F(z) \not\equiv 0$. Set $k = n + m_1 - m_3$ and let $\Gamma \in \mathbb{R}^{(n+m_1)\times k}$ be an isometry with $\operatorname{Im} \Gamma \perp \operatorname{Im} \widetilde{B}$. Then a minimal Weierstrass descriptor realization of the inverse of F is given by

$$F(z)^{-1} = D_{\text{inv}}^{\circ} + C_{\text{inv}}^{\circ T}(zE_{\text{inv}}^{\circ} - A_{\text{inv}}^{\circ})^{-1} B_{\text{inv}}^{\circ} \tag{3.5}$$

with

$$\begin{aligned} E_{\text{inv}}^{\circ} &= \begin{bmatrix} I_k & 0 & 0 \\ 0 & 0 & I_{m_3} \\ 0 & 0 & 0 \end{bmatrix}, \quad A_{\text{inv}}^{\circ} = \begin{bmatrix} A_{\text{inv}} & 0 & 0 \\ 0 & I_{m_3} & 0 \\ 0 & 0 & I_{m_3} \end{bmatrix}, \\ B_{\text{inv}}^{\circ} &= \begin{bmatrix} B_{\text{inv}} \\ 0 \\ -K_{\text{inv}} \end{bmatrix}, \quad C_{\text{inv}}^{\circ} = \begin{bmatrix} B_{\text{inv}} \\ K_{\text{inv}} \\ 0 \end{bmatrix}, \\ D_{\text{inv}}^{\circ} &= \begin{bmatrix} 0 & 0 & M_1^{-1} D_{13} \Phi_{33}^{-1} \\ 0 & D_{22}^{-1} & -D_{22}^{-1} \Phi_{23}^T \Phi_{33}^{-1} \\ -\Phi_{33}^{-1} D_{13}^T M_1^{-1} & \Phi_{33}^{-1} \Phi_{23} D_{22}^{-1} & \Phi_{33}^{-1} \Xi^T \widetilde{B}^T \widetilde{A} \widetilde{B} \Xi \Phi_{33}^{-1} \end{bmatrix}, \end{aligned} \tag{3.6}$$

where we define

$$A_{\text{inv}} = \Gamma^T \widetilde{A} \Gamma, \qquad K_{\text{inv}} = \begin{bmatrix} 0 & 0 & \Xi \Phi_{33}^{-1/2} \end{bmatrix}, \tag{3.7}$$

$$B_{\text{inv}} = \Gamma^T \begin{bmatrix} 0 & B_2 D_{22}^{-1} & (\Phi_{12} - B_2 D_{22}^{-1} \Phi_{23}) \Phi_{33}^{-1} \\ K_1^{-T} & -K_1^{-T} D_{12} D_{22}^{-1} & -K_1^{-T}(\Phi_{22} - D_{12} D_{22}^{-1} \Phi_{23}) \Phi_{33}^{-1} \end{bmatrix},$$

$$\Phi_{33} = B_3^T B_3 + D_{13}^T M_1^{-1} D_{13},$$

$$\Phi_{23} = B_2^T B_3 + D_{12}^T M_1^{-1} D_{13},$$

$$\Phi_{12} = A B_3 - B_1 M_1^{-1} D_{13}, \quad \Phi_{22} = B_1^T B_3 - D_{11} M_1^{-1} D_{13}$$

and where

$$\begin{aligned} \Xi^T \widetilde{B}^T \widetilde{A} \widetilde{B} \Xi = {} & B_3^T A B_3 - B_3^T B_1 M_1^{-1} D_{13} + D_{13}^T M_1^{-1} B_1^T B_3 \\ & - D_{13}^T M_1^{-1} D_{11} M_1^{-1} D_{13} - \Phi_{23} D_{22}^{-1} \Phi_{23}. \end{aligned}$$

Note that the descriptor realization for $F(z)^{-1}$ of Theorem 3.3 has precisely the form of the realization in Theorem 2.2. Reversing the argument in Section 2.1, we also obtain a realization of the type in Theorem 2.1.

Theorem 3.4. Let $F \in \mathcal{PRO}_m$ be given by (2.1)-(2.2) and decompose B, D, M with respect to the decomposition (3.1) of $\mathbb{R}^m$ as in (3.2). Assume $\det F(z) \not\equiv 0$. Then

$$F(z)^{-1} = zM_{\text{inv}} + D_{\text{inv}} + B_{\text{inv}}^T (zI_n - A_{\text{inv}})^{-1} B_{\text{inv}},$$

where B_{inv} and A_{inv} are as in (3.7), $D_{\text{inv}} = D_{\text{inv}}^{\circ}$ and $M_{\text{inv}} = K_{\text{inv}}^T K_{\text{inv}}$ with D_{inv}° as in (3.6) and K_{inv} as in (3.7). Moreover, the pair $(A_{\text{inv}}, B_{\text{inv}})$ is controllable.

Since Φ_{33} is invertible and Ξ an isometry, it is directly clear from the formula of M_{inv} that the pole multiplicity of $F(z)^{-1}$ at ∞ is equal to m_3, hence ∞ is a zero of F with multiplicity m_3. To say something about the zero multiplicities of F for finite zeros requires more analysis.

4. ZEROS AND POLES OF $\mathcal{PRO}_M$ FUNCTIONS

Recall that the zeros of F are defined as the poles of $F(z)^{-1}$. Hence, the finite zeros of F are given by the eigenvalues of A_{inv} with multiplicities equal to the dimensions of the corresponding eigenspaces. Thus, to understand the relation between zeros and poles one has to analyse the spectrum of A_{inv} in relation to the spectrum of A. There are three steps from A to A_{inv} that influence the eigenvalues:

(i) The extension of A into

$$\begin{bmatrix} A & B \\ -B^T & -D \end{bmatrix} = \begin{bmatrix} A & B_1 & B_2 & B_3 \\ -B_1^T & -D_{11} & -D_{12} & -D_{13} \\ -B_2^T & D_{12}^T & -D_{22} & 0 \\ -B_3^T & D_{13}^T & 0 & 0 \end{bmatrix}.$$

(ii) The transfer to $\widetilde{A}$ in (3.4) by taking the Schur complement with respect to $-D_{22}$.

(iii) The compression from $\widetilde{A}$ to $A_{\rm inv}$ in (3.7) via the isometry Γ.

The fact that all involved matrices are real skew-symmetric simplifies matters and enables us to use the Cauchy interlacing theorem, cf. Theorem 1 in Smith (1992), to arrive at the following result for the poles and zeros of functions in $\mathcal{PRO}_m$.

Theorem 4.1. Let $F \in \mathcal{PRO}_m$ be given by a minimal state space realization (2.1)-(2.2), so that F^{-1} has a minimal state space realization as in Theorem 3.4. Then for any integer $j \geq 0$ we have

$$\lambda_{j-\frac{m_2}{2}-m_3}(\mathrm{i}A_{\rm inv}) \leq \lambda_j(\mathrm{i}A) \leq \lambda_{j+1}(\mathrm{i}A) \leq \lambda_{j+\frac{m_2}{2}+m_1+1}(\mathrm{i}A_{\rm inv}),$$
$$\lambda_{j-\frac{m_2}{2}-m_1}(\mathrm{i}A) \leq \lambda_j(\mathrm{i}A_{\rm inv}) \leq \lambda_{j+1}(\mathrm{i}A_{\rm inv}) \leq \lambda_{j+\frac{m_2}{2}+m_3+1}(\mathrm{i}A).$$

In particular, if $0 \leq \omega_j < \omega_{j+1}$ are such that $\mathrm{i}\omega_j$ and $\mathrm{i}\omega_{j+1}$ are subsequent poles of F, then in the interval $(\mathrm{i}\omega_j, \mathrm{i}\omega_{j+1})$ on $\mathrm{i}\mathbb{R}$ F can have zeros whose multiplicities do not add up to more than m. Moreover, if $0 \leq \nu_j < \nu_{j+1}$ are such that $\mathrm{i}\nu_j$ and $\mathrm{i}\nu_{j+1}$ are subsequent zeros of F, then in the interval $(\mathrm{i}\nu_j, \mathrm{i}\nu_{j+1})$ on $\mathrm{i}\mathbb{R}$ F can have poles whose multiplicities do not add up to more than m.

Note that, unlike in the scalar case, for $m > 1$ it is possible that poles and zeros of $F \in \mathcal{PRO}_m$ occur at the same point on $\mathrm{i}\mathbb{R}$. Hence, as in the theorem, if $\mathrm{i}\omega_j$ and $\mathrm{i}\omega_{j+1}$ are subsequent poles of F, then zeros with a multiplicities adding up to at most m can occur between $\mathrm{i}\omega_j$ and $\mathrm{i}\omega_{j+1}$, but the theorem does not exclude the possibility that F also has zeros at $\mathrm{i}\omega_j$ and $\mathrm{i}\omega_{j+1}$.

5. CONCLUSION

We provided realization formulas for the inverses of functions in $\mathcal{PRO}_m$. These formulas enabled us to study the relations between zeros and poles of such functions. We also extended results on the Foster canonical form for functions in $\mathcal{PRO}_m$ by providing a necessary and sufficient condition for such a canonical form to give a function in $\mathcal{PRO}_m$ that does not seem to have appeared in the literature before.

We specifically focused on real-valued matrix functions, i.e., with $F(t) \in \mathbb{R}^{m\times m}$ for $t \in \mathbb{R}$, since without this condition we do not expect that so much can be said about the poles and zeros of such functions. However, we do expect that analogous results will exist for complex-valued lossless matrix functions regarding the realization formulas for their inverses as well as the Foster form. This may be a topic for future work. In this regard, it may also be interesting to investigate the case of reciprocal matrix functions in light of the results obtained here.

Abstract: In recent years various papers appeared that concentrate on inverse problems associated with work of Ellis and Gohberg on orthogonal matrix Wiener functions. Here we study such an inverse problem restricting to rational matrix functions on the real line. The functions used in stating the problem are assumed to be given by minimal state space realizations, and the necessary and sufficient solution criterion as well as the formulas for the solution presented here are described in terms of the matrices of the state space realizations along with solutions to certain Lyapunov equations associated with the data.

Keywords: Inverse problem, rational matrix functions, state space realizations.

1. INTRODUCTION

The monograph by Ellis et al. (2003) collects and expands work of the authors from about two decades on systems of orthogonal matrix polynomials and matrix functions, in some instances together with D.C. Lay; see Ellis et al. (1992, 1995, 1996) for some of the original work, along with the monograph for additional references. This work also contains several results on related inverse problems, but much of the work on these inverse problems, specifically for the case of non-square matrix functions, only appeared recently, in Kaashoek et al. (2014, 2016, 2019) and Ter Horst et al. (2017, 2019, 2020). Here we present some of the work that will mainly appear in Ter Horst et al. (2020).

2. FORMULATION OF THE PROBLEM

The inverse problem we consider here has a data set which consists of four proper rational matrix functions $\alpha, \beta, \gamma, \delta$ with sizes given by

$$\begin{aligned} &\alpha(\lambda) \in \mathbb{C}^{p\times p}, \quad \beta(\lambda) \in \mathbb{C}^{p\times q}, \\ &\gamma(\lambda) \in \mathbb{C}^{q\times p}, \quad \delta(\lambda) \in \mathbb{C}^{q\times q}, \end{aligned} \tag{2.1}$$

and where α and β have only poles in the open lower half plane $\mathbb{C}_-$, γ and δ have poles only in the open upper half plane $\mathbb{C}_+$, and with values at ∞ given by

$$\alpha(\infty) = I_p, \quad \beta(\infty) = 0, \quad \gamma(\infty) = 0, \quad \delta(\infty) = I_q.$$

When the above properties are fulfilled we call $\{\alpha, \beta, \gamma, \delta\}$ an *admissible rational data set.*

⋆ This work is based on research supported in part by the National Research Foundation of South Africa (Grant Numbers 118513 and 127364).
This is a resubmission of an extended abstract that was accepted for the 2020 MTNS conference.

Given an admissible rational data set $\{\alpha, \beta, \gamma, \delta\}$ the rational version of the twofold Ellis-Gohberg inverse problem is to find a strictly proper $p \times q$ rational matrix function g which has all its poles in $\mathbb{C}_-$ such that

$$\begin{aligned} &\alpha(\lambda) + g(\lambda)\gamma(\lambda) - I_p \text{ has poles only in } \mathbb{C}_+; \\ &g^*(\lambda)\alpha(\lambda) + \gamma(\lambda) \text{ has poles only in } \mathbb{C}_-; \\ &\delta(\lambda) + g^*(\lambda)\beta(\lambda) - I_q \text{ has poles only in } \mathbb{C}_-; \\ &g(\lambda)\delta(\lambda) + \beta(\lambda) \text{ has poles only in } \mathbb{C}_+. \end{aligned} \tag{2.2}$$

Here and in the remainder, for any rational matrix function $\varphi(\lambda)$ the *adjoint* of the function $\varphi(\lambda)$ indicates function $\varphi(\overline{\lambda})^*$ and will be denoted by $\varphi^*(\lambda)$. We shall refer to the above problem as the *twofold Rat-EG inverse problem.* Also in other contexts, EG will be used to abbreviate Ellis-Gohberg.

We briefly mention the direct EG-problem from which the inverse EG problem studied here is derived. The starting point is a strictly proper $p \times q$ rational matrix function g which has all its poles in $\mathbb{C}_-$, and the problem is to obtain an admissible rational data set $\{\alpha, \beta, \gamma, \delta\}$ such that (2.2) is satisfied. Solving this problem is equivalent to solving two linear equations, $Tx_1 = f_1$ and $Tx_2 = f_2$, where $T : \mathcal{X} \to \mathcal{X}$ is a structured linear operator defined by the given function g, and the right hand sides f_1 and f_2 are specific elements in $\mathcal{X}$ defined by g too; see formula (1.9) in Ter Horst et al. (2019) for more details. The solutions x_1 and x_2, if they exist, will uniquely determine the requested data set $\{\alpha, \beta, \gamma, \delta\}$. Moreover, under an additional simple finite dimensional condition, the inverse of T can be expressed in terms of the data set $\{\alpha, \beta, \gamma, \delta\}$.

3. OPERATOR THEORY SOLUTION

This version was investigated in the more general context of matrix Wiener class functions on the real line in Ter Horst et al. (2019), where necessary and sufficient conditions for the existence of solutions were obtained. Also, in case a solution exists, it is shown that this is the unique solution and two formulas for the solution are presented. Based on the results in Ter Horst et al. (2019), see Ter Horst et al. (2020) for details, it is easily verified that for the rational matrix data functions $\{\alpha, \beta, \gamma, \delta\}$ of an admissible rational data set, necessary conditions are:

$$\begin{aligned} &\text{(C1)} \quad \alpha^*(\lambda)\alpha(\lambda) - \gamma^*(\lambda)\gamma(\lambda) = I_p; \\ &\text{(C2)} \quad \delta^*(\lambda)\delta(\lambda) - \beta^*(\lambda)\beta(\lambda) = I_q; \\ &\text{(C3)} \quad \alpha^*(\lambda)\beta(\lambda) = \gamma^*(\lambda)\delta(\lambda). \end{aligned}$$

In addition to these three equations, in the Wiener class function inverse problem on the real line of Ter Horst et al. (2019), two more conditions are required to obtain necessary and sufficient conditions, and these conditions can be formulated as the required that two operators, determined by Hankel operators associated with the data functions, are one-to-one; see Theorem A.1 in Ter Horst et al. (2020). The main aim of the present research is to express the two operator conditions in a more computationally effective way, and use the new versions of these conditions to obtain new representations of the solutions.

4. STATE SPACE PRELIMINARIES

To obtain more computationally attractive solution criteria and a more explicit description of the solution, we assume our data functions are given in the form of finite dimensional state space realizations:

$$\begin{aligned} \alpha(\lambda) &= I_p + iC_1(\lambda I_{n_1} - iA_1)^{-1}B_1, \\ \beta(\lambda) &= iC_2(\lambda I_{n_2} - iA_2)^{-1}B_2, \\ \gamma(\lambda) &= -iC_3(\lambda I_{n_3} + iA_3)^{-1}B_3, \\ \delta(\lambda) &= I_q - iC_4(\lambda I_{n_4} + iA_4)^{-1}B_4. \end{aligned} \tag{4.3}$$

Here A_j, $1 \leq j \leq 4$, is a square matrix which is assumed to be stable, e.g., all eigenvalues of A_j are in the open left half plane $\mathbb{C}_{\text{left}}$. These stability conditions are automatically fulfilled if the realizations are minimal. In the latter case the McMillan degrees of $\alpha, \beta, \gamma, \delta$ are equal to n_1, n_2, n_3, n_4, respectively. Although the functions $\alpha, \beta, \gamma, \delta$ in an admissible rational data set can always be represented in this way, we shall not require the realizations in (4.3) to be minimal.

To state our solution to the twofold Rat-EG inverse problem we shall use the solution P_{ij}, for $i, j \in \{1, 2\}$ or $i, j \in \{3, 4\}$, to the following Lyapunov equation associated with the pairs (A_i, C_i) and (A_j, C_j):

$$\begin{aligned} &A_i^* P_{ij} + P_{ij} A_j + C_i^* C_j = 0, \\ &\text{with } i, j \in \{1, 2\} \text{ or } i, j \in \{3, 4\}. \end{aligned} \tag{4.4}$$

For $i = j$ we abbreviate P_{jj} to P_j. We also need the solution Q_j, for $1 \leq j \leq 4$, to the Lyapunov equation

$$A_j Q_j + Q_j A_j^* + B_j B_j^* = 0, \quad 1 \leq j \leq 4. \tag{4.5}$$

Since the matrices A_j, $1 \leq j \leq 4$, are all stable, the solutions P_{ij} and Q_j to the Lyapunov equations (4.4) and (4.5) are unique, and given explicitly by

$$P_{ij} = \int_0^\infty e^{sA_i^*} C_i^* C_j e^{sA_j}\, ds, \; Q_j = \int_0^\infty e^{sA_j} B_j B_j^* e^{sA_j^*}\, ds.$$

From the latter identities it follows that the matrices $P_j = P_{jj}$ and Q_j, $1 \leq j \leq 4$, are nonnegative. Furthermore, we have $P_{12}^* = P_{21}$ and $P_{34}^* = P_{43}$. See Section 3.8 in Zhou et att. (1996) for the basic theory of Lyapunov equations; see also Theorem I.5.5 in Gohberg et al. (1990).

5. SOLUTION IN TERMS OF STATE SPACE REALIZATIONS

Since P_2 and Q_2 are nonnegative, the matrix $I_{n_2} + Q_2 P_2$ is invertible. Similarly, $I_{n_3} + Q_3 P_3$ is invertible because P_3 and Q_3 are nonnegative. Using the matrices defined above, we set

$$\begin{aligned} N_1 &:= P_1 - P_{12}(I_{n_2} + Q_2 P_2)^{-1} Q_2 P_{21}, \\ N_4 &:= P_4 - P_{43}(I_{n_3} + Q_3 P_3)^{-1} Q_3 P_{34}. \end{aligned} \tag{5.6}$$

Now we are ready to formulate our first main result, which provides necessary and sufficient conditions for the twofold Rat-EG inverse problem.

Theorem 1. The twofold Rat-EG inverse problem associated with the rational data set $\{\alpha, \beta, \gamma, \delta\}$ given by state space realizations (4.3) has a solution if and only if the following conditions are satisfied:

$$\begin{aligned} &\text{(R1)} \quad (C_1 + B_1^* P_1)(\lambda I_{n_1} - iA_1)^{-1} B_1 = \\ &\qquad = B_3^*(\lambda I_{n_3} - iA_3^*)^{-1} P_3 B_3; \\ &\text{(R2)} \quad (C_4 + B_4^* P_4)(\lambda I_{n_4} + iA_4)^{-1} B_4 = \\ &\qquad = B_2^*(\lambda I_{n_2} + iA_2^*)^{-1} P_2 B_2; \\ &\text{(R3a)} \quad B_1^*(\lambda I_{n_1} + iA_1^*)^{-1} P_{12} B_2 = B_3^* P_{34}(\lambda I_{n_4} + iA_4)^{-1} B_4; \\ &\text{(R3b)} \quad (C_2 + B_1^* P_{12})(\lambda I_{n_2} - iA_2)^{-1} B_2 = \\ &\qquad = B_3^*(\lambda I_{n_3} - iA_3^*)^{-1}(C_3^* + P_{34} B_4) \\ &\text{(R4)} \quad \text{the matrices } I_{n_1} - Q_1 N_1 \text{ and } I_{n_4} - Q_4 N_4 \text{ are invertible.} \end{aligned}$$

Moreover, in that case the solution is unique.

In case the necessary and sufficient conditions of the previous theorem are satisfied, it is possible to describe the unique solution g as in the following result.

Theorem 2. Assume the functions of the rational data set $\{\alpha, \beta, \gamma, \delta\}$ are given by state space realizations (4.3), and assume the conditions (R1)-(R4) are satisfied. Then the unique solution g to the twofold Rat-EG inverse problem is given by

$$\begin{aligned} g(\lambda) = &-iC_1(\lambda I_{n_1} - iA_1)^{-1} Y_1 + \\ &- iC_2(\lambda I_{n_2} - iA_2)^{-1} \left(Y_2 - \widetilde{Y_2} \right). \end{aligned}$$

Here Y_2 and $\widetilde{Y_2}$ are matrices of size $n_2 \times q$, and Y_1 is a matrix of size $n_1 \times q$, and these three matrices are defined by

$$\begin{aligned} Y_1 &= (I_{n_1} - Q_1 N_1)^{-1} Q_1 P_{12}(I_{n_2} + Q_2 P_2)^{-1} B_2, \\ Y_2 &= (I_{n_2} + Q_2 P_2)^{-1} B_2, \\ \widetilde{Y_2} &= (I_{n_2} + Q_2 P_2)^{-1} Q_2 P_{21} Y_1. \end{aligned}$$

The results of Ter Horst et al. (2019) also provide an alternative formula for the unique solution, which can be presented in terms of the state space formulas for the data functions and the associated matrices as in the next theorem.

Theorem 3. Assume the functions of the rational data set $\{\alpha, \beta, \gamma, \delta\}$ are given by state space realizations (4.3), and

assume the conditions (R1)-(R4) are satisfied. Then the unique solution g to the twofold Rat-EG inverse problem is given by

$$g(\lambda) = -iX_1(\lambda I_{n_4} - iA_4^*)^{-1}C_4^* + \\ - i\left(X_2 - \widetilde{X_2}\right)(\lambda I_{n_3} - iA_3^*)^{-1}C_3^*.$$

In this case X_2 and $\widetilde{X_2}$ are matrices of size $p \times n_3$, and X_1 is a matrix of size $p \times n_4$, and these three matrices are defined by

$$X_1 = B_3^*(I_{n_3} + P_3Q_3)^{-1}P_{34}Q_4(I_{n_4} - N_4Q_4)^{-1},$$
$$X_2 = B_3^*(I_{n_3} + P_3Q_3)^{-1},$$
$$\widetilde{X_2} = X_1P_{43}Q_3(I_{n_3} + P_3Q_3)^{-1}.$$

On the Risks of Feedback-Trading

Michael Heinrich Baumann *

* *University of Bayreuth, 95447 Bayreuth, Germany (e-mail: michael.baumann@uni-bayreuth.de).*

Abstract: It has been shown in the literature that for certain trading strategies based on control techniques, namely for the so-called simultaneously long short strategies under relatively weak market assumptions in continuous time, the so-called robust positive expectation property holds. This means that for such strategies, if the assumptions are fulfilled, in expectation positive profits can be proven. Of course, arguments such as trading costs or trading constraints can be used when discussing these unexpected results. But there are also risks inherent in the strategies themselves, such as short-selling risks, discretization risks, or momenta. In this talk, we will present these risks and show how they can possibly be controlled.

Keywords: Feedback Trading, Financial Mathematics, Risk Measures, Skewness, Control-based Trading Strategies, Discretization, Simultaneously Long Short Trading, Stochastic Processes

EXTENDED ABSTRACT

Trading with stocks or, in general, assets means buying and selling them according to certain criteria. For this purpose, there is a wide variety of investment strategies. The strategy we will look at in this paper, the Simultaneously Long Short (SLS) strategy, belongs to a class of strategies called feedback strategies. These strategies are inspired and often analyzed by methods originating from control theory. As the name SLS suggests, this strategy invests both long and short, shifting more investment to the better performing side. Short selling means to sell assets that one does not own but only borrows. In such a negative investment profits are obtained for falling prices and losses for rising prices.

If we consider a single-asset market with price $p(t) \geq 0$ with $t = 0, h, 2h, \ldots, T$ with $h > 0$ or with $t \in [0, T]$ and denote by $I(t)$ the investment at time t, i.e. the number of shares held ($\nu(t)$) times their price per unit ($p(t)$), we can calculate the cumulative gain/loss via $g(t) = \sum_{i=1}^{t} \nu((i-1)h)(p(ih) - p((i-1)h)) = \sum_{i=1}^{t} I((i-1)h)\left(\frac{p(ih)}{p((i-1)h)} - 1\right)$ resp. $g(t) = \int_0^t \frac{I(t)}{p(t)} dp(t)$. The idea behind feedback strategies is that not only the profit is a function of the investment, but also the investment is a function of the profit, i.e., $I(t) = f(g(t))$ for an appropriate function f. Two possible choices for feedback strategies are the linear feedback strategies I^L and I^S with $f_L(x) = I_L^* + K_L \cdot x$ with $I_L^*, K_L > 0$ and $f_S(x) = I_S^* + K_S \cdot x$ with $I_S^*, K_S < 0$. The SLS strategy is defined as follows: $I^{SLS} = I^L + I^S$, where $I^* := I_L^* = -I_S^* > 0$ and $K := K_L = -K_S > 0$. Observe that when the time axis and the price process are continuous, the strategy I^L always invests long and the strategy I^S always invests short under the same conditions. Note that it is important that the gains of the long and the short side (g_L, g_S) are calculated separately (since otherwise gain and investment of the SLS rule would always be zero).

Performance properties of the SLS strategy are analyzed in various papers. Expected gains are calculated for prices governed by geometric Brownian motions (Barmish and Primbs, 2011, 2016; Dokuchaev, 2012; Dokuchaev and Savkin, 1998), by Merton's jump diffusion model (Baumann, 2017), by tree models (Iwarere and Barmish, 2014), in discrete time models with constant trend (Malekpour and Barmish, 2016; Baumann and Grüne, 2017), as well as in models with variable trends, so-called time-varying geometric Brownian motions (Primbs and Barmish, 2013) and discrete time models with variable parameters (Baumann, 2021), and also in other models. [1] The discrete time models are of particular interest since they try to avoid the joint hypotheses problem (i.e. the problem of simultaneously assuming a market model and the market efficiency hypothesis). Variances of gains of SLS strategies are calculated, e.g., for geometric Brownian motions (Barmish and Primbs, 2011), Merton's jump diffusion model (Baumann, 2017), discrete time models with constant and varying trends (Baumann, 2021), etc. The most interesting result concerning SLS trading is that under certain assumptions, in most of the mentioned models under almost all parameter settings the expected gain is positive. An exception are discrete time models with varying trends (Baumann, 2021), which gives a first hint on possible risks traders using the SLS rule—or, generally, feedback strategies—face. In the following, we explain four risks, some obvious, some hidden. And we show which questions might be quite interesting for future research.

Unreasonable assumptions

In theoretical results often assumptions are made, which might not be fulfilled in real-world. For example, trading costs might be neglected or it may be assumed that traders do not influence the price. There might be neither trading delay nor restrictions. All amounts of assets (long

[1] Please note that the cited literature represents only a small part of the available literature.

and short) may be available, and so on. Clearly, these assumptions must not hold true in real world. One solution would be to provide trading statistics with historical price data. However, then the researcher faces the problem of overfitting (Bailey et al., 2014; Wilmott, 2000). Also, p-hacking has to be kept in mind.

Short selling

While traders cannot lose more money on long investments than they invest, the possible loss on short sales—no matter how small—is in principle unbounded. Even if only a small amount is sold short, if the stock rises sharply, for example, because the underlying company receives a takeover bid, the investor may incur a very large loss. This is the reason why private persons or companies without very large financial reserves tend to avoid short sales. However, in order to profit from falling prices resp. to bet on falling prices, there are derivatives that have a similar payoff profile, but whose worst case risk can be limited. Infinitely large worst-case losses create a serious risk. It may be possible to circumvent or hedge this risk by means of derivatives such as put options—but how does such a hedging strategy influence the performance of the SLS rule?

Skewness and other higher momenta

Generally, it is rather hard or even impossible to calculate any classical risk measures for the SLS strategy. An exception is the case of geometric Brownian motions since there the density of the gain/loss distribution is known (Barmish and Primbs, 2011). A way to include risk in the performance investigations of SLS trading might be to calculate the skewness, which could be done with the same methodology and under similar assumptions as for the variance (Baumann, 2021). However, there is a fundamental problem: it is not clear whether higher or lower skewed gains are more risky/preferable. Highly skewed gains mean that there is a small chance to make high gains and a high risk to make small losses (as typically when thinking about lottery or betting slips); low skewed gains mean there is a small probability for a high loss and a high chance for small gains.

For example, consider the random variables X, Y modeling profits (defined on appropriate spaces). We assume that X is -1 with probability 99% and 99 with 1% and Y that is -99 with probability 1% and 1 with 99%. It holds: $\mathbb{E}[X] = \mathbb{E}[Y] = 0$ and $Var(X) = Var(Y) = 99$. Clearly, X has a high skewness ($v(X) \approx 9,85$) while Y has a small skewness ($v(Y) \approx -9,85$).

When considering the probability of loosing ($P(X < 0) = 99\%$, $P(Y < 0) = 1\%$), Y is preferable. When considering the worst case, X is preferable. Next, we have look at a classical risk measure, the Value at Risk (Föllmer and Schied, 2011, Sec. 4.4). It holds $V@R_{1\%}(X) = 1$ and $V@R_{1\%}(Y) = -1$, thus, one would prefer Y, but $V@R_{0.5\%}(X) = 1$ and $V@R_{0.5\%}(Y) = 99$, speaking for X.

Discretization risks

The presumably most important risk is the discretization risk. Baumann (2021) shows that in discrete time (and all real trades take place in discrete time) traders face the risk of switching trends. While sign switching trends are not any problem for the continuous time SLS, they are in discrete time. For all two points in time where the sign of the trend is either positive or negative, the trader may expect a profit. Every time the trend switches its sign, the trader faces an expected loss. One way out would be to modify the strategy by model assumptions or by estimators, but this would be against the fundamental idea of feedback trading.

CONCLUSION

While for the SLS strategy one can show performance characteristics such as positive expected returns, both in theory and based on backtesting, its risks have not yet been studied in sufficient detail. In this work, we have presented the presumably most important risks and outlined against which risks one may or may not protect oneself. Further research on these topics, based on theory and backtesting, is desirable.

Spectrahedral Shadows and Completely Positive Maps on Real Closed Fields

Mario Kummer *

* *Technische Universität Dresden, Bereich Mathematik und Naturwissenschaften, Fakultät Mathematik, Institut für Geometrie (e-mail: mario.kummer@tu-dresden.de).*

Abstract: We provide a new characterization of spectrahedral shadows. We use this to show that the cone of copositive matrices of size at least five is not a spectrahedral shadow, a convex semialgebraic set that resisted the efforts of Scheiderer (2018). This is a joint work with Manuel Bodirsky and Andreas Thom.

Keywords: Spectrahedral shadows, real closed fields, completely positive maps, sums of squares. AMS subject classification: 11E25, 12D15, 90C22.

1. INTRODUCTION

Semidefinite programming is a generalization of linear programming whose feasible sets are called *spectrahedral shadows*. These are convex semialgebraic sets that (are the image under an affine linear map of a set that) can be described by symmetric linear matrix inequalities. Nemirovski (2007) asked whether every convex semialgebraic set is a spectrahedral shadow. Later Helton and Nie (2009) conjectured that the answer to this question is in fact *yes*. This conjecture was recently disproved by Scheiderer (2018). Further counter-examples were subsequently given by Fawzi (2021) and Bettiol et al. (2021). However, the techniques used in these articles were essentially the same as the ones developed by Scheiderer (2018). In a joint work with Manuel Bodirsky and Andreas Thom we provide new techniques for proving that a certain semialgebraic set is not a spectrahedral shadow. We use these to prove that the set of all *copositive matrices* of size m, i.e. the cone of all symmetric $m \times m$ matrices A such that $x^t Ax \geq 0$ for all $x \in \mathbb{R}^m_{\geq 0}$, is not a spectrahedral shadow whenever $m \geq 5$. In the following, we describe our techniques in more detail.

2. PRIMITIVE DEFINABILIY

Let X be a set and $R_i \subset X^{r_i}$, $i \in I$, a collection of relations over X. A first-order formula over the *relational structure* $\Gamma = (X; \{R_i : i \in I\})$ is *primitive positive* if it is of the form

$$\exists x_1, \ldots, x_n (\psi_1 \wedge \cdots \wedge \psi_m)$$

where $\psi_1, \ldots, \psi_m$ are atomic formulas formed with relations R_i, $i \in I$. In particular, no negation, disjunction, and universal quantification is allowed. An *endomorphism* of the relational structure Γ is a function $f : X \to X$ such that $R_i(x_1, \ldots, x_{r_i})$ implies $R_i(f(x_1), \ldots, f(x_{r_i}))$ for all $x_1, \ldots, x_{r_i} \in X$ and $i \in I$. An easy but important observation is that if R is a relation over X that can be defined using a primitive positive formula over Γ, then R is preserved by all endomorphisms of Γ. In many cases, the converse holds true as well. This was for instance shown by Bodnarčuk et al. (1969) in the case when X is finite.

3. A CHARACTERIZATION OF SPECTRAHEDRAL SHADOWS

Now let $\mathbf{R}$ be a real closed extension of $\mathbb{R}$. We consider the relational structure on $\mathbf{R}$ that is given by all spectrahedral shadows $R \subset \mathbf{R}^m$ which are defined by matrices with entries in $\mathbb{R}$. A function $f : \mathbf{R} \to \mathbf{R}$ is an endomorphism of this relational structure if and only if f is $\mathbb{R}$-linear, unital and completely positive in the sense that applying f entry-wise to a positive semidefinite matrix over $\mathbf{R}$ gives a positive semidefinite matrix. We use this observation to prove the following abstract characterization of spectrahedral shadows.

Theorem 1. Let $S \subset \mathbb{R}^n$ be a semi-algebraic set. Then S is a spectrahedral shadow if and only if for all real closed field extensions $\mathbf{R}$ of $\mathbb{R}$ and all $\mathbb{R}$-linear, unital and completely positive functions $f : \mathbf{R} \to \mathbf{R}$ the base-change $S(\mathbf{R}) \subset \mathbf{R}^n$ is preserved by component-wise application of f.

Here the base-change $S(\mathbf{R})$ of a semialgebraic set $S \subset \mathbb{R}^n$ is the semialgebraic subset of $\mathbf{R}^n$ defined by the same inequalities as S.

4. NEW COUNTER-EXAMPLES TO THE HELTON–NIE CONJECTURE

Relating Theorem 1 to sums of squares in the group ring of the abelian group $\mathbb{Q}^n$, we are able to prove the following criterion for the convex hull of the positive part of a toric variety to be a spectrahedral shadow.

Theorem 2. Let $S \subset \mathbb{Z}^m_{\geq 0}$ be a finite set of cardinality n. Let $X \subset \mathbb{R}^n$ be the image of $\mathbb{R}^m_{\geq 0}$ under the monomial map

$$\mathbb{R}^m \to \mathbb{R}^n,\ x \mapsto (x^\alpha : \alpha \in S).$$

The closed convex hull of X is a spectrahedral shadow if and only if for every real closed field $\mathbf{R}$ and every nonnegative polynomial $P \in \mathbf{R}[x_1, \ldots, x_m]$ with support

in S there is a $d \in \mathbb{Z}_{>0}$ such that $P(x_1^d, \ldots, x_m^d)$ is a sum of squares of polynomials.

The cone of *completely positive matrices* is the closed convex hull of the image of $\mathbb{R}^m_{\geq 0}$ under the monomial map given by all monomials of degree 2. We apply Theorem 2 to the *Horn polynomial*

$$(x_1+x_2+x_3+x_4+x_5)^2-4\cdot(x_1x_2+x_2x_3+x_3x_4+x_4x_5+x_5x_1)$$

that was studied by Hall jun. and Newman (1963). Like this, we prove that the cone of completely positive matrices is not a spectrahedral shadow for $m \geq 5$. This implies that its dual cone, the cone of copositive matrices, is not a spectrahedral shadow either.

Abstract: Multi-agent systems are known to exhibit stable emergent behaviors, including polarization, over $\mathbb{R}^n$ or highly symmetric nonlinear spaces. In this article, we eschew linearity and symmetry of the underlying spaces, and study the stability of polarized equilibria of multi-agent gradient flows evolving on general hypersurfaces. The agents attract or repel each other according to the partition of the communication graph that is connected but otherwise arbitrary. The hypersurfaces are outfitted with geometric features styled "dimples" and "pimples" that characterize the absence of flatness. The signs of inter-agent couplings together with these geometric features give rise to stable polarization under various sufficient conditions.

Keywords: polarization, manifolds, multi-agent systems, gradient flows, nonlinear systems

1. INTRODUCTION

We study polarization in multi-agent gradient flow systems confined to manifolds embedded in the Euclidean space. Polarization refers to the emergent state where the agents converge to two distinct clusters. The gradient descent flow, being a sufficiently simple optimizing process, is amenable to rigorous stability analysis and thus widely adopted by many agent-based models as coordinating protocols for robot swarms. Works on nonlinear spaces is less common than those in $\mathbb{R}^n$, and are predominantly focused on highly symmetric spaces, see Sarlette and Sepulchre (2009); Sepulchre (2011); Lageman and Sun (2016). Possible applications in clustering algorithms, cellular division, and social dynamics call for studies of multi-agent systems on more general manifolds.

There are a few polarization studies on manifolds in the literature, where the n-sphere has received the most attention. Gaitonde et al. (2021) proved almost sure convergence for a class of Markov processes on the hypersphere. Hong and Strogatz (2011) found traveling wave polarization in a variant of the Kuramoto model over the unit circle with conformist and contrarian oscillators. Ha et al. (2020) derived stability conditions for a higher dimensional Kuramoto model featuring positive and negative couplings between agents. More elaborate state-dependent interaction rules inspired by neuroscience are considered by Crnkić and Jaćimović (2018) over a 3-sphere through a quaternion formulation. Another neuronal model called the principal component analysis flow is studied by Zhang et al. (2021) to obtain stability of the antipodal equilibrium. For ring graphs over the 2-sphere, Song et al. (2017) obtained asymptotically stable polarization with even number of agents. For more general manifolds, a recent work by Aydogdu et al. (2017) explored geodesic and chordal interactions between agents on general Riemannian manifolds without stability analysis.

In view of these related works, our contribution is that we provide rigorous stability analysis of polarized equilibria for the multi-agent gradient descent system with arbitrary connected network topology over more general manifolds. Our investigation is realized by outfitting the manifolds with special geometric features styled "dimples" and "pimples". The interplay between these geometric features and the cooperative/antagonistic interactions among agents then gives rise to different routes to polarization.

2. SETUP

2.1 Geometric features of the manifold

Consider a closed, connected, and orientable hypersurface embedded in the Euclidean ambient space

$$\mathcal{H}^n = \{y \in \mathbb{R}^{n+1} \,|\, c(y) = 0\}$$

implicitly characterized by a smooth C^2 function $c : \mathbb{R}^{n+1} \to \mathbb{R}$. The hypersurface $\mathcal{H}^n$ separates its complement $\mathbb{R}^{n+1} - \mathcal{H}^n$ into two disjoint sets, one where c is positive and the other where c is negative (Lima (1988)). Without loss of generality, we identify the former with the unbounded set outside $\mathcal{H}^n$, and the latter with the bounded set inside $\mathcal{H}^n$. The unit normal $n(x) = \nabla c(x)/\|\nabla c(x)\|$ is outward-pointing (i.e., pointing towards the unbounded set), where the usual restriction applies: the gradient in $\mathbb{R}^{n+1}$ satisfies $\nabla c(x) \neq 0$ for every $x \in \mathcal{H}^n$.

The hypersurface $\mathcal{H}^n$ is equipped with special features: dimples and pimples. To define them, introduce a height function $h_x \colon \mathcal{H}^n \to \mathbb{R}$ with respect to a fixed x

$$h_x(y) := \langle n(x), y \rangle, \quad \forall y \in \mathcal{H}^n.$$

The height function gives the altitude of a point y along the axis spanned by $n(x)$. For notational convenience, if

⋆ This work is funded by the Luxembourgish state agency FNR through their funding instrument CORE OPEN.

the fixed x carries a subscript, e.g. x_i, then h_{x_i} is shortened as h_i. Now we are ready to introduce the definitions for a dimple and a pimple.

Definition 1. If for some $x \in \mathcal{H}^n$, $y = x$ is a strict local minimizer of $h_x(y)$ in a sufficiently small neighborhood $\mathcal{I}_x = \{y \in \mathcal{H}^n \,|\, \|y - x\| < \epsilon\}$, then $\mathcal{I}_x$ is referred to as a dimple, and x the bottom of the dimple. Similarly, if for some $x \in \mathcal{H}^n$, $y = x$ is a strict local maximizer of $h_x(y)$ in a sufficiently small neighborhood $\mathcal{I}_x$, then $\mathcal{I}_x$ is referred to as a pimple, and x the bottom of the pimple.

Figure 1 illustrates the concepts of dimples and pimples in $\mathbb{R}^3$ by some fruits and donuts.

Remark 2.1. The features $\mathcal{I}_x$ does not necessarily contain only one bottom x. That is, another point $y \neq x$ may also be a bottom with respect to the height function h_y. It may be that $\mathcal{I}_x$ has a single set of bottoms covering all or part of $\mathcal{I}_x$, or there are multiple disjoint sets of bottoms within $\mathcal{I}_x$. We require $\mathcal{I}_x$ to be sufficiently small in Definition 1 to exclude the latter case, by shrinking the radius ϵ of the neighborhood around x. However, it is not possible to completely avoid disjoint sets of bottoms when, e.g., the embedding of the hypersurface is not analytic.

2.2 Multi-agent networks

Evolving on the hypersurface is a homogeneous multi-agent system with N agents, associated with an undirected, connected, and weighted graph structure $\mathcal{G} = (\mathcal{V}, \mathcal{E}, A)$. The adjacency matrix $A = [a_{ij}]$ is symmetrical and has non-negative entries. The vertices $\mathcal{V}$ are divided into two groups $\mathcal{V}_\mathrm{u} = \{1, 2, \dots M\}$ and $\mathcal{V}_\mathrm{l} = \{M+1, \dots N\}$ for $1 < M < N$. The edge set $\mathcal{E}$ is partitioned into intragroup and intergroup sets $\mathcal{E}_+ = \{\{i, j\} \in \mathcal{E} \,|\, i, j \in \mathcal{V}_\mathrm{u} \text{ or } i, j \in \mathcal{V}_\mathrm{l}\}$ and $\mathcal{E}_- = \{\{i, j\} \in \mathcal{E} \,|\, i \in \mathcal{V}_\mathrm{l}, j \in \mathcal{V}_\mathrm{u}\}$.

Such a partition is introduced to enforce different coupling rules over edges in $\mathcal{E}_+$ and $\mathcal{E}_-$. The couplings are positive over all edges in $\mathcal{E}_+$, whereas those over $\mathcal{E}_-$ can be either all positive or all negative.

2.3 Gradient flow dynamics

Denote the states of the agents individually by x_i and collectively by $\chi := (x_i)_{i=1}^N$. The agents evolve according to a simple rule of gradient descent flow in continuous time. Given a disagreement function $V : \mathcal{H}^n \to \mathbb{R}$ with a smooth extension $\bar{V} : \mathbb{R}^{n+1} \to \mathbb{R}$, the dynamics of each agent is

$$\dot{x}_i = -\operatorname{grad}_i V(\chi) = -\mathrm{P}_i \left(\nabla_i \bar{V}(\chi)\right), \tag{1}$$

where grad_i is the intrinsic gradient on the tangent space $\mathsf{T}_{x_i}\mathcal{H}^n$ at the point x_i, $\mathrm{P}_i = I - n(x_i)n(x_i)'$ is an orthogonal projection matrix on $\mathsf{T}_{x_i}\mathcal{H}^n$, and $\nabla_i \bar{V}(\chi)$ is the standard gradient in the Euclidean space of the disagreement function.

As mentioned in §2.2, the partition of the N agents into $\mathcal{V}_\mathrm{u}$ and $\mathcal{V}_\mathrm{l}$ allows us to assign attractive or repulsive intergroup interactions. For the case of attractive intragroup coupling and repulsive intergroup coupling, the disagreement function is

$$V_-(\chi) := \frac{1}{2} \sum_{\{i,j\} \in \mathcal{E}_+} a_{ij} \|x_j - x_i\|^2 - \frac{1}{2} \sum_{\{i,j\} \in \mathcal{E}_-} a_{ij} \|x_j - x_i\|^2. \tag{2}$$

For purely attractive coupling, we simply change the sign of the second term in (2):

$$V_+(\chi) = \frac{1}{2} \sum_{\{i,j\} \in \mathcal{E}} a_{ij} \|x_j - x_i\|^2. \tag{3}$$

Substituting (2) and (3) into (1) respectively yields

$$\begin{aligned} \dot{x}_i &= \mathrm{P}_i \left(\sum_{j \in \mathcal{V}_\mathrm{u}} a_{ij} \left(x_j - x_i\right) - \sum_{j \in \mathcal{V}_\mathrm{l}} a_{ij} \left(x_j - x_i\right) \right), \quad i \in \mathcal{V}_\mathrm{u} \\ \dot{x}_i &= \mathrm{P}_i \left(\sum_{j \in \mathcal{V}_\mathrm{l}} a_{ij} \left(x_j - x_i\right) - \sum_{j \in \mathcal{V}_\mathrm{u}} a_{ij} \left(x_j - x_i\right) \right), \quad i \in \mathcal{V}_\mathrm{l} \end{aligned} \tag{4}$$

and

$$\dot{x}_i = \mathrm{P}_i \sum_{j \in \mathcal{V}} a_{ij} \left(x_j - x_i\right), \quad i \in \mathcal{V}. \tag{5}$$

2.4 The assemblage

Assembling the aforementioned ingredients in §2.2 and §2.3, we have a multi-agent gradient flow system with attractive (4) or repulsive (5) intergroup interactions evolving on a hypersurface $\mathcal{H}^n$. The hypersurface is equipped with a pair of dimples or pimples as illustrated in Fig. 1, each containing one of the two groups of agents $\mathcal{V}_\mathrm{u}$ and $\mathcal{V}_\mathrm{l}$. We are interested in possible polarization arising in this setting as a result of the interplay between the graph couplings and the geometry of the underlying nonlinear space.

Definition 2. (Polarization). The agents are said to be polarized if $x_i = x_j$ for all $\{i, j\} \in \mathcal{E}_+$ and $x_i \neq x_j$ for all $\{i, j\} \in \mathcal{E}_-$.

Definition 2 characterizes a polarized configuration without specifying whether the states are in equilibrium, limit-cycle, or other non-stationary modes. We focus on polarized equilibria and its stability properties, because gradient flows must converge to either an equilibrium or a set of equilibria (Helmke and Moore, 1996, App. C.12).

For the definitions of Lyapunov and asymptotic stability, while those of an equilibrium point are well known, those of a set of equilibria is perhaps less standard. Introduce the *Hausdorff distance* between two sets $\mathcal{Y}, \mathcal{Z} \subset \mathbb{R}^n$,

$$d_\mathrm{H}(\mathcal{Y}, \mathcal{Z}) := \max\{\sup_{y \in \mathcal{Y}} \inf_{z \in \mathcal{Z}} \|y - z\|, \sup_{z \in \mathcal{Z}} \inf_{y \in \mathcal{Y}} \|y - z\|\}.$$

Definition 3. (Stability). A set of equilibria $\mathcal{S}$ is Lyapunov stable if, for each $\epsilon > 0$, there is $\delta = \delta(\epsilon)$ such that $d_\mathrm{H}(x, \mathcal{S})|_{t=0} < \delta$ implies $d_\mathrm{H}(x, \mathcal{S})|_t < \epsilon$ for all $t \geq 0$; is asymptotically stable if it is stable and δ can be chosen such that $d_\mathrm{H}(x, \mathcal{S})|_{t=0} < \delta$ implies $\lim_{t \to \infty} d_\mathrm{H}(x, \mathcal{S}) = 0$.

We collect a few previous results and associated definitions that will pave the way for later development.

Definition 4. (Local minimizer). A set $\mathcal{S} \subset \mathcal{M}$ is said to be a *local minimizer* of a real function $f : \mathcal{M} \to \mathbb{R}$ from a metric space $(\mathcal{M}, d_\mathrm{H})$ if for some $\epsilon > 0$, there is an open neighborhood $\mathcal{N}(\mathcal{S}) = \{x \in \mathcal{M} \,|\, d_\mathrm{H}(x, \mathcal{S}) < \epsilon\}$ such that $f|_\mathcal{S} \leq f(x)$ for all $x \in \mathcal{N}(\mathcal{S})$. Moreover, if the inequality is strict for all $x \in \mathcal{N}(\mathcal{S}) \backslash \mathcal{S}$, then $\mathcal{S}$ is said to be a *strict local minimizer*.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Fig. 1. Fruits and donuts illustrating Definition 1. From left to right: a lemon with a pair of pimples, an apple with a pair of dimples, a lemon donut with a pair of dimples, and an apple donut with a pair of pimples.

Definition 5. (Isolated critical). A set $\mathcal{S} \subset \mathcal{M}$ of critical points of a real function $f : \mathcal{M} \to \mathbb{R}$ from a metric space $(\mathcal{M}, d_{\mathrm{H}})$ is said to be *isolated critical* if for some $\epsilon > 0$, there is an open neighborhood $\mathcal{N}(\mathcal{S}) = \{x \in \mathcal{M} \,|\, d_{\mathrm{H}}(x, \mathcal{S}) < \epsilon\}$ such that $\mathcal{N}(\mathcal{S}) \backslash \mathcal{S}$ is void of critical points.

Proposition 6. (Prop. 3 Markdahl (2021b)). Let $\mathcal{M}$ be a closed manifold and take any $V : \mathcal{M} \to \mathbb{R}$ that is C^2. Let $\mathcal{S}$ be a compact set of local minimizers of V. If $\mathcal{S}$ is a strict local minimizer, then $\mathcal{S}$ is a Lyapunov stable equilibrium set of $\dot{x} = -\operatorname{grad} V$. If $\mathcal{S}$ is also isolated critical, then it is asymptotically stable.

3. MAIN RESULTS

In this section, we present and discuss our main results concerning the stability properties of polarized equilibria. They arise in different combinations of attractive/repulsive interactions with dimple/pimple geometric features, best exemplified in Fig. 1. Despite the symmetrical shapes exhibited in the figure, we emphasize that our general results do not require any spatial symmetry of the hypersurface embedding.

3.1 Dimple pairs with attractive intergroup couplings

Consider the setting of a pair of dimples on the hypersurface, one containing the group $\mathcal{V}_{\mathrm{u}}$ and the other $\mathcal{V}_{\mathrm{l}}$. Thus, we operate under the following assumption in this section:

Assumption 1. The sets $\mathcal{I}_{\mathrm{u}}$ and $\mathcal{I}_{\mathrm{l}}$ are a pair of dimples, and $x_i \in \mathcal{I}_{\mathrm{u}}$ for all $i \in \mathcal{V}_{\mathrm{u}}$, $x_i \in \mathcal{I}_{\mathrm{l}}$ for all $i \in \mathcal{V}_{\mathrm{l}}$.

Now we investigate stability of a polarized equilibrium that exists in the system (5) if the manifold resembles the apple in Fig. 1. The set of interest is the following:

$$\chi^* := \{\chi \in (\mathcal{H}^n)^N \,|\, x_i = x_{\mathrm{u}}\,, i \in \mathcal{V}_{\mathrm{u}}, x_i = x_{\mathrm{l}}\,, i \in \mathcal{V}_{\mathrm{l}}\}. \quad (6)$$

Let $r_o = \frac{1}{2}\|x_{\mathrm{u}} - x_{\mathrm{l}}\|$ denote the half distance between the dimple bottoms x_{u} and x_{l}.

Proposition 7. For system (5) under Assumption 1, if there exists a pair of distinct dimple bottoms $x_{\mathrm{u}} \in \mathcal{I}_{\mathrm{u}}$ and $x_{\mathrm{l}} \in \mathcal{I}_{\mathrm{l}}$ such that

(1) $x_{\mathrm{u}} - x_{\mathrm{l}}$ is parallel to $n(x_{\mathrm{u}})$, and
(2) $h_{\mathrm{u}}(x_{\mathrm{l}})$ is a local maximum satisfying $h_{\mathrm{u}}(x_{\mathrm{l}}) < h_{\mathrm{u}}(x_{\mathrm{u}})$,

then a strict local minimum of V_+ is $V_+^* := 2r_o^2 \sum_{\{i,j\} \in \mathcal{E}_-} a_{ij}$, and the corresponding strict local minimizer is χ^* defined in (6).

To prove it, we look at the disagreement contributions from $\mathcal{E}_-$ and $\mathcal{E}_+$ in (3) separately. Those from $\mathcal{E}_-$ obeys

$$\begin{aligned}\|x_j - x_i\|^2 &\geq \langle x_j - x_i, n(x_{\mathrm{u}})\rangle^2 = \big(h_{\mathrm{u}}(x_j) - h_{\mathrm{u}}(x_i)\big)^2 \\ &\geq (h_{\mathrm{u}}(x_{\mathrm{u}}) - h_{\mathrm{u}}(x_{\mathrm{l}}))^2 = 4r_o^2,\end{aligned}$$

whereas those from $\mathcal{E}_+$ are lower bounded by 0 since agents from the same group can simply converge to a single point. Both lower bounds are achieved simultaneously only by the configuration χ^* under the conditions of 7, thus the conclusion.

Lyapunov stability of (6) is then obtained by applying Prop. 6 to Prop. 7. For asymptotic stability, we need $\mathcal{I}_{\mathrm{u}}$ and $\mathcal{I}_{\mathrm{l}}$ to live on nice manifolds.

Theorem 8. For system (5) under Assumption 1, if the two dimples $\mathcal{I}_{\mathrm{u}}$ and $\mathcal{I}_{\mathrm{l}}$ satisfy the properties given in Prop. 7, and in addition, there is a neighborhood $\mathcal{N}_{\mathrm{a}}(\chi^*)$ on $(\mathcal{H}^n)^N$ that belongs to an analytic manifold, then χ^* defined in (6) is an asymptotically stable polarized equilibrium.

Proof. Following a variant (Kurdyka et al., 2000, Sec. 9) of the Łojasiewicz inequality valid on analytic Riemannian manifolds, the analytic function $V_+(\chi)$ in (3) behaves in the following way in a neighborhood of the polarized equilibrium $\mathcal{N}_{\mathrm{l}}(\chi^*) \subset \mathcal{N}_{\mathrm{a}}(\chi^*)$:

$$|V_+(\chi) - V_+(\chi^*)|^\alpha \leq \kappa \|\operatorname{grad} V_+(\chi)\|,$$

for $\alpha < 1$ and $\kappa > 0$, and where grad is the intrinsic gradient on the tangent space. Suppose that $\chi \notin \chi^*$ is an equilibrium in $\mathcal{N}_{\mathrm{l}}(\chi^*)$, then $\operatorname{grad} V_+(\chi) = 0$, c.f. (1). Consequently, $V_+(\chi) = V_+(\chi^*)$. However, Prop. 7 says that the local minimum V_+^* is achieved only by $\chi = \chi^*$, a contradiction. Therefore, there is no equilibrium except χ^* in $\mathcal{N}_{\mathrm{l}}(\chi^*)$, rendering χ^* isolated critical as per Definition 5. Thus, χ^* is asymptotically stable by Prop. 6. □

3.2 Pimple pairs with repulsive intergroup couplings

Consider a pair of pimples on the hypersurface, one containing the group of agents $\mathcal{V}_{\mathrm{u}}$ and the other $\mathcal{V}_{\mathrm{l}}$. The assumption in this section is then

Assumption 2. The sets $\mathcal{I}_{\mathrm{u}}$ and $\mathcal{I}_{\mathrm{l}}$ are a pair of pimples, and $x_i \in \mathcal{I}_{\mathrm{u}}$ for all $i \in \mathcal{V}_{\mathrm{u}}$, $x_i \in \mathcal{I}_{\mathrm{l}}$ for all $i \in \mathcal{V}_{\mathrm{l}}$.

For the dynamics, we are interested in (4) with attractive intragroup coupling and repulsive intergroup coupling corresponding to the disagreement function (2). Thus, we may picture the system (4) evolving on a lemon-like manifold in Fig. 1 left.

Denote a *closed* ball centered at a point x with radius r as $\mathcal{B}_r(x)$. Let $x_o = \frac{1}{2}(x_{\mathrm{u}} + x_{\mathrm{l}})$ denote the midpoint between x_{u}

and x_l, and recall r_o as before is the half distance between them. The following results concern the set

$$\mathcal{C}_\mathrm{lem} \coloneqq \{\chi \in (\mathcal{H}^n)^N \mid x_i = x \ \forall i \in \mathcal{V}_\mathrm{u}, x_i = y \ \forall i \in \mathcal{V}_\mathrm{l}, (x,y) \in Y\}, \tag{7}$$

where $Y \coloneqq \{(x,y) \in \mathcal{I}_\mathrm{u} \times \mathcal{I}_\mathrm{l} \,|\, \|x-y\| = 2r_o\}$. This set has at least one element $\chi^* \in \mathcal{C}_\mathrm{lem}$. It may contain other elements when, for instance, the pair of pimples belongs to a sphere.

Proposition 9. For system (4) under Assumption 2, if there exists a pair of distinct pimple bottoms $x_\mathrm{u} \in \mathcal{I}_\mathrm{u}$ and $x_\mathrm{l} \in \mathcal{I}_\mathrm{l}$ such that $\mathcal{I}_\mathrm{u}$ and $\mathcal{I}_\mathrm{l}$ are entirely contained in $\mathcal{B}_{r_o}(x_o)$, then a strict local minimum of V_- is $V_-^* \coloneqq -2r_o^2 \sum_{\{i,j\}\in\mathcal{E}_-} a_{ij}$, and the corresponding strict local minimizer is a compact set of polarized configurations $\mathcal{C}_\mathrm{lem}$ defined in (7).

Similar to the proof of Prop. 7, we look at disagreement contributions from $\mathcal{E}_-$ and $\mathcal{E}_+$ separately. The main difference is that under the condition in Prop. 9, we have $\|x_j - x_i\| \le 2r_o = \|x_\mathrm{u} - x_\mathrm{l}\|$ for all $\{i,j\} \in \mathcal{E}_-$. Likewise, Lyapunov stability can be concluded for $\mathcal{C}_\mathrm{lem}$ by applying Prop. 6 to Prop. 9.

Theorem 10. For system (4) under Assumption 2, if the two pimples $\mathcal{I}_\mathrm{u}$ and $\mathcal{I}_\mathrm{l}$ satisfy the conditions given in Prop. 9, and in addition, there is a neighborhood $\mathcal{N}_\mathrm{a}(\mathcal{C}_\mathrm{lem})$ on $(\mathcal{H}^n)^N$ that belongs to an analytic manifold, then $\mathcal{C}_\mathrm{lem}$ defined in (7) is an asymptotically stable set of polarized equilibria.

Theorem 10 concerns the asymptotic stability of an equilibrium set, rather than an equilibrium point as the singleton set χ^* in Theorem 8. The accompanying subtlety requires a more involved proof; the line of reasoning is similar to the proof of (Markdahl, 2021a, Thm. 8).

Remark 3.1. The additional requirement on the analyticity of the manifold in Theorems 8 and 10 is a local one. In fact, the sole purpose of introducing the neighborhood $\mathcal{N}_\mathrm{a}(\bullet)$ is to emphasize this local nature. We do not require the whole manifold to be analytic for $\mathcal{C}_\mathrm{lem}$ or χ^* to be asymptotically stable. For instance, $\mathcal{N}_\mathrm{a}(\mathcal{C}_\mathrm{lem})$ may be a subset of $(\mathcal{H}^n)^N \cap \mathcal{M}^N$, where $\mathcal{H}^n$ is the hypersurface on which the agents inhabit, whereas $\mathcal{M}$ is an analytic manifold.

3.3 Dimples and pimples on a torus

Stable polarization with a pair of dimples is found not only in (5) as discussed in §3.1. It also exists in the system (4) with repulsive intergroup coupling, if the normals of the two dimples point toward each other, see the lemon donut in Fig. 1. The stability conditions in the following result is identical to that in Prop. 9 and Theorem 10.

Proposition 11. For system (4) under Assumption 1, if there exists a pair of distinct dimple bottoms $x_\mathrm{u} \in \mathcal{I}_\mathrm{u}$ and $x_\mathrm{l} \in \mathcal{I}_\mathrm{l}$ such that $\mathcal{I}_\mathrm{u}$ and $\mathcal{I}_\mathrm{l}$ are entirely contained in $\mathcal{B}_{r_o}(x_o)$, then $\mathcal{C}_\mathrm{lem}$ defined in (7) is Lyapunov stable. Furthermore, if there is a neighborhood $\mathcal{N}_\mathrm{a}(\mathcal{C}_\mathrm{lem})$ on $(\mathcal{H}^n)^N$ that belongs to an analytic manifold, then $\mathcal{C}_\mathrm{lem}$ is asymptotically stable.

For the apple donut in Fig. 1 with attractive intergroup coupling, we have the following result analogous to that for the apple in §3.1, although the condition here has a switched inequality (compare to Prop. 7).

Proposition 12. For system (5) under Assumption 2, if there exists a pair of distinct pimple bottoms $x_\mathrm{u} \in \mathcal{I}_\mathrm{u}$ and $x_\mathrm{l} \in \mathcal{I}_\mathrm{l}$ such that $x_\mathrm{u} - x_\mathrm{l}$ is parallel to $n(x_\mathrm{u})$, and $h_\mathrm{u}(x_\mathrm{l})$ is a local minimum satisfying $h_\mathrm{u}(x_\mathrm{l}) > h_\mathrm{u}(x_\mathrm{u})$, then χ^* defined in (6) is Lyapunov stable. Furthermore, if there is a neighborhood $\mathcal{N}_\mathrm{a}(\chi^*)$ on $(\mathcal{H}^n)^N$ that belongs to an analytic manifold, then χ^* is asymptotically stable.

Abstract: During the last couple of years the theory of why and when Model Predictive Control (MPC) generates stable, feasible and near optimal closed-loop solutions has significantly matured. In this talk we give a survey about the contribution of the dissipativity concept in this line of research.

Keywords: Model Predictive Control, strict dissipativity, stability, near optimality, feasibility, detectability

1. INTRODUCTION

During the last couple of years the theory of why and when Model Predictive Control (MPC) generates stable, feasible and near optimal closed-loop solutions has significantly matured. In this talk we give a survey about the contribution of the dissipativity concept in this line of research.

2. PROBLEM FORMULATION

We present our results for discrete-time nonlinear control systems of the form

$$x(k+1) = f(x(k), u(k)), \quad x(0) = x_0 \tag{1}$$

with $x(k) \in X$ and $u(k) \in U$ for normed vector spaces X and U. Most of the results in this talk hold in an analogous way for continuous time systems.

MPC then computes a control input $u_{MPC}(\cdot)$ by solving a sequence of optimal control problems on finite, overlapping time horizons. Here, the finite horizon optimal control problem is given as follows. For a given constraint set $\mathbb{Y} \subset X \times U$, a terminal constraints set $\mathbb{X}_f$, a stage cost $\ell : \mathbb{Y} \to \mathbb{R}$, a terminal cost $F : \mathbb{X}_f \to \mathbb{R}$, and a time horizon $N \in \mathbb{N}$ we define the finite horizon functional

$$J_N(x_0, u(\cdot)) := \sum_{k=0}^{N-1} \ell(x(k), u(k)) + F(x(N)), \tag{2}$$

where $x(\cdot)$ solves (1). Then we solve

$$\text{minimize}_{u(\cdot)} J_N(x_0, u(\cdot)) \tag{3}$$

subject to the constraints $(x(k), u(k)) \in \mathbb{Y}$ for all $k = 0, \ldots, N-1$ and $x(N) \in \mathbb{X}_f$. We call a control $u(\cdot)$ *admissible* (for x_0) when these constraints are satisfied. Moreover, we set $\mathbb{X} := \{x \in X \,|\, \text{there is } u \in U \text{ with } (x,u) \in \mathbb{Y}\}$.

The pair $(\mathbb{X}_f, F)$ is referred to as *terminal condition* and in the trivial case $\mathbb{X}_f = \mathbb{X}$ and $F \equiv 0$ we refer to (2) as a problem *without terminal conditions*.

Associated to the optimal control problems (3) we define the *optimal value function*

$$V_N(x_0) := \inf_{u(\cdot) \text{ admissible}} J_N(x_0, u(\cdot))$$

and we call an admissible control $u^*(\cdot)$ *optimal* (for x_0), if $J_N(x_0, u^*(\cdot)) = V_N(x_0)$.

The corresponding MPC scheme then reads as follows (for much more detailed expositions we refer to Rawlings et al. (2017); Grüne and Pannek (2017)):

Given an initial condition $x_{MPC}(0) := \hat{x}_0 \in \mathbb{X}$ and an optimisation horizon $N \in \mathbb{N}$, for $n = 0, 1, 2, \ldots$ we perform the following steps:

(1) Let $x_0 := x_{MPC}(n)$ denote the current state of the system.
(2) Solve the finite horizon optimal control problem (3) in order to obtain the optimal control sequence $u^*(\cdot)$.
(3) Apply the first element of the optimal control sequence $u^*(\cdot)$ as a feedback control value until the next time instant, i.e., set $u_{MPC}(n) := u^*(0)$ and $x_{MPC}(n+1) := f(x_{MPC}(n), u^*(0))$.
(4) Set $n := n+1$ and go to Step 1.

Here, we consider general cost functions ℓ that do not need to have any a priori structure. This setting is typically termed *economic* MPC in the literature, although *general* MPC might be a more appropriate name.

When dealing with MPC, some of the central questions are:

- **Stability:** Does the MPC closed-loop solution exhibit stable behaviour?

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

- **Optimality:** Does the MPC closed-loop solution enjoy (approximate) optimality properties?

- **Feasibility:** Does the MPC closed-loop solution maintain the constraints and are the optimal control problems in Step (2) of the algorithm always feasible?

As we will explain in the next section, a suitable dissipativity concept helps to give positive answers to all questions.

3. STRICT DISSIPATIVITY

The appropriate dissipativity concept is the following strict dissipativity notion. In this extended abstract we limit ourselves to strict dissipativity at an equilibrium $(x^e, u^e) \in \mathbb{Y}$ (i.e., $f(x^e, u^e) = x^e$). Extensions to periodic and general time-varying trajectories are possible and will be briefly explained in the talk.

Definition 3.1. The optimal control problem is called *strictly dissipative* at an equilibrium (x^e, u^e), if there exists a *storage function* $\lambda : \mathbb{X} \to \mathbb{R}$, bounded from below, and a function [1] $\alpha \in \mathcal{K}_\infty$ such that the inequality

$$\lambda(f(x,u)) \le \lambda(x) + \ell(x,u) - \ell(x^e,u^e) - \alpha(\|x - x^e\|)$$

holds for all $(x,u) \in \mathbb{Y}$ with $f(x,u) \in \mathbb{X}$. Here, the function $s(x,u) = \ell(x,u) - \ell(x^e,u^e)$ is called the supply rate.

The optimal control problem is called *dissipative* if the above inequality holds with $\alpha \equiv 0$.

It follows immediately that if (not necessarily strict) dissipativity holds, then (x^e, u^e) is an optimal equilibrium, in the sense that $\ell(x^e,u^e) \le \ell(\tilde{x},\tilde{u})$ for all equilibria $(\tilde{x},\tilde{u}) \in \mathbb{Y}$ with $\tilde{x} \ne x^e$.

The dissipativity notion for control systems was introduced by Willems (1972) in continuous time, the discrete time version used here is due to Byrnes and Lin (1994). It is interesting that *strict* dissipativity has not played a significant role in the literature until quite recently. The reason is that in the past the specific form of the suppy function often did not play a role. In this case, any dissipative system is also strictly dissipative; it suffices to replace $s(x,u)$ by $s(x,u) + \alpha(\|x - x^e\|)$. However, if the supply function s is linked to the cost function of the optimal control problem as in Definition 1, then it is not possible to modify it. In this sense, the application to MPC and optimal control are probably the main motivation for studying *strict* dissipativity.

4. STABILITY AND AVERAGED OPTIMALITY

The observation that dissipativity is beneficial for MPC was first made in Diehl et al. (2011), where it was observed that strict duality — which is nothing but strict dissipativity with a linear storage function — implies asymptotic stability of the optimal equilibrium for the MPC closed-loop under appropriate terminal conditions. This paper already contains the key idea of all dissipativity-based MPC stability results, namely the fact that the optimal value function of the optimal control problem with rotated cost

$$\tilde{\ell}(x,u) = \ell(x,u) - \ell(x^e,u^e) + \lambda(x) - \lambda(f(x,u))$$

can be used as a Lyapunov function for the closed loop. The observation that this construction can be extended without additional effort from strict duality to strict dissipativity was then made in Angeli and Rawlings (2010).

The decisive contribution of the terminal condition in these papers lies in the fact that under this condition the optimal trajectories of the optimal control problems with cost ℓ and $\tilde{\ell}$, respectively, coincide. The properties of the terminal conditions needed for this were given in Amrit et al. (2011) and a special case was already used earlier in Angeli et al. (2009) in order to prove average optimality of the MPC closed-loop, i.e., that

$$\overline{J}_\infty(\hat{x}_0, u_{MPC}(\cdot)) = \inf_{u \text{ admissible}} \overline{J}_\infty(\hat{x}_0, u).$$

for $\overline{J}_\infty(x_0,u) := \lim_{K\to\infty} \frac{1}{K} \sum_{k=0}^{K-1} \ell(x(k),u(k))$. We remark that, in contrast to most other results discussed here, for this proof strict dissipativity is not needed. However, it needs optimal operation of the system at the equilibrium (x^e, u^e), which under a controllability condition implies (non-strict) dissipativity, see Müller (2014).

The fact that the optimal trajectories with cost ℓ and $\tilde{\ell}$ coincide is no longer the case for MPC without terminal conditions. However, as first observed in Grüne (2013), then refined in Grüne and Stieler (2014) and later streamlined in Chapter 8 of Grüne and Pannek (2017), the solutions are still very similar up to a certain time P. The reason for this is the so-called *turnpike property* in optimal control, which demands that the optimal trajectory most of the time stays near the optimal equilibrium. As noted in Grüne (2013), this property is implied by strict dissipativity under a reachability condition (conceptually similar results are much older and can be found, e.g., in Carlson et al. (1991)). Besides the possibility of building a Lyapunov function, its implication of the turnpike property is the second important feature of strict dissipativity. For more information on the turnpike property we refer to the recent survey Faulwasser and Grüne (2022).

As a consequence of this similarity, without terminal conditions we can still conclude near average optimality, i.e.,

$$\overline{J}_\infty(\hat{x}_0, u_{MPC}(\cdot)) = \inf_{u \text{ admissible}} \overline{J}_\infty(\hat{x}_0, u) + \varepsilon(N)$$

with $\varepsilon(N) \to 0$ as $N \to \infty$, and practical asymptotic stability of the closed loop, i.e., asymptotically stable behaviour outside a small neighbourhood of x^e, whose size also tends to 0 as N tends to infinity. This is due to the fact that the optimal value function for cost $\tilde{\ell}$ is still an approximate Lyapunov function for the MPC closed loop. These two properties hold provided the optimal value functions for different time horizons satisfy a uniform continuity condition at the optimal equilibrium x^e, which is needed in order to avoid that the small differences in the optimal trajectories cause large differences in the closed-loop behaviour.

[1] As usual, we define $\mathcal{K}_\infty$ to be the space of continuous functions $\alpha : [0,\infty) \to [0,\infty)$ with $\alpha(0) = 0$ and α is strictly increasing to ∞.

5. TRANSIENT OPTIMALITY

While average optimality is a good measure to assess the performance of trajectories on very long time horizons, it does not tell much on short horizons. The reason is that a large cost on a short horizon contributes only very little to the average over a long horizon. Hence, a low average cost on a very long horizon does not allow for any conclusions about the cost on short horizons of the same trajectory. To this end, the concept of *transient optimality* is useful. Recall that under the strict dissipativity condition the closed-loop solutions converge to x^e (with appropriate terminal conditions) or to a small neighbourhood thereof (without terminal conditions). Hence, if we fix a sufficiently large time $K \in \mathbb{N}$ (that may be much larger than N), then we can find a small $\varepsilon > 0$ such that $\|x_{MPC}(n) - x^e\| \leq \varepsilon$ for all $n \geq K$. We can now compare the cost of this trajectory up to time K, i.e.,

$$J_K(\hat{x}_0, u_{MPC}(\cdot))$$

with the cost of all other trajectories that also end up in an ε-neighbourhood of x^e, i.e., with $V_K^{tr}(x_0) :=$

$$\inf\{J_K(x_0, u(\cdot)) \,|\, u(\cdot) \text{ admissible}, \|x(K) - x^e\| \leq \varepsilon\}.$$

It turns out that there exist two functions $\varepsilon_1(N), \varepsilon_2(K) \to 0$ as $N, K \to \infty$, such that

$$J_K(\hat{x}_0, u_{MPC}(\cdot)) \leq V_K^{tr}(\hat{x}_0) + \varepsilon_1(N) + \varepsilon_2(K)$$

in the case with terminal conditions and

$$J_K(\hat{x}_0, u_{MPC}(\cdot)) \leq V_K^{tr}(\hat{x}_0) + K\varepsilon_1(N) + \varepsilon_2(K)$$

in the case without terminal conditions. The former was proved in Grüne and Panin (2015) and the latter in Grüne and Stieler (2014); a unified treatment of both cases was later given in (Grüne and Pannek, 2017, Chapter 8).

6. FEASIBILITY

In all statements so far we have tacitly assumed that the solution $x_{MPC}(n)$ exists for all $n \geq 0$. However, this requires that in each sampling instance in Step (2) of the MPC scheme there exists an admissible control $u(\cdot)$ for the initial condition $x_0 = x_{MPC}(n)$. In this case, we call $x_0 = x_{MPC}(n)$ *feasible* and the question is thus whether $x_{MPC}(n)$ is feasible for all $n \geq 0$ In case of MPC with terminal conditions, feasibility for $x_{MPC}(n)$ follows if $x_{MPC}(n-1)$ is feasible — a property called *recursive feasibility* — provided the terminal constrained $\mathbb{X}_f$ is viable, i.e., for each $x \in \mathbb{X}_f$ there is $u \in U$ with $(x, u) \in \mathbb{Y}$ and $f(x, u) \in \mathbb{X}_f$, see, e.g., Mayne et al. (2000). This procedure and the related proofs are completely unrelated to dissipativity.

However, in the absence of terminal conditions, strict dissipativity or, more precisely, the turnpike property again play an important role. If we assume that the optimal equilibrium x^e lies in the interior of the state constraint set $\mathbb{X}$, then for all sufficiently large horizons N the turnpike property implies feasibility for all points that lies on the part of the optimal trajectory that approaches the turnpike. From this observation, it is then possible to conclude recursive feasibility, see Faulwasser and Bonvin (2015); Faulwasser et al. (2018).

7. CONCLUSION AND RECENT DEVELOPMENTS

Strict dissipativity allows to conclude a variety of desirable properties for the closed-loop system generated by MPC schemes with general cost functions. The two decisive features of strict dissipativity in the context of MPC are (i) that it allows to build a Lyapunov function for the closed-loop based on an optimal control problem with cost $\tilde{\ell}$ and (ii) that it implies the turnpike property.

This has motivated extensive studies about the nature of strict dissipativity. A very interesting connection for linear quadratic problems is that strict dissipativity is closely related to detectability properties, see Grüne and Guglielmi (2018, 2021), which in turn are again closely linked to the turnpike property in a very general infinite-dimensional evolution equation setting, see Grüne et al. (2019, 2020, 2021). This relation will also be explained in the talk. Dissipativity also turned out to be very useful for understanding the long-term behavior of infinite-horizon optimal control problems, see Faulwasser and Kellett (2021).

* *Università degli Studi della Campania "Luigi Vanvitelli", 81012 Caserta, Italy (e-mail: ferdinando.zullo@unicampania.it).*

Abstract: Cyclic subspace codes gained a lot of attention especially because they may be used in random network coding for correction of errors and erasures. Roth, Raviv and Tamo in 2018 established a connection between cyclic subspace codes (with certain parameters) and Sidon spaces, introduced by Bachoc, Serra and Zémor in 2017 in relation with the linear analogue of Vosper's Theorem. This connection allowed Roth, Raviv and Tamo to construct large classes of cyclic subspace codes with one or more orbits. In this abstract we will consider an extension of the notion of Sidon space, which turns out to be related to cyclic subspace codes with more than one orbit. Moreover, we will also use the geometry of linear sets to provide some bounds on the parameters of a cyclic subspace code.

Keywords: cyclic subspace code; Sidon space; multi-Sidon space; linear set; orbit.

1. INTRODUCTION

Let k be a non-negative integer with $k \leq n$, the set of all k-dimensional $\mathbb{F}_q$-subspaces of $\mathbb{F}_{q^n}$, viewed as $\mathbb{F}_q$-vector space, forms a **Grassmanian space** over $\mathbb{F}_q$, which is denoted by $\mathcal{G}_q(n,k)$. A **constant dimension subspace code** is a subset C of $\mathcal{G}_q(n,k)$ endowed with the metric defined as follows

$$d(U,V) = \dim_{\mathbb{F}_q}(U) + \dim_{\mathbb{F}_q}(V) - 2\dim_{\mathbb{F}_q}(U \cap V),$$

where $U, V \in C$. This metric is also known as **subspace metric**. Subspace codes have been recently used for the error correction in random network coding, see Koetter and Kschischang (2008). The first class of subspace codes studied was the one introduced in Etzion and Vardy (2011), which is known as **cyclic subspace codes**. A subspace code $C \subseteq \mathcal{G}_q(n,k)$ is said to be **cyclic** if for every $\alpha \in \mathbb{F}_{q^n}^*$ and every $V \in C$ then $\alpha V \in C$.

Let $V \in \mathcal{G}_q(n,k)$, the **orbit** of V is the set $C_V = \{\alpha V : \alpha \in \mathbb{F}_{q^n}^*\}$, and its size is $(q^n-1)/(q^t-1)$, for some t which divides n, see (Otal and Özbudak, 2017, Theorem 1).

In particular, every orbit of a subspace $V \in \mathcal{G}_q(n,k)$ defines a cyclic subspace code of size $(q^n-1)/(q^t-1)$, for some $t \mid n$. From now on, assume $k > 1$. Clearly, a cyclic subspace code generated by an orbit of a subspace V with size $(q^n-1)/(q-1)$ has minimum distance at most $2k-2$ and in Trautmann et al. (2013) the authors conjectured the existence of a cyclic code of size $\frac{q^n-1}{q-1}$ in $\mathcal{G}_q(n,k)$ and minimum distance $2k-2$ for every positive integers n, k such that $1 < k \leq n/2$.

⋆ The research of Ferdinando Zullo was supported by the project "VALERE: VAnviteLli pEr la RicErca" of the University of Campania "Luigi Vanvitelli" and was partially supported by the Italian National Group for Algebraic and Geometric Structures and their Applications (GNSAGA - INdAM).

In Ben-Sasson et al. (2016) the authors used subspace polynomials to generate cyclic subspace codes with size $\frac{q^n-1}{q-1}$ and minimum distance $2k-2$, proving that the conjecture is true for any given k and infinitely many values of n. Such result was then improved in Otal and Özbudak (2017). Finally, the conjecture was solved in Roth et al. (2017) for most of the cases, by making use of Sidon spaces originally introduced in Bachoc et al. (2017).

The connection between cyclic subspace codes and Sidon spaces relies on the following result.

Theorem 1. (Roth et al., 2017, Lemma 34) Let U be an $\mathbb{F}_q$-subspace of $\mathbb{F}_{q^n}$ of dimension t. Then C_U is a cyclic subspace code of size $\frac{q^n-1}{q-1}$ and minimum distance $2t-2$ if and only if U is a Sidon space.

In this abstract we provide a generalization of the notion of Sidon space via Theorem 1, introducing the multi-Sidon space notion, which is a collection of $\mathbb{F}_q$-subspaces in $\mathbb{F}_{q^n}$ with a special patterns of intersection with the elements of their orbits. We then show a link between multi-Sidon spaces of maximum dimension and cyclic subspace codes with certain parameters, which yields to a canonical form for such codes. Then we propose a geometric interpretation of the Sidon (and the multi-Sidon) property by means of linear sets, which will give us an upper bound on the number of subspaces that a cyclic subspace codes associated with a multi-Sidon space can have. The results rely on the paper Zullo (2021).

2. PRELIMINARIES

2.1 Linear sets

A point set L of $\Lambda = \mathrm{PG}(V, \mathbb{F}_{q^n}) = \mathrm{PG}(r-1, q^n)$ is said to be an $\mathbb{F}_q$**-linear set** of Λ of rank k if it is defined by the

non-zero vectors of a k-dimensional $\mathbb{F}_q$-vector subspace U of V, i.e.

$$L = L_U := \{\langle \mathbf{u} \rangle_{\mathbb{F}_{q^n}} : \mathbf{u} \in U \setminus \{\mathbf{0}\}\}.$$

We denote the rank of an $\mathbb{F}_q$-linear set L_U by $\mathrm{Rank}(L_U)$. For any subspace $S = \mathrm{PG}(Z, \mathbb{F}_{q^n})$ of Λ, the **weight** of S in L_U is defined as $w_{L_U}(S) = \dim_{\mathbb{F}_q}(U \cap Z)$. If N_i denotes the number of points of Λ having weight $i \in \{0, \dots, k\}$ in L_U, the following relations hold:

$$|L_U| \leq \frac{q^k - 1}{q - 1}, \tag{1}$$

$$|L_U| = N_1 + \ldots + N_k, \tag{2}$$

$$N_1 + N_2 \frac{q^2 - 1}{q - 1} + \ldots + N_k \frac{q^k - 1}{q - 1} = \frac{q^k - 1}{q - 1}. \tag{3}$$

For further details on linear sets see Lavrauw and Van de Voorde (2015); Polverino (2010).

2.2 Sidon spaces

Sidon spaces were introduced recently in Bachoc et al. (2017) as an important tool to prove the linear analogue of Vosper's Theorem, which analyze the equality in the linear analouge of Kneser's theorem proved in Bachoc et al. (2018); Hou et al. (2002). An $\mathbb{F}_q$-subspace U of $\mathbb{F}_{q^n}$ is called a **Sidon space** if the product of any two elements of U has a unique factorization over U, up to multiplying by some elements in $\mathbb{F}_q$. Formally, U is a Sidon space if for all nonzero $a, b, c, d \in U$, if $ab = cd$, then

$$\{a\mathbb{F}_q, b\mathbb{F}_q\} = \{c\mathbb{F}_q, d\mathbb{F}_q\},$$

where if $e \in \mathbb{F}_{q^n}$ then $e\mathbb{F}_q = \{e\lambda : \lambda \in \mathbb{F}_q\}$. Sidon spaces may be seen as the q-analogue of **Sidon sets**, see O'Bryant (2004).

3. MULTI-SIDON SPACES AND CYCLIC SUBSPACE CODES

Although Sidon spaces are defined purely algebraically, they can be defined (via Theorem 1) as those subspaces of $\mathbb{F}_{q^n}$ meeting each elements of its orbit in dimension at most one. Taking this into account, the following definition arises naturally.

Let $\{U_1, \dots, U_r\}$ be a set of $\mathbb{F}_q$-subspaces of $\mathbb{F}_{q^n}$ such that $\mathrm{Orb}(U_i) \cap \mathrm{Orb}(U_j) = \emptyset$, for every $i, j \in \{1, \dots, r\}$ with $i \neq j$. Let $k_i = \dim_{\mathbb{F}_q}(U_i) \geq 2$ for any $i \in \{1, \dots, r\}$ and suppose that $|\mathrm{Orb}(U_i)| = \frac{q^n - 1}{q - 1}$ for every $i \in \{1, \dots, r\}$. If $\dim_{\mathbb{F}_q}(U_i \cap \alpha U_j) \leq 1$, for every $\alpha \in \mathbb{F}_{q^n}$ and $i, j \in \{1, \dots, r\}$ such that $U_i \neq \alpha U_j$ then we call $\{U_1, \dots, U_r\}$ a **multi-Sidon space**.

Clearly, when $r = 1$ a multi-Sidon space is a Sidon space. Moreover, if $\{U_1, \dots, U_r\}$ is a multi-Sidon space then U_i is a Sidon space for every $i \in \{1, \dots, r\}$.

Let U and V be two $\mathbb{F}_q$-subspaces of $\mathbb{F}_{q^n}$. Denote by $\langle U^2 \rangle$ the $\mathbb{F}_q$-span of $\{st : s, t \in U\}$, $U^{-1} = \{u^{-1} : u \in U \setminus \{0\}\}$ and $U \cdot V = \{uv : u \in U, v \in V\}$.

Bachoc, Serra and Zémor proved a lower bound on the dimension of $\langle U^2 \rangle$ when U is a Sidon space in (Bachoc et al., 2017, Theorem 18) and hence, putting together with the trivial upper bound on the dimension of $\langle U^2 \rangle$, the following result holds.

Theorem 2. If U is a Sidon space in $\mathbb{F}_{q^n}$ of dimension $k \geq 3$, then

$$2k \leq \dim_{\mathbb{F}_q}(\langle U^2 \rangle) \leq \binom{k+1}{2}.$$

We can hence apply the above result to all the subspaces of a multi-Sidon space, obtaining the following bounds.

Corollary 3. Let $\{U_1, \dots, U_r\}$ is a multi-Sidon space of $\mathbb{F}_{q^n}$. Let $k_i = \dim_{\mathbb{F}_q}(U_i)$ for any $i \in \{1, \dots, r\}$. Then

$$2\sum_{i=1}^{r} k_i \leq \dim_{\mathbb{F}_q}(\langle U_1^2 \rangle \times \ldots \times \langle U_r^2 \rangle) \leq \sum_{i=1}^{r} \binom{k_i + 1}{2}.$$

In particular, $k_i \leq n/2$ for each $i \in \{1, \dots, r\}$.

Let $\{U_1, \dots, U_r\}$ be a multi-Sidon space of $\mathbb{F}_{q^n}$ and let $k_i = \dim_{\mathbb{F}_q}(U_i)$ for any $i \in \{1, \dots, r\}$. Similarly to (Roth et al., 2017, Definition 4), we say that $\{U_1, \dots, U_r\}$ is **minimum-span** if $\dim_{\mathbb{F}_q}(\langle U_1^2 \rangle \times \ldots \times \langle U_r^2 \rangle) = 2\sum_{i=1}^{r} k_i$ and we say that it is **maximum-span** if $\dim_{\mathbb{F}_q}(\langle U_1^2 \rangle \times \ldots \times \langle U_r^2 \rangle) = \sum_{i=1}^{r} \binom{k_i+1}{2}$.

A multi-Sidon space $\{U_1, \dots, U_r\}$ of $\mathbb{F}_{q^n}$, with $k_i = \dim_{\mathbb{F}_q}(U_i)$ for any $i \in \{1, \dots, r\}$, is said to be **maximum** if n is even and $k_i = n/2$ for every $i \in \{1, \dots, r\}$.

Denote by $\mathcal{L}_t$ the following set of polynomials

$$\mathcal{L}_t = \left\{ \sum_{i=0}^{t-1} a_i x^{q^i} : a_i \in \mathbb{F}_{q^t} \right\} \subset \mathbb{F}_{q^t}[x].$$

This polynomials are known as **linearized polynomials**, see Wu and Liu (2013) for more details.

We can give a canonical form for a maximum multi-Sidon space, see (Zullo, 2021, Theorem 4.5) and also (Napolitano et al., 2021, Theorem 4.6).

Theorem 4. Let $n = 2t$ and suppose that $\mathcal{U} = \{U_1, \dots, U_r\}$ is a set of $\mathbb{F}_q$-subspaces in $\mathbb{F}_{q^n}$ with dimension t. Then, up to replacing the subspaces of $\mathcal{U}$ by an element of the relative orbit, $\mathcal{U}$ coincides with

$$\{W_{f_1,\eta_1}, \dots, W_{f_r,\eta_r}\},$$

where $f_1(x), \dots, f_r(x) \in \mathcal{L}_t$, $\eta_1, \dots, \eta_r \in \mathbb{F}_{q^n} \setminus \mathbb{F}_{q^t}$ and

$$W_{f_i,\eta_i} = \{x + \eta_i f_i(x) : x \in \mathbb{F}_{q^t}\},$$

for every $i \in \{1, \dots, r\}$. Let $\eta_i = A_{i,j}\eta_j + B_{i,j}$ and $\eta_i^2 = a_i\eta_i + b_i$ with $A_{i,j}, B_{i,j}, a_i, b_i \in \mathbb{F}_{q^t}$ for any $i, j \in \{1, \dots, r\}$. Moreover, $\mathcal{U}$ is a multi-Sidon space if and only if for every $i, j \in \{1, \dots, r\}$ and $\alpha_0, \alpha_1 \in \mathbb{F}_{q^t}$ the following linearized polynomials in $\mathcal{L}_t$

$$F_{i,j}(x) = f_i(\alpha_0 x) + f_i(\alpha_1 A_{j,i} b f_j(x)) + f_i(\alpha_0 B_{j,i} f_j(x))$$
$$-\alpha_1 x - \alpha_0 A_{j,i} f_j(x) - \alpha_1 A_{j,i} a_i f_j(x) - \alpha_1 B_{j,i} f_j(x)$$

have at most q roots over $\mathbb{F}_{q^t}$.

For multiple orbits codes we have the following connection with multi-Sidon spaces, which immediately follows by the definition of the subspace metric.

Proposition 5. Let $n = 2t$ and let $U_1, \dots, U_r$ be $\mathbb{F}_q$-subspaces of dimension t in $\mathbb{F}_{q^n}$ and let

$$C = \bigcup_{i \in \{1,\dots,r\}} C_{U_i} \subseteq \mathcal{G}_q(n,t)$$

be a subspace code. Then C is a cyclic subspace code of size $r\frac{q^n-1}{q-1}$ and minimum distance $2t-2$ if and only if $\{U_1, \dots, U_r\}$ is a multi-Sidon space.

Proof. First suppose that C is a cyclic subspace code of size $r\frac{q^n-1}{q-1}$ and minimum distance $2t-2$. Observe that the size of the orbits of the U_i's is $\frac{q^n-1}{q-1}$ for every i, since the code C has size $r\frac{q^n-1}{q-1}$. The minimum distance of C is $2t-2$ which implies that

$$\dim_{\mathbb{F}_q}(U_i \cap \alpha U_j) \leq 1$$

for every $\alpha \in \mathbb{F}_{q^n}$ and $i, j \in \{1, \dots, r\}$ with $i \neq j$ and for every $\alpha \in \mathbb{F}_{q^n} \setminus \mathbb{F}_q$ if $i = j$, that is $\{U_1, \dots, U_r\}$ is a multi-Sidon space. Conversely, assume that $\{U_1, \dots, U_r\}$ is a multi-Sidon space. By construction, the code C has size $r\frac{q^n-1}{q-1}$ and its minimum distance is less than or equal to $2t-2$. The proof concludes once we note that there exists an element $\alpha \in \mathbb{F}_{q^n} \setminus \mathbb{F}_q$ such that $\dim_{\mathbb{F}_q}(U_i \cap \alpha U_j) = 1$ because of its orbit size.

Combining Theorem 4 and Proposition 5 we obtain the following canonical form for cyclic subspace code whose subspaces have dimension $n/2$, with the description of a condition equivalent to the request of having minimum distance $2k-2$.

Corollary 6. Let $n = 2t$ and let $U_1, \dots, U_r$ be $\mathbb{F}_q$-subspaces of dimension t in $\mathbb{F}_{q^n}$ and let

$$C = \bigcup_{i \in \{1,\dots,r\}} C_{U_i} \subseteq \mathcal{G}_q(n,t)$$

be a subspace code. Then

$$C = \bigcup_{i \in \{1,\dots,r\}} W_{f_i,\eta_i},$$

where $f_1(x), \dots, f_r(x) \in \mathcal{L}_t$, $\eta_1, \dots, \eta_r \in \mathbb{F}_{q^n} \setminus \mathbb{F}_{q^t}$ and

$$W_{f_i,\eta_i} = \{x + \eta_i f_i(x) \colon x \in \mathbb{F}_{q^t}\},$$

for every $i \in \{1, \dots, r\}$. Let $\eta_i = A_{i,j}\eta_j + B_{i,j}$ and $\eta_i^2 = a_i\eta_i + b_i$ with $A_{i,j}, B_{i,j}, a_i, b_i \in \mathbb{F}_{q^t}$ for any $i, j \in \{1, \dots, r\}$. Moreover, C has minimum distance $2t-2$ if and only if for every $i, j \in \{1, \dots, r\}$ and $\alpha_0, \alpha_1 \in \mathbb{F}_{q^t}$ the following linearized polynomials in $\mathcal{L}_t$

$$\begin{aligned} F_{i,j}(x) = f_i(\alpha_0 x) + f_i(\alpha_1 A_{j,i} b f_j(x)) + f_i(\alpha_0 B_{j,i} f_j(x)) \\ -\alpha_1 x - \alpha_0 A_{j,i} f_j(x) - \alpha_1 A_{j,i} a_i f_j(x) - \alpha_1 B_{j,i} f_j(x) \end{aligned}$$

have at most q roots over $\mathbb{F}_{q^t}$.

4. LINEAR SETS AND CYCLIC SUBSPACE CODES

In this section we first give a geometric description of the Sidon property in terms of linear sets. With the aid of Proposition 5 we then translate this description in terms of cyclic subspace codes.

Theorem 7. Let U be a k-dimensional $\mathbb{F}_q$-subspace of $\mathbb{F}_{q^n}$. Then U is a Sidon space if and only if the only points of $L_{U\times U} \subseteq \mathrm{PG}(1, q^n) = \mathrm{PG}(\mathbb{F}_{q^n} \times \mathbb{F}_{q^n}, \mathbb{F}_{q^n})$ of weight greater than one are those in $L_{U\times U} \cap \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$. Furthermore, the weight of such points is k.

In particular, if U is a Sidon space then the size of $L_{U\times U}$ is

$$\frac{q^k-1}{q-1}(q^k - q) + q + 1.$$

Proof. Let $\alpha \in \mathbb{F}_{q^n}^*$. Let $\langle(1,\alpha)\rangle_{\mathbb{F}_{q^n}} \in L_{U\times U}$. Then there exists $\rho \in \mathbb{F}_{q^n}^*$ such that

$$\rho(1,\alpha) \in U \times U,$$

that is $\rho \in U \cap \alpha^{-1}U$. Therefore, if U is a Sidon space by Theorem 1 it follows that $\dim_{\mathbb{F}_q}(U \cap \alpha^{-1}U) \leq 1$ if $\alpha \notin \mathbb{F}_q$ and $\dim_{\mathbb{F}_q}(U \cap \alpha^{-1}U) = k$ if $\alpha \in \mathbb{F}_q$. So $w_{L_{U\times U}}(\langle(1,\alpha)\rangle_{\mathbb{F}_{q^n}}) = 1$ if and only if $\alpha \notin \mathbb{F}_q$ and if $w_{L_{U\times U}}(\langle(1,\alpha)\rangle_{\mathbb{F}_{q^n}}) \geq 2$ then $\alpha \in \mathbb{F}_q$ and $w_{L_{U\times U}}(\langle(1,\alpha)\rangle_{\mathbb{F}_{q^n}}) = k$. Suppose now that the only points of $L_{U\times U} \subseteq \mathrm{PG}(1, q^n)$ of weight greater than one are those in $L_{U\times U} \cap \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$. Then if $\alpha \notin \mathbb{F}_q$ we have $\dim_{\mathbb{F}_q}(U \cap \alpha^{-1}U) \leq 1$ and so by Theorem 1 the subspace U turns out to be a Sidon space. The last part follows by 2 and 3.

The above result can be extended to the case of multi-Sidon spaces.

Theorem 8. Let $\{U_1, \dots, U_r\}$ be a set of $\mathbb{F}_q$-subspaces in $\mathbb{F}_{q^n}$ and let $k_i = \dim_{\mathbb{F}_q}(U_i)$ for every $i \in \{1, \dots, r\}$. Then $\{U_1, \dots, U_r\}$ is a multi-Sidon space if and only if

- the only points of $L_{U_i\times U_i} \subseteq \mathrm{PG}(1, q^n) = \mathrm{PG}(\mathbb{F}_{q^n} \times \mathbb{F}_{q^n}, \mathbb{F}_{q^n})$ of weight greater than one are those in $L_{U_i\times U_i} \cap \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$, for every $i \in \{1, \dots, r\}$;
- $L_{U_i\times U_i} \cap L_{U_j\times U_j} = \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$, for every $i, j \in \{1, \dots, r\}$ with $i \neq j$.

Proof. Let $\alpha \in \mathbb{F}_{q^n}^*$. Let $\langle(1,\alpha)\rangle_{\mathbb{F}_{q^n}} \in L_{U_i\times U_i} \cap L_{U_j\times U_j}$, with $i \neq j$. In particular, there exists $\rho \in \mathbb{F}_{q^n}^*$ such that

$$\rho(1,\alpha) = (u, \overline{u}),$$

for some $u, \overline{u} \in U_i$. Hence, $\alpha = \rho^{-1}\overline{u} = \overline{u}/u$. Similarly, $\alpha = \overline{v}/v$, for some $v, \overline{v} \in U_j$. So that $\alpha \in U_i \cdot U_i^{-1} \cap U_j \cdot U_j^{-1}$. The assertion now follows by (Zullo, 2021, Theorem 3.6) and by Theorem 7.

We can hence derive some bounds that involve the number and the dimensions of the subspaces of a multi-Sidon space, the degree of the field extension and q.

Theorem 9. Let $\{U_1, \dots, U_r\}$ be a multi-Sidon space and let $k_i = \dim_{\mathbb{F}_q}(U_i)$ for every $i \in \{1, \dots, r\}$. Then

$$\sum_{i=1}^{r} \frac{q^{k_i}-1}{q-1}(q^{k_i} - q) \leq q^n - q.$$

In particular, if $\{U_1, \dots, U_r\}$ is a maximum multi-Sidon space then

$$r \leq \frac{(q^n-q)(q-1)}{(q^{n/2}-q)(q^{n/2}-1)}.$$

If $n > 4$ then $r \leq q-1$ and if $n = 4$ then $r \leq q$.

Proof. By Theorem 8, the $L_{U_i \times U_i}$'s pairwise intersect each other only in $\mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$, so that

$$\left| \left(\bigcup_{i=1}^{r} L_{U_i \times U_i} \right) \setminus \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q) \right| = \sum_{i=1}^{r} \frac{q^{k_i} - 1}{q - 1} (q^{k_i} - q).$$

Since $(\bigcup_{i=1}^{r} L_{U_i \times U_i}) \setminus \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q) \subseteq \mathrm{PG}(1, q^n) \setminus \mathrm{PG}(\mathbb{F}_q \times \mathbb{F}_q, \mathbb{F}_q)$, the assertion follows.

Combining Proposition 5 and Theorem 9 we obtain the following bound on the number of orbits that a cyclic subspace codes (whose subspaces have dimension $n/2$) can have.

Corollary 10. Let $n = 2t$ and let $U_1, \ldots, U_r$ be $\mathbb{F}_q$-subspaces of dimension t in $\mathbb{F}_{q^n}$ and let

$$C = \bigcup_{i \in \{1,\ldots,r\}} C_{U_i} \subseteq \mathcal{G}_q(n, t)$$

be a subspace code. If the minimum distance of C is $2t-2$, then $r \leq q - 1$ if $n \geq 4$ and $r \leq q$ if $n = 4$.

We do not know if the above bound is tight but in (Roth et al., 2017, Construction 37) a construction of cyclic subspace codes as in Corollary 10 with r equals to roughly $q/2$ has been shown.

5. CONCLUSION

In this abstract we first give a generalization of the notion of Sidon space with the notion of multi-Sidon space. Then we show a link between multi-Sidon spaces of maximum dimension and cyclic subspace codes with certain parameters, which yields to a canonical form for such codes. Then we propose a geometric interpretation of the Sidon (and the multi-Sidon) property by means of linear sets, which give us an upper bound on the number of subspaces that a cyclic subspace codes associated with a multi-Sidon space can have. However, further combining the algebraic and geometric approaches, more results on cyclic subspace codes can be obtained. For instance, using the canonical form in Theorem 4, more examples of cyclic subspace codes could be shown.

ACKNOWLEDGEMENTS

I would like to thank Oriol Serra, who suggested me to study Sidon spaces during the conference *Discretaly* (2018).

Abstract: This abstract summarizes our recent results on reachability analysis using dissipation inequalities. We first outline a method to outer-approximate forward reachable sets (FRS) on finite horizons for uncertain polynomial systems. This method makes use of time-dependent polynomial storage functions that satisfy appropriate dissipation inequalities that account for $\mathcal{L}_2$ disturbances, uncertain parameters, and perturbations characterized by time-domain, integral quadratic constraints (IQC). By introducing IQCs to reachability analysis, we now allow for various types of uncertainty, including unmodeled dynamics. We next discuss backward reachable sets (BRS), and decompose control synthesis process into two steps: first we construct storage functions whose sublevel sets are used for BRS estimation, and then we compute control laws using these storage functions through quadratic programs (QP). In a separate result we simultaneously compute an under-approximation to the BRS, as well as an explicit control law in order to incorporate input saturation limits. These methods make use of the generalized S-procedure and Sum-of-Squares techniques to derive algorithms with the goal of finding the tightest approximation to the reachable sets.

Keywords: Nonlinear Systems and Control.

1. INTRODUCTION

Reachability analysis is of vital importance for safety-critical systems: it can verify whether a system is able to reach a target and avoid an obstacle. There are two fundamental types of reachable sets (Mitchell, 2007): forward and backward. The forward reachable set (FRS) is the set of all the successors of a given set of initial conditions under the system dynamics. The backward reachable set (BRS) is the set of initial conditions whose successors can be maintained safely inside a given state constraint set using an admissible control. In our works (Yin et al., 2018, 2019a,b), the forward and backward reachability problems are considered with finite horizons, since in many practical settings, systems only undergo finite-time trajectories. We make use of time-dependent storage functions that satisfy certain dissipation inequalities to characterize the FRS and BRS. The use of dissipation inequalities allows us to accommodate various sources of uncertainty, including $\mathcal{L}_2$ disturbances, uncertain parameters and perturbations Δ (e.g. unmodeled dynamics, uncertain time delay, and control saturation), whose input output properties are described by integral quadratic constraints (IQCs) (Megretski and Rantzer, 1997; Veenman et al., 2016). The generalized S-procedure and sum-of-squares (SOS) relaxation for polynomial non-negativity are used to derive computation algorithms for obtaining storage functions.

The work in (Yin et al., 2018) addresses the computation of an outer-approximation to the FRS by merging the dissipation inequality and IQCs. Therefore, although our nominal systems are assumed to be polynomials, including IQCs allows us to extend our analysis framework to non-polynomial systems. We formulate the FRS computation as generalized SOS optimization problems that are quasi-convex, which can be solved effectively by bisection, and for which global optimal solutions can be achieved. The work in (Yin et al., 2019a) studies backward reachability: we compute a storage function that characterizes an inner-approximation to the BRS first, and then we obtain the min-norm control law as the closed-form solution to the quadratic programming (QP) based on the computed storage function. The control law is not restricted to polynomial functions. In (Yin et al., 2019b), the BRS inner-approximation and control law are computed at the same time in order to account for control saturation. In these two works, the derived optimizations are nonconvex due to bilinearity in decision variables. Therefore, algorithms are designed to alternate the search over bilinear variables.

In the existing literature, there are various approaches to reachability analysis, including polytopic methods (Borrelli et al., 2011), Hamilton-Jacobi methods (Mitchell and Tomlin, 2000), ellipsoid methods (Kurzhanskiy and Varaiya, 2007) and interval analysis (Jaulin et al., 2001). Finite horizon forward reachability analysis is also considered in (Majumdar and Tedrake, 2017), but it only allows parametric uncertainty. The BRS is *outer-approximated* in (Henrion and Korda, 2014) by taking the complement of

the initial set from which no trajectory is able to reach the target set for any admissible inputs. The result in (Henrion and Korda, 2014) is complementary to our works (Yin et al., 2019a,b), since we provide inner-approximations to the BRS, as well as an explict control law.

The abstract is organized as follows. In Section 2, the method for forward reachability analysis from (Yin et al., 2018) is described. In Section 3.1, the QP based control synthesis method from (Yin et al., 2019a) is discussed. In Section 3.2, the method from (Yin et al., 2019b) that synthesizes the storage function and control law at the same time is summarized. Section 4 provides the way of formulating SOS problems. Section 5 summarizes the results and gives possible directions for the future work.

2. FORWARD REACHABILITY ANALYSIS

The proposed forward reachability analysis framework considers the following uncertain nonlinear system:

$$\dot{x} = f(t, x, w, l), \tag{1a}$$
$$v = h(t, x, w, l), \tag{1b}$$
$$l = \Delta(v), \tag{1c}$$

with $x \in X \subset \mathbb{R}^n$, $l \in \mathbb{R}^{n_l}$, $w \in \mathbb{R}^{n_w}$, $v \in \mathbb{R}^{n_v}$, where f, h define the nominal system G and the perturbation Δ is an operator $\Delta : \mathcal{L}_2^{n_v}[0,T] \to \mathcal{L}_2^{n_l}[0,T]$. The uncertain system (1), denoted as $F_u(G,\Delta)$, is an interconnection of Δ and G, as shown in Fig. 1.

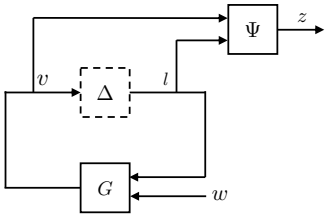

Fig. 1. Interconnection $F_u(G,\Delta)$ of a nominal system G and a perturbation Δ

Assumption 1. (i) the disturbance w has bounded $\mathcal{L}_2$ energy: $\int_0^T w^\top(t)w(t)dt \le R^2$, with R given, and (ii) all the trajectories $x(t)$ of $F_u(G,\Delta)$ start in the set $X_0 \subset X$.

Under this assumption, let $FRS(T; X_0) := \{x(T) \mid x(t) \in X_0\}$ denote the FRS of $F_u(G,\Delta)$. Our goal is to outer-approximate this $FRS(T; X_0)$.

The perturbation Δ is characterized by IQCs. To define an IQC we introduce a virtual Ψ (shown in Fig. 1) that is an LTI system, driven by the input and output of Δ, and with zero initial condition $x_\psi(0) = 0$. The dynamics of Ψ are given by

$$\dot{x}_\psi = A_\psi x_\psi + B_{\psi 1} v + B_{\psi 2} l, \tag{2a}$$
$$z = C_\psi x_\psi + D_{\psi 1} v + D_{\psi 2} l, \tag{2b}$$

where $x_\psi \in \mathbb{R}^{n_\psi}$, and $z \in \mathbb{R}^{n_z}$. A hard IQC is a quadratic constraint enforced on the output z of Ψ associated with a matrix $M \in \mathbb{S}^{n_z}$ over all finite horizons. Δ is said to satisfy the hard IQC defined by (Ψ, M), if for all $v \in \mathcal{L}_2^{n_v}[0,T]$, $l = \Delta(v)$, we have

$$\int_0^t z(\tau)^\top M z(\tau) d\tau \ge 0, \ \forall t \in [0,T]. \tag{3}$$

The notation $\Delta \in \text{HardIQC}(\Psi, M)$ is used to indicate that Δ satisfies the corresponding hard IQC. Therefore, a perturbation can be replaced by a filter Ψ and an IQC (3). The outer-approximation to the FRS of $F_u(G,\Delta)$ is then computed using an extended system, which is an interconnection of G and Ψ with its corresponding IQC (3). Assume M is constrained to a convex set $\mathcal{M}$, which is described by linear matrix inequalities (LMIs). For more details on $\mathcal{M}$, the reader is referred to (Veenman et al., 2016). The following constraints, including dissipation inequality (4a), provide the analysis conditions for $F_u(G,\Delta)$ with $\Delta \in$ IQC(Ψ, M):

$$\partial_t V + \partial_x V \cdot f(t,x,w,l) + \partial_{x_\psi} V \cdot (A_\psi x_\psi + B_{\psi 1} v + B_{\psi 2} l) + z^\top M z \le w^\top w, \quad \forall (t, x, x_\psi, l, w) \in [0,T] \times X \times \mathbb{R}^{n_\psi} \times \mathbb{R}^{n_l} \times \mathbb{R}^{n_w}, \tag{4a}$$
$$X_0 \subseteq \{x : V(0,x,0) \le 0\}, \tag{4b}$$
$$\{x : V(t,x,x_\psi) \le R^2\} \subseteq X, \forall (t, x_\psi) \in [0,T] \times \mathbb{R}^{n_\psi}, \tag{4c}$$
$$M \in \mathcal{M}, \tag{4d}$$

where $V(t,x,x_\psi)$ and M are decision variables, while (G,Ψ) and (T,R,X,X_0) are fixed. The set X is the region, over which the dissipation inequality holds. If constraints (4) hold, then $\{(x,x_\psi) : V(T,x,x_\psi) \le R^2\}$ outer-approximates the FRS of the extended system (G,Ψ) at the terminal time T from the initial set $X_0 \times 0$. Finally the projection of $\{(x,x_\psi) : V(T,x,x_\psi) \le R^2\}$ on the x space outer-approximates the FRS of $F_u(G,\Delta)$.

3. BACKWARD REACHABILITY ANALYSIS AND SYNTHESIS

The backward reachability analysis and synthesis framework focuses on nonlinear systems of the form

$$\dot{x} = f(t,x) + g(t,x)u + g_w(t,x)w, \tag{5}$$

where the control input $u \in \mathbb{R}^{n_u}$ and the external disturbance $w \in \mathbb{R}^{n_w}$ enter the system affinely. Assume that we are given a target set $X_T \subset \mathbb{R}^n$ for the system (5) to reach at the terminal time T. Assume (i) w has bounded $\mathcal{L}_2$ energy: $\int_0^T w^\top(t)w(t)dt \le R^2$, with R given, (ii) w satisfies an $\mathcal{L}_\infty$ constraint: $w(t) \in W := \{\eta \in \mathbb{R}^{n_w} : \eta^\top \eta \le \alpha\}$, for all $t \in [0,T]$. Let $x(t; x_0, u)$ define the solution to the system (5) at time t, from the initial condition $x(0) = x_0$ under the control u. The BRS is defined as $BRS(T, X_T) := \{\xi \in \mathbb{R}^n : \exists u(\cdot), \text{ s.t. } x(T;\xi,u) \in X_T\}$. The goal is to inner-approximate the BRS, and to find a control law that is able to steer all the trajectories initialized from the inner-approximation to X_T.

3.1 QP based Synthesis

In this section, we describe the method presented in (Yin et al., 2019a), where the computation of BRS estimation and control law is decomposed into two steps. The first step is to compute the storage function that characterizes the BRS inner-approximation, and the second is to solve for the minimum-norm control law using a QP that involves the obtained storage function. The following constraints characterize the storage function to be found in the first step:

$$\partial_t V + \partial_x V \cdot (f(t,x) + g_w(t,x)w) \leq w^\top w, \forall (t,x,w) \text{ s.t.}$$
$$\partial_x V \cdot g(t,x) = 0,\ V(t,x) \leq R^2,\ t \in [0,T],\ w \in W, \quad (6a)$$
$$\{x : V(T,x) \leq R^2\} \subseteq X_T, \quad (6b)$$

where (f,g,g_w,R,T,W,X_T) are fixed, while $V(t,x)$ is the decision variable. (6a) implies that we can always find a u of proper sign and sufficiently large magnitude such that the following dissipation inequality holds

$$\partial_t V + \partial_x V \cdot (f(t,x) + g(t,x)u(t) + g_w(t,x)w) \leq w^\top w,$$
$$\forall (t,x,w) \text{ s.t. } V(t,x) \leq R^2, t \in [0,T], w \in W.$$

Therefore, if (6) holds, then there exists a control $u(\cdot)$, such that $x(T) \in X_T$ for all $x(0) \in \{x : V(0,x) \leq 0\}$, in other words, the set $\{x : V(0,x) \leq 0\}$ is an inner-approximation to the BRS.

After V is obtained, we look for the input $u(t)$ that ensures the satisfaction of the dissipation inequality, with the magnitude of the input been minimized. To achieve it, the min-nrom input $u^\star(t)$ is given as the closed-form solution to the following QP:

$$\min_{u \in \mathbb{R}^{n_u}} u^\top u \quad (7a)$$
$$\text{s.t. } \max_{w \in W} \{\partial_t V + \partial_x V \cdot (f + gu + g_w w) \leq w^\top w\}. \quad (7b)$$

Since (7b) is quadratic in w, we can solve for the worst-case disturbance $w^\star$ using KKT conditions, and obtain $w^\star(t,x) =$

$$\begin{cases} \dfrac{\sqrt{\alpha}}{\sqrt{c(t,x)^\top c(t,x)}} c(t,x), & \text{if } c(t,x)^\top c(t,x) \geq 4\alpha, \\ \dfrac{1}{2} c(t,x), & \text{else,} \end{cases} \quad (8)$$

where $c := (\partial_x V \cdot g_w)^\top$. Substituting (8) back into (7b) yields two QPs corresponding to two cases listed in (8). Solving both QPs using KKT conditions gives the explicit expressions for the min-norm control input

$$u^\star(t,x) = \begin{cases} 0, & \text{if } b(t,x) \leq 0, \\ \dfrac{-b(t,x)}{a(t,x)a(t,x)^\top} a(t,x)^\top & \text{else,} \end{cases}$$

where $a := \partial_x V \cdot g$ and

$$b := \begin{cases} \partial_t V + \partial_x V \cdot f + \sqrt{\alpha c^\top c} - \alpha, & \text{if } c^\top c \geq 4\alpha \\ \partial_t V + \partial_x V \cdot f + c^\top c/4 - \alpha, & \text{else.} \end{cases}$$

An advantage of this method is that given a storage function, explicit control laws with smallest feasible magnitude can be derived, and they are not restricted to polynomials. However, control saturation is not considered in this framework.

3.2 $V - k$ iterative Synthesis

In this section, we summarize the method in (Yin et al., 2019b), where we search for a storage function V and a control law k at the same time so as to take control saturation into account. Let $k : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^{n_u}$ define a memoryless time-varying state feedback control by $u(t) = k(t, x(t))$. Assume the set of control constraints is given as a polytope $U = \{u \in \mathbb{R}^{n_u} : Au \leq h\}$, where $A \in \mathbb{R}^{n_c \times m}$ and $h \in \mathbb{R}^{n_c}$. Now the goal for the controller is to steer system (5) from the BRS inner-approximation to X_T at time T, while satisfying $u(t) \in U$ for all $t \in [0,T]$. Here we provide the sufficient conditions for V to characterize inner-approximations and k to achieve the control objective:

$$\partial_t V + \partial_x V \cdot (f(t,x) + g(t,x)k(t,x) + g_w(t,x)w) \leq w^\top w,$$
$$\forall (t,x,w) \text{ s.t. } V(t,x) \leq R^2, t \in [0,T], w \in W, \quad (9a)$$
$$\{x : V(T,x) \leq R^2\} \subseteq X_T, \quad (9b)$$
$$Ak(t,x) \leq h,\ \forall (t,x) \text{ s.t. } V(t,x) \leq R^2, t \in [0,T], \quad (9c)$$

where $V(t,x)$ and $k(t,x)$ are decision variables. If constraints (9) hold, then for all $x(0) \in \{x : V(0,x) \leq 0\}$, we guarantee $x(T) \in X_T$, under control law k. The main idea behind the constraint (9c) is that while a state $x(t)$ stays in the set $\{x : V(t,x) \leq R^2\}$, the control input derived from $u(t) = k(t, x(t))$ satisfies the control saturation.

4. SUM-OF-SQUARES FORMULATIONS

In general, looking for a generic function V that satisfies (4) or (6), and (V,k) that satisfy (9) could be difficult. Therefore, we use sum-of-squares programming in finding those decision variables. Notice that (4), (6) and (9) are all set-containment constraints, which can be certified by the generalized S-procedure, along with a method to check non-negativity. SOS relaxations can be used in checking non-negativity if all functions are restricted to polynomials. Therefore, we restrict the system model, control law and storage function to be polynomials, and we assume all the sets X_0, X_T, X are sublevel sets of polynomials. Now we are ready to derive SOS optimization problems. Take (9a) for example, if the following conditions hold, then (9a) is satisfied: s_a, s_b, s_c are SOS polynomials, and

$$-(\dot{V} - w^\top w) + (V - R^2)s_a - t(T-t)s_b - (\alpha - w^\top w)s_c$$

is an SOS polynomial, where decision variables s_a, s_b, and s_c are called S-procedure certificate. Checking if a polynomial is an SOS polynomial can be done by solving a corresponding semidefinite programming (Parrilo, 2000). Convex SOS problem can be derived for (4). However, (6) and (9) result in nonconvex SOS problems, due to the bilinearity in V, and (k, s_i). But we can still tackle these nonconvex problems by alternating the search over V and (k, s_i).

5. CONCLUSIONS AND FUTURE WORK

This extended abstract summarizes the works from (Yin et al., 2018, 2019a,b), where dissipation inequality based methods are proposed to approximate the reachable sets and synthesize control laws. In (Yin et al., 2018), the computation of an outer-approximation to the FRS is proposed, where IQCs are incorporated to model a large variety of uncertainties. In (Yin et al., 2019a), a storage function that characterizes an inner-approximation to the BRS is computed first, and a min-norm control law is obtained by solving a QP that involves the computed storage function. Finally, in (Yin et al., 2019b), a BRS inner-approximation and control law are computed simultaneously to consider input saturation limits. In both (Yin et al., 2019a,b), $\mathcal{L}_2$ disturbances and uncertain parameters are considered.

As for future work, we will continue to improve the computational efficiency and scalability of the reachability algorithms that are currently being developed. In addition we will combine these algorithms with data-driven methods

for estimating reachable sets with probabilistic guarantees. We will develop a formal definition of a data-driven reachable set approximation that is correct in a probabilistic sense, and devise appropriate sampling schemes to generate such approximations.

Abstract: We consider adaptive ouput feedback tracking control of linear time-invariant systems which are not necessarily minimum phase. The zero dynamics is split into a stable and an unstable part, we show that a flat output of the unstable part can contribute to the design of a funnel controller of the system. More precisely, we consider an auxiliary output based of the "true output" of the system and the flat output of the unstable part of the zero dynamics. The funnel controller is designed for this auxiliary output, and the consequences for the true output are discussed.

Keywords: linear systems; robust control; non-minimum phase; funnel control; relative degree

1. SYSTEM CLASS

We consider stabilizable linear systems given by

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t), \qquad x(0) = x^0 \in \mathbb{R}^n, \\ y(t) &= Cx(t), \end{aligned} \tag{1}$$

where $A \in \mathbb{R}^{n\times n}$ and $B, C^\top \in \mathbb{R}^{n\times m}$, with the same number of inputs $u : \mathbb{R}_{\geq 0} \to \mathbb{R}^m$ and outputs $y : \mathbb{R}_{\geq 0} \to \mathbb{R}^m$. We assume that (1) has strict relative degree $r \in \mathbb{N}$, that is

$$CA^kB = 0,\ k = 0, \ldots, r-2,\ CA^{r-1}B \in \mathrm{Gl}_n(\mathbb{R}), \tag{2}$$

cf. Isidori (1995). While adaptive control of minimum phase linear systems is well-studied, see e.g. the classical works Byrnes and Willems (1984); Khalil and Saberi (1987); Morse (1983), we stress that we do not assume that (1) is minimum phase or, equivalently, its zero dynamics are asymptotically stable. The latter would mean that $\mathrm{rk}\left[\begin{smallmatrix} A-\lambda I_n & B \\ C & 0 \end{smallmatrix}\right] = n + m$ for all $\lambda \in \mathbb{C}_-$, see e.g. Ilchmann et al. (2007); Isidori (1995). By the Byrnes-Isidori form (Ilchmann et al., 2007, Lem. 3.5) (see also Isidori (1995)) we have that, if (2) is satisfied, there exists a state-space transformation $U \in \mathrm{Gl}_n(\mathbb{R})$ such that $Ux(t) = \big(y(t)^\top, \dot{y}(t)^\top, \ldots, y^{(r-1)}(t)^\top, \eta(t)^\top\big)^\top$, where $\eta : \mathbb{R}_{\geq 0} \to \mathbb{R}^{n-rm}$, transforms (1) into

$$\begin{aligned} y^{(r)}(t) &= \sum_{i=1}^{r} R_i y^{(i-1)}(t) + S\eta(t) + \Gamma u(t), \\ \dot{\eta}(t) &= Py(t) + Q\eta(t) + d_\eta(t), \end{aligned} \tag{3}$$

where $R_i \in \mathbb{R}^{m\times m}$ for $i = 1, \ldots, r$, $S, P^\top \in \mathbb{R}^{m\times(n-rm)}$, $Q \in \mathbb{R}^{(n-rm)\times(n-rm)}$, and $\Gamma := CA^{r-1}B$. Furthermore, (1) is minimum phase if, and only if, $\sigma(Q) \subseteq \mathbb{C}_-$. The second equation in (3) represents the internal dynamics of the linear system (1); if $y = 0$, then these dynamics are called zero dynamics.

Our assumption is that the system does not have any zeros on the imaginary axis. Consequently, there exists $T \in \mathrm{Gl}_{n-rm}(\mathbb{R})$ and $\ell \in \mathbb{N}$ such that

$$TQT^{-1} = \begin{bmatrix} \hat{Q}_1 & \hat{Q}_2 \\ 0 & \tilde{Q} \end{bmatrix}, \quad TP = \begin{bmatrix} \hat{P} \\ \tilde{P} \end{bmatrix}, \tag{4}$$

where $\hat{Q}_1 \in \mathbb{R}^{(n-rm-\ell)\times(n-rm-\ell)}$, $\hat{Q}_2 \in \mathbb{R}^{(n-rm-\ell)\times\ell}$, $\tilde{Q} \in \mathbb{R}^{\ell\times\ell}$, $\hat{P} \in \mathbb{R}^{(n-rm-\ell)\times m}$. $\tilde{P} \in \mathbb{R}^{\ell\times m}$ with $\sigma(\hat{Q}_1) \subseteq \mathbb{C}_-$, and $(\tilde{Q}, \tilde{P})$ is controllable.

2. CONTROL OBJECTIVE

To treat the non-minimum phase property of system (1) the system parameters A, B, C need to be known, at least partially, and additional components of the state x need to be available to the controller. For the time being, assume that the measurement of a partial state $\hat{x}(t) = Hx(t)$ is available, where H will be specified by the presented controller design. We stress that the measurement of the full state $x(\cdot)$ or knowledge of the full initial value x^0 is, in general, not required. Therefore, the objective is to design a dynamic partial state feedback of the form

$$\begin{aligned} \dot{z}(t) &= F\big(t, z(t), \hat{x}(t), y_{\mathrm{ref}}(t)\big), \quad z(0) = z^0, \\ u(t) &= G\big(t, z(t), \hat{x}(t), y_{\mathrm{ref}}(t)\big), \end{aligned} \tag{5}$$

where $y_{\mathrm{ref}} : \mathbb{R}_{\geq 0} \to \mathbb{R}^m$ is a sufficiently smooth reference signal, such that in the closed-loop system the tracking error $e(t) = y(t) - y_{\mathrm{ref}}(t)$ evolves within a prescribed performance funnel

$$\mathcal{F}_\varphi := \{\ (t, e) \in \mathbb{R}_{\geq 0} \times \mathbb{R}^m \ \mid \varphi(t)\|e\| < 1\ \}, \tag{6}$$

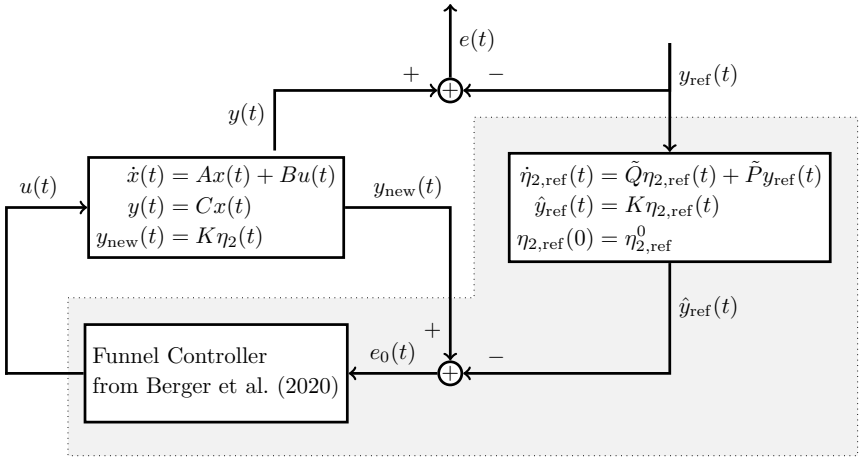

Fig. 1. The funnel controller, indicated by the grey box, applied to system (1) with new output as in (8). The controller consists of the generator of the new reference signal (9) and the funnel controller developed in Berger et al. (2020).

which is determined by a positive function $\varphi \in \mathcal{C}^r(\mathbb{R}_{\geq 0} \to \mathbb{R})$ with bounded $\varphi, \dot{\varphi}, \ldots, \varphi^{(r)}$, and $\liminf_{\tau\to\infty} \varphi(\tau) > 0$.

Furthermore, all signals x, u, z should remain bounded, even though (1) is non-minimum phase.

The funnel boundary is given by the reciprocal of φ as depicted in Fig. 2. Each performance funnel with φ as

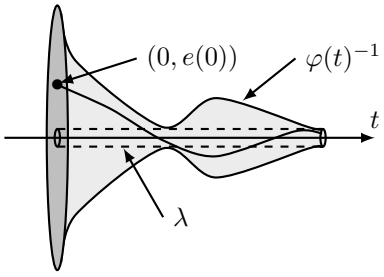

Fig. 2. Error evolution in a funnel with boundary $\varphi(t)^{-1}$.

above is bounded away from zero.

3. THE CONTROLLER

With the decomposition of Q as in (4) we may further transform the system from (3) using $T\eta = (\eta_1^\top, \eta_2^\top)^\top$ with $\eta_1 : \mathbb{R}_{\geq 0} \to \mathbb{R}^{n-rm-\ell}$, $\eta_2 : \mathbb{R}_{\geq 0} \to \mathbb{R}^\ell$ into

$$\begin{aligned} y^{(r)}(t) &= \sum_{i=1}^{r} R_i y^{(i-1)}(t) + S_1\eta_1(t) + S_2\eta_2(t) + \Gamma u(t), \\ \dot{\eta}_1(t) &= \hat{Q}_1\eta_1(t) + \hat{Q}_2\eta_2(t) + \hat{P}y(t), \\ \dot{\eta}_2(t) &= \tilde{Q}\eta_2(t) + \tilde{P}y(t), \end{aligned} \tag{7}$$

where $[S_1, S_2] = ST^{-1}$. Since $(\tilde{Q}, \tilde{P})$ is controllable, it is possible to construct an artificial output

$$y_{\text{new}}(t) := K\eta_2(t), \tag{8}$$

which is flat in the sense of Fliess et al. (1995). It can be shown that such an output can be chosen in a way that the system with input u and output y_{new} has a well-defined vector relative degree in the sense of Berger et al. (2020); Mueller (2009). This enables to apply the funnel controller from Berger et al. (2020) for systems with vector relative degree. By the construction of the new output in (8), the new reference signal is generated by the corresponding subsystem of (7) when the original reference signal is inserted for the original output, i.e.,

$$\begin{aligned} \dot{\eta}_{2,\text{ref}}(t) &= \tilde{Q}\eta_{2,\text{ref}}(t) + \tilde{P}y_{\text{ref}}(t), \quad \eta_{2,\text{ref}}(0) = \eta^0_{2,\text{ref}}, \\ \hat{y}_{\text{ref}}(t) &= K\eta_{2,\text{ref}}(t). \end{aligned} \tag{9}$$

The overall controller structure is depicted in Fig. 1.

We show that this controller results in a global and bounded solution, and we will discuss the performance of the output $y(\cdot)$ and its distance to the reference trajectory y_{ref}.

Abstract: We present a stochastic optimal control problem for a serial network. The dynamics of the network are governed by transport equations with a special emphasis on the nonlinear damping function. The demand profile at the network sink is modeled by a stochastic differential equation. An explicit optimal inflow into the network is determined and numerical simulations are presented to show the effects for different choices of the nonlinear damping.

Keywords: Optimal stochastic control, uncertain demands, transport equations, nonlinear damping
AMS Classification: 93E20, 65C20, 60H10

1. INTRODUCTION

Energy networks or supply networks in a more general setting can be analyzed from different perspectives. Mathematically, there is a strong interest to describe the dynamics inside the network to better understand the underlying physical or economic processes. Typical applications range from electric transmission lines Göttlich et al. (2015) and gas networks Banda et al. (2006) to production systems D'Apice et al. (2010), wherein the dynamics is governed by nonlinear hyperbolic transport equations Bressan et al. (2014). Generally, nonlinearities might appear due to complex flow patterns or additional interaction terms such as resistance or friction. For many applications the question arises how such a network can be controlled to satisfy consumer demands. Since demands usually include a kind of uncertainty, this leads to a challenging stochastic optimal control problem. To reduce the complexity of the problem, we therefore start with the consideration of linearized dynamics and nonlinear damping combined with stochasticity of demands in an abstract setting.

This work is based on ideas originally presented in Göttlich and Schillinger (2021); Göttlich et al. (2019). Basically, we consider a network framework consisting of three ingredients. At the network source an optimal inflow shall be injected into the system such that a given demand is met. On every arc of the network transport equations of hyperbolic type describe the dynamics. In our case we focus on linear flux functions and add unlike Göttlich and Schillinger (2021) a nonlinear damping term. However, we are still able to compute an explicit representation of the optimal input. As a last component, we consider uncertain demands at the sinks of the network. These are described by a stochastic process, given by a stochastic differential equation. In this work, we assume that demands are described by Jacobi processes, as recently proposed by Coskun and Korn (2021). These are mean-reverting processes which stay in a bounded interval and are therefore very suitable for various applications we have in mind. The goal of this contribution is to show under which assumptions we will be able to explicitly derive the optimal inflow subject to the network dynamics and the stochastic demand.

The organization of the article is the following. In Section 2 we present the full optimal control framework. The discussion of the objective function and the availability of information is executed in Section 3. The key result is presented in Section 4, where we extensively describe how an explicit formula for the optimal inflow can be calculated in the setting of nonlinear damping terms. Section 5 concludes with a numerical study of different nonlinear damping functions.

2. THE OPTIMAL CONTROL PROBLEM

We consider the control problem in (1), where we aim to determine the optimal input $u(t)$ given some stochastic demand D_t and the network dynamics in terms of scalar transport equations. More precisely, we make use of the following notation: For a directed serial network, the set C denotes the demand node and J the set of the inner nodes. We control the network inflow $u(t)$ defined in (1d) and solve an optimization problem for the demand node. At the demand node we consider a demand process $(D_t)_{t\in[t_0,T]}$ for which we assume a Jacobi process. A main advantage of the Jacobi process apart from the mean-reverting behaviour is its boundedness such that negative or arbitrarily large demands cannot be attained. It can be described by a stochastic differential equation given in (1f)-(1g), where θ is a time-dependent mean reversion level, κ the mean reversion speed and σ the scaling of the stochastic disturbances coming from a Brownian motion $(W_t)_{t\in[t_0,T]}$. In this work, we only consider Jacobi processes on $[0,1]$, which can be easily translated on any bounded interval.

$$\min_{\substack{u\in L^2\\ i:v_i\in C}} \int_{t_0}^{T} \mathbb{E}\left[\left(D_s - f^{(i)}(z^{(i)}(1,s),s)\right)^2 \;\middle|\; \mathcal{F}_{\hat{t}}\right] ds \quad \text{(1a)}$$

$$\text{s.t. } z_t^{(i)}(x,t) + f^{(i)}(z^{(i)}(x,t),t)_x + g^{(i)}(z^{(i)}(x,t),t) = 0 \tag{1b}$$

$$z^{(i)}(x,t_0) = z_0^{(i)}(x), \quad \forall i \text{ s.t. } v_i \in J \cup C \tag{1c}$$

$$f^{(1)}(z^{(1)}(0,t),t) = u(t) \tag{1d}$$

$$f^{(i+1)}(z^{(i+1)}(0,t),t) = f^{(i)}(z^{(i)}(1,t),t) \quad \forall i \in J \tag{1e}$$

$$dD_t = \kappa\left(\theta(t) - D_t\right) + \sigma\sqrt{D_t\left(1-D_t\right)}dW_t \tag{1f}$$

$$D_0 = d_0. \tag{1g}$$

We aim to minimize the expected quadratic deviation between the demand process and the outflow of the network with respect to a filtration $(\mathcal{F}_t, t \geq 0)$, see (1a). In the objective function, we condition on a time $\hat{t} \leq t_0$ up to which demand information is available. Section 3 presents further strategies about demand updates. On the network arcs i we consider hyperbolic partial differential equations for the quantities $z^{(i)}$ in (1b), where the flux functions $f^{(i)}$ are linear with respect to $z^{(i)}$ and possibly nonlinear in time, accompanied with some initial data (1c). In comparison to the work in Göttlich and Schillinger (2021), the damping functions $g^{(i)}$ are allowed the be nonlinear in the quantities $z^{(i)}$. The choices of the damping functions will be discussed in Section 4. At each inner node due to the serial network structure, there is exactly one ingoing and one outgoing arc at which we ensure flux conservation (1e).

3. SOLUTION TO THE OBJECTIVE FUNCTION AND DEMAND UPDATES

The optimal control problem in (1) has a stochastic component given by the stochastic differential equation (SDE) for the demand process (1f). But when minimizing the expected quadratic deviation of demand and network supply the optimal solution for a square integrable demand process is given by $\mathbb{E}[D_t|\mathcal{F}_{\hat{t}}]$ (see Corollary 8.17 in Klenke (2020)). Therefore, the particular structure of the demand process, apart from the first two conditional moments, does not matter to solve the optimal control problem. Their explicit forms in case of the Jacobi process can e.g. be found in Delbaen and Shirakawa (2002). As a next step, we want to generalize the control problem a little further. So far, we have assumed that there is one time $\hat{t} \leq t_0$ at which the demand levels are updated. However, we now consider a sequence of update times $(\hat{t}_j)_{j\in\mathbb{N}}$ which allow for additional information about the demands. Then, we end up with a sequence of optimal control problems on time intervals $[\hat{t}_j, \hat{t}_{j+1})$. To account for the correct time intervals, the objective function from (1a) then reads

$$\min_{\substack{u\in L^2 \\ i:v_i\in C}} \int_{\tilde{t}(v_i,\hat{t}_j)}^{\tilde{t}(v_i,\hat{t}_{j+1})} \mathbb{E}\Bigg[\Bigg(D_s - f^{(i)}(z^{(i)}(1,s),s)\Bigg)^2 \;\Big|\; \mathcal{F}_{\hat{t}_j}\Bigg] ds,$$

where $\tilde{t}(v_i,t)$ denotes the time at which the inflow inserted at the source node at time t reaches the demand node v_i. Additionally, for all updates except the first one, the initial data has to correspond to the state of the system of the time interval before. Therefore, the equations (1c) and (1g) read

$$z^{(i)}(x,\hat{t}_j) = z_{\text{old}}^{(i)}(x,\hat{t}_j), \quad \forall i \text{ s.t. } v_i \in J \cup C$$
$$D_{\hat{t}_j} = D_{\hat{t}_j}^{\text{old}},$$

where $z_{\text{old}}^{(i)}(x,\hat{t}_j)$ and $D_{\hat{t}_j}^{\text{old}}$ denote the final quantity of arc i at position x and the final demand at node v_i in the previous time interval, respectively.

4. NETWORK DYNAMICS WITH NONLINEAR DAMPING

In this section, we focus on the dynamics in the network on all arcs i given by constraint (1b) of the optimal control problem, i.e. the shape of the functions $f^{(i)}$ and $g^{(i)}$ governed by

$$z_t^{(i)}(x,t) + f^{(i)}(z^{(i)}(x,t),t)_x + g^{(i)}(z^{(i)}(x,t),t) = 0, \tag{2}$$

where $f^{(i)}$ denotes the flux function and $g^{(i)}$ is the damping function. Here, we restrict to functions $f^{(i)}$ that are linear in $z^{(i)}$ but nonlinear in the time and potentially nonlinear functions $g^{(i)}$ in $z^{(i)}$ and t. The damping reflects a loss in the transported quantity over time, which may be due to some physical property as for instance friction or electrical resistance. The linearity of the flux-functions will play a very important role because characteristic curves do not cross and hence no discontinuities may appear, see LeVeque (2002) for an overview. For simplicity, all investigations are executed in the 1-1-network case and can be generalized to arbitrary serial networks in a straightforward way.

We restrict to nonlinear damping functions in which the nonlinearities of time and quantity are separated, i.e.

$$g^{(i)}(z,t) = \mu_i(t)\hat{g}_i(z), \tag{3}$$

where $\mu_i \in L^1([t_0,T])$ is chosen to be a non-negative function and $\hat{g}_i$ is a Lipschitz-continuous function whose antiderivative is explicitly known. Additionally, we assume $\hat{g}_i \geq 0$ and $\hat{g}_i = 0$ only on a Lebesgue null-set. This allows for the natural choice of $\hat{g}_i(0) = 0$, but still preserves some important properties we will exploit. The flux function on arc i is chosen as $f^{(i)}(z,t) = \lambda_i(t)z$ with strictly positive velocity $\lambda_i(\cdot)$.

Next, we calculate the optimal inflow for a 1-1 network. Denote by $\mu_i(t)$ a time-dependent damping factor for arc i and $\hat{g}_i(z) = \frac{1}{\bar{g}_i(z)}$ the nonlinear damping function for arc i such that the overall damping term is given by $g_i(z,t) = \frac{\mu_i(t)}{\bar{g}_i(z)}$. We make use of the network from Figure 1, where we have one source node v_0, an inner intersection v_1 and a demand node v_2.

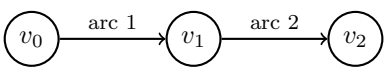

Fig. 1. The supply system as a 1-1-network with one source v_0 and one demand node v_2.

To relate the injection time at the source node v_0 and the output time at the demand node v_2 we consider a characteristic curve $(x(t),t)$ of a unit for which t_2 is the time in which the unit injected at t_{in} reaches the demand node v_2 and t_1 the time when it reaches node v_1. If the velocity functions λ_i have an antiderivative $\Lambda_i, i = 1,2$

which is invertible, for some injection time t_{in} the values of t_1 and t_2 are explicitly given by

$$\begin{aligned} t_1 &= \Lambda_1^{-1}(1+\Lambda_1(t_{\text{in}})) \\ t_2 &= \Lambda_2^{-1}(1+\Lambda_2(\Lambda_1^{-1}(1+\Lambda_1(t_{\text{in}})))), \end{aligned} \tag{4}$$

where we for simplicity assume that every arc has length 1 (see Göttlich and Schillinger (2021)).

Staying on such a characteristic curve, in a setting without damping, the transported quantity $z(x(t),t)$ remains constant. If we introduce the damping term, the quantity z is reduced by the damping. This can be formulated by the following ordinary differential equation (ODE)

$$\frac{d}{dt} z^{(i)}(x(t),t) = -g_i(z^{(i)}(x(t),t),t) = -\frac{\mu_i(t)}{\tilde{g}_i(z^{(i)}(x(t),t))}. \tag{5}$$

This ODE can be uniquely solved due the Lipschitz-continuity of $\tilde{g}$. The technique of separation of variables even allows for the calculation of an explicit solution. To do so, we assume that an antiderivative of $\tilde{g}_i$ is explicitly given by $\tilde{G}_i$ and we consider time points $t_{k-1} < t_k$. Integrating (5) both sides of the equation over t_{k-1} to t_k and applying the fundamental theorem of calculus leads to

$$\begin{aligned} &\int_{t_{k-1}}^{t_k} \frac{d}{ds}\left(z^{(i)}(x(s),s)\right) \cdot \tilde{g}_i(z^{(i)}(x(s),s))ds \\ &= -\int_{t_{k-1}}^{t_k} \mu_i(s)ds \;\Leftrightarrow\; z^{(i)}(x(t_{k-1}),t_{k-1}) \\ &= \tilde{G}_i^{-1}\left(\tilde{G}_i\left(z^{(i)}(x(t_k),t_k)\right) + \int_{t_{k-1}}^{t_k} \mu_i(s)ds\right). \end{aligned}$$

The antiderivative of $\tilde{g}_i$ is continuous and strictly increasing because $\tilde{g}_i$ is strictly positive, apart from a Lebesgue null-set. Then, there exists the inverse function $(\tilde{G}_i)^{-1}$ of $\tilde{G}_i$ and the solution is well-defined. The integral of the damping function stays bounded since $\mu_i \in L^1([t_0,T])$. Note that we are going to perform a backward calculation for the optimal inflow under the assumption that we know the corresponding optimal outflow of the network. Therefore, we consider an end value problem here, this means we have upstream information at time t_k and calculate the corresponding initial values at time t_{k-1}. We start this procedure at demand node v_2.

$$z^{(2)}(1,t_2) = \frac{f^{(2)}(z^{(2)}(1,t_2),t_2)}{\lambda_2(t_2)} \tag{6}$$

Following the characteristic curve and using the result of the ODE solution we can calculate the resulting quantity at the beginning of arc 2 at time t_1 by

$$z^{(2)}(0,t_1) = \tilde{G}_2^{-1}\left(\tilde{G}_2\left(z^{(2)}(1,t_2)\right) + \int_{t_1}^{t_2} \mu_2(s)ds\right).$$

Using this and (6), we can calculate the ingoing flux into arc 2 at time t_1 by

$$\begin{aligned} &f^{(2)}(z^{(2)}(0,t_1),t_1) = \lambda_2(t_1) z^{(2)}(0,t_1) \\ &= \lambda_2(t_1)\tilde{G}_2^{-1}\left(\tilde{G}_2\left(\frac{f^{(2)}(z^{(2)}(1,t_2),t_2)}{\lambda_2(t_2)}\right) + \int_{t_1}^{t_2} \mu_2(s)ds\right). \end{aligned}$$

Accounting for flux conservation at the intersection it must hold that

$$f^{(2)}(z^{(2)}(0,t_1),t_1) = f^{(1)}(z^{(1)}(1,t_1),t_1).$$

Then, we can deduce the corresponding quantity at the end of arc 1 by

$$\begin{aligned} z^{(1)}(1,t_1) = \frac{\lambda_2(t_1)}{\lambda_1(t_1)} \cdot \tilde{G}_2^{-1}\Bigg(&\tilde{G}_2\left(\frac{f^{(2)}(z^{(2)}(1,t_2),t_2)}{\lambda_2(t_2)}\right) \\ &+ \int_{t_1}^{t_2} \mu_2(s)ds\Bigg). \end{aligned}$$

Now again applying the ODE solution on arc 1 we get for the initial quantity

$$\begin{aligned} &z^{(1)}(0,t_{\text{in}}) \\ &= \tilde{G}_1^{-1}\Bigg(\tilde{G}_1\left[\frac{\lambda_2(t_1)}{\lambda_1(t_1)} \cdot \tilde{G}_2^{-1}\Bigg(\tilde{G}_2\left(\frac{f^{(2)}(z^{(2)}(1,t_2),t_2)}{\lambda_2(t_2)}\right) \\ &\quad + \int_{t_1}^{t_2} \mu_2(s)ds\Bigg)\right] + \int_{t_{\text{in}}}^{t_1} \mu_1(s)ds\Bigg). \end{aligned}$$

The ingoing flux into the 1-1 network is now a direct consequence of the quantity at the beginning of arc 1 and given by

$$\begin{aligned} &f^{(1)}(z^{(1)}(0,t_{\text{in}}),t_{\text{in}}) \\ &= \lambda_1(t_{\text{in}})\tilde{G}_1^{-1}\Bigg(\tilde{G}_1\left[\frac{\lambda_2(t_1)}{\lambda_1(t_1)}\tilde{G}_2^{-1}\Big(\tilde{G}_2\left(\frac{f^{(2)}(z^{(2)}(1,t_2),t_2)}{\lambda_2(t_2)}\right) \\ &\quad + \int_{t_1}^{t_2} \mu_2(s)ds\Big)\right] + \int_{t_{\text{in}}}^{t_1} \mu_1(s)ds\Bigg). \end{aligned}$$

Since the optimal outflow of the network should match the corresponding conditional expected demand we obtain for the optimal inflow

$$\begin{aligned} &u(t_{\text{in}}) \\ &= \lambda_1(t_{\text{in}}) \cdot \tilde{G}_1^{-1}\Bigg(\tilde{G}_1\left[\frac{\lambda_2(t_1)}{\lambda_1(t_1)} \cdot \tilde{G}_2^{-1}\Bigg(\tilde{G}_2\left(\frac{\mathbb{E}\left[D_{t_2}|\mathcal{F}_{\hat{t}}\right]}{\lambda_2(t_2)}\right) \\ &\quad + \int_{t_1}^{t_2} \mu_2(s)ds\Bigg)\right] + \int_{t_{\text{in}}}^{t_1} \mu_1(s)ds\Bigg), \end{aligned}$$

where $\hat{t} < t_{\text{in}}$ is the time of the latest demand update. Iteratively, this procedure can be extended to larger 1-1 networks.

5. NUMERICAL EXPERIMENTS

Finally, we numerically compare the solutions to (1) for different nonlinear damping functions $\hat{g}_i(z)$. Classical choices for such nonlinear damping functions are monomials (Ikeda et al. (2017)), i.e. functions of the type

$$\hat{g}^{(n)}(z) = C_n z^n,$$

where C_n is a constant depending on the degree which has to be determined. By construction it holds that $\hat{g}^{(n)}(0) = 0$. For better illustration purposes, we choose the same damping functions on both arcs. To be able to compare the damping functions we request that

$$\int_0^{\frac{1}{10}} \hat{g}^{(n)}(z)dz = \frac{1}{20}, \quad n \in \mathbb{N}$$

and choose the constant C_n accordingly. For our analysis we compare monomials up to order 4, which are given by

$$\begin{aligned} &\hat{g}^{(1)}(z) = z, \quad \hat{g}^{(2)}(z) = 15z^2, \\ &\hat{g}^{(3)}(z) = 200z^3, \quad \hat{g}^{(4)}(z) = 2500z^4. \end{aligned} \tag{7}$$

Additionally we consider scenarios without any damping, i.e $\mu_i(t) = 0$. Note that also different approaches for $\hat{g}$ can

be used, but since monomials give a good impression on the different scaling we do not extend the study at that point.

For the demand process we choose a Jacobi process with $\theta(t) = 0.45 + 0.2\sin(\pi t + 1)$, $\kappa = 2$, $\sigma = 0.9$ and initial demand of $D_0 = 0.4$.

A truncated Euler-Maruyama scheme is used for the simulation of the Jacobi process. We consider a time grid $(t_j)_{j\in\mathbb{N}}$ with temporal stepsize $\Delta t = \frac{1}{1000}$, i.e.

$$D^*_{j+1} = D_j + \Delta t\kappa(\theta(t_j) - D_j) + \sigma\sqrt{\Delta t D_j(1-D_j)}X_j,$$

where X_j is a realization of a standard normal distributed random variable. To numerically avoid values outside the interval $[0,1]$ for D_{j+1} due to the unboundedness of X_j, we add a truncation into the Euler-Maruyama scheme such that the process D^*_{j+1} is reflected into $[0,1]$:

$$D_{j+1} = \begin{cases} 1, & D^*_{j+1} \geq 1 \\ D^*_{j+1}, & D^*_{j+1} \in (0,1) \\ 0, & D^*_{j+1} \leq 0. \end{cases}$$

The time horizon is chosen to $T = 2.5$ and we consider an update strategy at the source node with 7 equidistant updates. The flux functions on the arcs are all linear with respect to the quantity $z^{(i)}$ and have the time-dependent factor $\lambda_i(t) = 14 + \sin(2\pi t)$. The temporal factor of the damping in (3) is chosen to be $\mu_i(t) = 5 + \sin(\pi t)$, where $\hat{g}$ are the monomials from (7).

For the discretization of (2) we use an adaptive upwind-scheme with spatial stepsize $\Delta x = \frac{1}{200}$ on a grid $(x_l)_{l\in\mathbb{N}}$. The damping is incorporated by a splitting algorithm which first performs the step from the upwind-scheme and then applies the damping in a second step. The temporal step sizes are chosen such that the CFL-condition (LeVeque (2002)) is satisfied with equality in every time step, i.e. $\frac{\Delta t_j^{(i)}}{\Delta x}\lambda_i(t_j^{(i)}) = 1$. Therefore, the temporal grids depend on the velocity functions of the particular arc:

$$\tilde{z}_l^{(i),j+1} = z_l^{(i),j} + \frac{\Delta t_j^{(i)}}{\Delta x}\lambda_l(t_j^{(i)})\left(z_l^{(i),j} - z_{l-1}^{(i),j}\right).$$

In a second step we take into account the damping and calculate $z_l^{(i),j+1}$ by

$$z_l^{(i),j+1} = \tilde{z}_l^{(i),j+1} - \Delta t_j^{(i)} g_i\left(\tilde{z}_l^{(i),j+1}, t_{j+1}^{(i)}\right).$$

In Figure 2 we present results for a 1-1 network and show the inflows for five different types of damping (from no damping to a quartic damping monomial in (7)) in the upper part as well as the outflow and demand at the demand node in the lower part. Note that the supplies and demands do not differ significantly among the different damping settings. The shape of the curves is mainly influenced by the temporal nonlinearities in the flux functions and the sinusoidal rhythm of the demand mean reversion levels. First, we observe that in a setting without damping the inflow is always below the inflows of the damped setting. As a second observation, we see that the inflows for the monomials are ordered differently depending on the amount of the inflow and the corresponding quantities. For larger quantities the inflows for the second and third order monomial damping function are higher, whereas for lower inflows the inflows resulting from linear damping have the highest values. In the outflow plot we observe that the supply adjust overall to the shape of demand, where the jumps in supply result from demand updates.

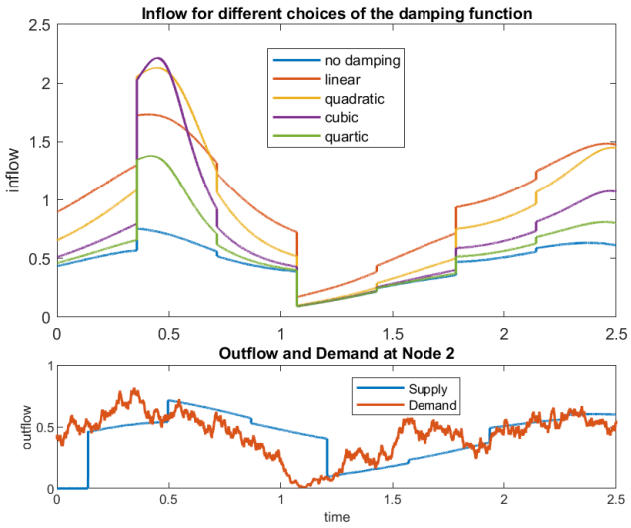

Fig. 2. Comparison of different inflows for different choices of the damping function and the corresponding supply and demand for one realization.

Keywords: Discounted Optimal Control, Dissipativity, Turnpike

1. INTRODUCTION

Recent results in the literature have provided connections between the turnpike property, near optimality of closed-loop solutions, and strict dissipativity. In this talk, based on the recent paper Grüne and Krügel (2021) (to which we refer for all proofs), we consider optimal control problems with discounted stage cost. In contrast to non-discounted optimal control problems, it is more likely that several asymptotically stable optimal equilibria coexist. Due to the discounting and transition cost from a local to the global equilibrium, it may be more favourable staying in a local equilibrium than moving to the global "cheaper" equilibrium. In this talk, we propose a local notion of discounted strict dissipativity and a local turnpike property, both depending on the discount factor. Using these concepts, we investigate the local behaviour of (near-)optimal trajectories and develop conditions on the discount factor to ensure convergence to a local asymptotically stable optimal equilibrium.

2. SETTING

We consider discrete time nonlinear systems of the form

$$x(k+1) = f(x(k), u(k)), \quad x(0) = x_0 \tag{1}$$

for a map $f : X \times U \to X$, where X and U are normed spaces. We impose the constraints $(x, u) \in \mathbb{Y} \subset X \times U$ on the state x and the input u and define $\mathbb{X} := \{x \in X \mid \exists u \in U : (x, u) \in \mathbb{Y}\}$ and $\mathbb{U} := \{u \in U \mid \exists x \in X : (x, u) \in \mathbb{Y}\}$. A control sequence $u \in \mathbb{U}^N$ is called admissible for $x_0 \in \mathbb{X}$ if $(x(k, x_0), u(k)) \in \mathbb{Y}$ for $k = 0, \dots, N-1$ and $x(N) \in \mathbb{X}$. In this case, the corresponding trajectory $x(k)$ is also called admissible. The set of admissible control sequences is denoted by $\mathbb{U}^N(x_0)$. Likewise, we define $\mathbb{U}^\infty(x_0)$ as the set of all control sequences $u \in \mathbb{U}^\infty$ with $(x(k, x_0), u(k)) \in \mathbb{Y}$ for all $k \in \mathbb{N}_0$. Furthermore, we assume that $\mathbb{X}$ is controlled invariant, i.e. that $\mathbb{U}^\infty(x_0) \neq \emptyset$ for all $x_0 \in \mathbb{X}$. The trajectories of (1) are denoted by $x_u(k, x_0)$ or simply by $x(k)$ if there is no ambiguity about x_0 and u.

We will make use of comparison-functions defined by

$$\mathcal{K} := \{\alpha : \mathbb{R}_0^+ \to \mathbb{R}_0^+ | \alpha \text{ is continuous and strictly increasing with } \alpha(0) = 0\}$$
$$\mathcal{K}_\infty := \{\alpha : \mathbb{R}_0^+ \to \mathbb{R}_0^+ | \alpha \in \mathcal{K}, \alpha \text{ is unbounded}\}$$

⋆ The authors are supported by DFG Grant Gr 1569/13-2.

Moreover, with $\mathcal{B}_\varepsilon(x_0)$ we denote the open ball with radius $\varepsilon > 0$ around x_0.

In this talk we consider infinite horizon discounted optimal control problems, i.e. problems of the type

$$\min_{u \in \mathbb{U}^\infty(x_0)} J_\infty(x_0, u) \quad \text{with } J_\infty(x_0, u) = \sum_{k=0}^{\infty} \beta^k \ell(x(k, x_0), u(k)). \tag{2}$$

Herein, the number $\beta \in (0, 1)$ is called the discount factor. The optimal value function of the problem is defined by

$$V_\infty(x_0) := \min_{u \in \mathbb{U}^\infty(x_0)} J_\infty(x_0, u).$$

3. GLOBAL TURNPIKE

The central structural assumption on this optimal control problem is a strict dissipativity condition. Here we first introduce a global version, which will later be relaxed to a local assumption:

We say that the system (1) is discounted strictly dissipative at an equilibrium (x^β, u^β) if there exists a storage function $\lambda : \mathbb{X} \to \mathbb{R}$ bounded from below with $\lambda(x^\beta) = 0$ and a class $\mathcal{K}_\infty$-function α such that the inequality

$$\ell(x, u) - \ell(x^\beta, u^\beta) + \lambda(x) - \beta\lambda(f(x, u)) \geq \alpha(\|x - x^\beta\|) \tag{3}$$

holds for all $(x, u) \in \mathbb{Y}$ with $f(x, u) \in \mathbb{X}$. We remark that this discounted version of discrete-time strict dissipativity was studied in Grüne et al. (2021), based on the original undiscounted definitions from Byrnes and Lin (1994) and Willems (1972).

For a strictly dissipative problem we can define the modified or rotated stage cost

$$\widetilde{\ell}(x, u) = \ell(x, u) - \ell(x^\beta, u^\beta) + \lambda(x) - \beta\lambda(f(x, u)). \tag{4}$$

It was shown in Grüne et al. (2021) that the optimal trajectories of the optimal control problems with stage cost ℓ and $\widetilde{\ell}$ coincide if the storage function λ is bounded.

With a combination of arguments from Gaitsgory et al. (2018), one can prove that if the optimal value function $\widetilde{V}_\infty$ of the modified problem satisfies

$$\widetilde{V}_\infty(x) \leq \alpha_V(\|x - x^\beta\|) \quad \text{and} \quad \widetilde{V}_\infty(x) \leq C \inf_{u \in \mathbb{U}} \tilde{\ell}(x, u) \tag{5}$$

for all $x \in \mathbb{X}$, a function $\alpha_V \in \mathcal{K}_\infty$, and a constant $C \geq 1$ exist satisfying

$$C < 1/(1-\beta). \tag{6}$$

Then the optimal control problem has the following turnpike property, cf. (Grüne et al., 2017, Definition 4.2):

For each $\varepsilon > 0$ and each bounded set $\mathbb{X}_b \subset \mathbb{X}$ there exists a constant $P > 0$ such that for each $M \in \mathbb{N}$ there is a $\delta > 0$, such that for all $x_0 \in \mathbb{X}_b$ and $u \in \mathbb{U}^\infty(x_0)$ with $J_\infty(x_0, u) \leq V_\infty(x_0) + \delta$, the set $\mathcal{Q}(x_0, u, \varepsilon, M, \beta) := \{k \in \{0, \dots, M\} \mid \|x_u(k, x_0) - x^\beta\| \geq \varepsilon\}$ has at most P elements.

Figure 1 gives an illustration of the set $\mathcal{Q}(x_0, u, \varepsilon, M, \beta)$ from this definition.

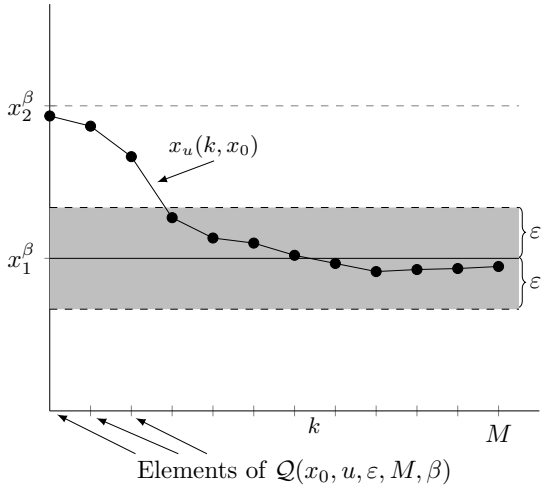

Fig. 1. Illustration of the set $\mathcal{Q}(x_0, u, \varepsilon, M, \beta)$

4. LOCAL TURNPIKE

In discounted optimal control, several optimal equilibria (x_l^β, u_l^β) with different optimal values $\ell(x_l^\beta, u_l^\beta)$ can coexist, even if the system is completely controllable. This is because the transition cost for passing from an equilibrium to a region in the state space with lower cost may dominate the benefit from reaching this "cheaper" region, because the discounting reduces the relative weight of this benefit. This means that local turnpike properties may emerge, in which the solutions only approach a certain equilibrium x_l^β if the initial value is close to this equilibrium, and show a different long time behavior otherwise. The closer the discount rate is to 1, the less weight is put on the transition cost, hence the less likely a local turnpike behavior becomes if the equilibrium is not globally strictly dissipative. Hence, a local turnpike property is more likely to occur for discount rates $\beta \ll 1$ than for discount rates $\beta \approx 1$. On the other hand, the conditions (5) and (6) will also be needed for a local turnpike property and thus provide a lower bound on the possible discount rates. Hence, we can expect that there is an interval of discount rates for which a local turnpike property occurs.

In order to formalize this intuitive description, we first introduce a local strict dissipativity property:

Given a discount factor $\beta \in (0,1)$, we say that the system (1) is locally discounted strictly dissipative at an equilibrium (x_l^β, u_l^β) if there exists a storage function $\lambda : \mathbb{X} \to \mathbb{R}$ bounded from below with $\lambda(x_l^\beta) = 0$ and a class $\mathcal{K}_\infty$-function α_β such that the inequality

$$\ell(x,u) - \ell(x_l^\beta, u_l^\beta) + \lambda(x) - \beta\lambda(f(x,u)) \geq \alpha_\beta(\|x - x_l^\beta\|) \tag{7}$$

holds for all $(x,u) \in \mathbb{X}_\mathcal{N} \times \mathbb{U}$ with $f(x,u) \in \mathbb{X}$.

Further, we say that system (1) is locally discounted strictly (x,u)-dissipative at the equilibrium (x_l^β, u_l^β) with supply rate $s : \mathbb{X} \times \mathbb{U} \to \mathbb{R}$ if the same holds with the inequality

$$\begin{aligned} &\ell(x,u) - \ell(x_l^\beta, u_l^\beta) \\ &+\lambda(x) - \beta\lambda(f(x,u)) \geq \alpha_\beta(\|(x - x_l^\beta\| + \|u - u_l^\beta)\|). \end{aligned} \tag{8}$$

The main theorem we are going to present in this talk is now the following. For a proof see (Grüne and Krügel, 2021, Theorem 6.1).

Theorem 1. Consider a discounted optimal control problem (2) subject to system (1) with f continuous and stage cost ℓ bounded from below. Assume local strict (x,u)-dissipativity at an equilibrium (x_l^β, u_l^β) according to (8) with bounded storage function λ. Assume furthermore that there is an interval $(\beta_1, \beta^\star)$ of discount rates, such that for each $\beta \in (\beta_1, \beta^\star)$ the inequalities (5) and (6) hold for all $x \in \mathbb{X}_\mathcal{N}$ with x_l^β in place of x^β.

Then there is $\beta_2 \in (0,1)$, depending on the problem data, such that for all $\beta \in (\beta_1, \beta_2)$ there exists a neighbourhood $\mathcal{N}$ of x_l^β on which the system exhibits a local turnpike property in the following sense:

For each $\varepsilon > 0$ there exist a constant $P > 0$ such that for each $M \in \mathbb{N}$ there is a $\delta > 0$, such that for all $x_0 \in \mathcal{N}$ and all $u \in \mathbb{U}^\infty(x_0)$ with $J_\infty(x_0, u) \leq V_\infty(x_0) + \delta$, the set $\mathcal{Q}(x, u, \varepsilon, M, \beta) := \{k \in \{0, \dots, M\} \mid \|x_u(k, x_0) - x_l^\beta\| \geq \varepsilon\}$ has at most P elements.

Particularly, if $J_\infty(x_0, u) = V_\infty(x_0)$, i.e., if the trajectory is optimal, then for each $\varepsilon > 0$ the set $\mathcal{Q}(x, u, \varepsilon, \infty, \beta) := \bigcup_{M \in \mathbb{N}} \mathcal{Q}(x, u, \varepsilon, M, \beta)$ has at most P elements, implying the convergence $x_u(k, x_0) \to x_l^\beta$ as $k \to \infty$.

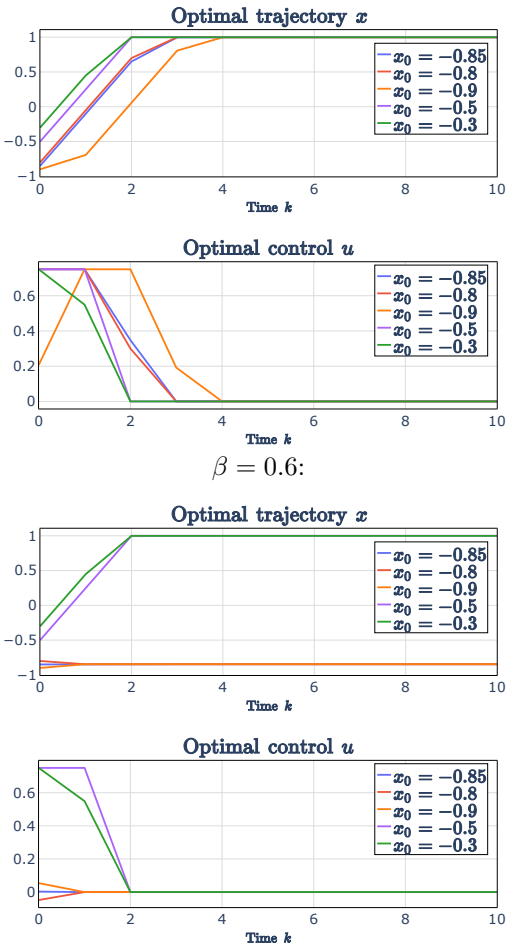
We note that the fact that β_2 depends on the problem data is important for this theorem to yield a meaningful statement, because otherwise the assertion is always trivially true for any $\beta_2 < \beta_1$ since then the interval (β_1, β_2) is empty. We will explain in the talk that β_2 depends on the the cost to leave the neighborhood $\mathbb{X}_\mathcal{N}$ and the minimum of $\widetilde{\ell}$ over $\mathbb{Y}$. The larger these two values become, the larger β_2 becomes.

5. ILLUSTRATIVE EXAMPLE

For illustrating our results, consider the one-dimensional dynamics $f(x,u) = x + u$ and the stage cost $\ell(x,u) = x^4 - \frac{1}{4}x^3 - \frac{7}{4}x^2$. It turns out that the resulting optimal control problem has two optimal equilibria in $x_l^\beta = \frac{3-\sqrt{905}}{32} \approx -0.846$ and $x_g^\beta = \frac{3+\sqrt{905}}{32} \approx 1.034$, where $\ell(x_g^\beta) < \ell(x_l^\beta)$. Note that the equilibria do not depend on β in this example, while in general they may do so. Both optimal equilibria are strictly dissipative, x_l^β only locally and x_g^β also globally. Using the construction in the proof of (Grüne and Krügel, 2021, Theorem 6.1), one computes that $\beta_2 \approx 0.67$. Hence one would expect that a local turnpike property is visible for β below this value and

ceases to exist for β above this value. The numerical simulations of optimal trajectories in Figure 5 show that this is precisely what happens. The figure shows optimal trajectories and control functions with initial values x_0 between -1 and -0.3 and $\beta = 0.7$ and $\beta = 0.6$. While for $\beta = 0.7$ all solutions converge to the globally optimal equilibrium x_g^β, for $\beta = 0.6$ solutions with x_0 sufficiently close to x_l^β converge to x_l^β. Hence, this illustrates the existence of the local turnpike property.

$\beta = 0.7$:



$\beta = 0.6$:

Fig. 2. Optimal trajectories and control functions for $\beta = 0.7$ (above) and $\beta = 0.6$ (below) for different initial values x_0

Abstract: Solving high-dimensional optimal control problems and their corresponding Hamilton-Jacobi partial differential equations is an important but challenging problem. In particular, handling optimal control problems with state-dependent running costs or constraints on the control presents an additional challenge. We present two representation formulas: one is a Hopf-type representation formula for solving a class of optimal control problems with certain non-smooth state-dependent running costs, and the other is a Lax-Oleinik-type representation formula for solving a class of optimal control problems with certain control constraints. Based on these formulas, we propose efficient algorithms that overcome the curse of dimensionality. As such, our proposed methods have the potential to serve as a building block for solving more complicated high-dimensional optimal control problems in real-time.

Keywords: Optimal Control, Hamilton-Jacobi Partial Differential Equations, Grid-Free Numerical Methods, High Dimensions

1. INTRODUCTION

It is well-studied that solving optimal control problems is related to solving Hamilton-Jacobi partial differential equations (HJ PDEs). However, the computational complexity of standard grid-based numerical algorithms for solving HJ PDEs scales exponentially with respect to the dimension. This exponential scaling in dimension is often referred to as the "curse of dimensionality" (CoD) [Bellman (1961)]. Due to the CoD, these grid-based methods are infeasible for solving high-dimensional problems (e.g., dimensions greater than five) and thus are infeasible for many practical optimal control applications, which often have dimension much greater than five.

To overcome the CoD, many grid-free methods approximate the original optimal control problem by some simpler, more easily computable optimal control problems. Thus, an important research direction is to enlarge the class of optimal control problems with easily computable solutions; these problems and their corresponding exact solvers can then serve as building blocks for solving more complicated optimal control problems. Some well-known techniques for solving optimal control problems that often serve as these building blocks include: the linear-quadratic regulator [Li and Todorov (2004); Sideris and Bobrow (2005); McEneaney (2006); Coupechoux et al. (2019)], the Hopf and Lax-Oleinik representation formulas [Darbon (2015); Darbon and Meng (2020); Darbon and Osher (2016); Yegorov and Dower (2017)], and the max-plus (or min-plus) technique [Akian et al. (2006, 2008); Dower et al. (2015); Fleming and McEneaney (2000); Gaubert et al. (2011); McEneaney (2006, 2007); McEneaney et al. (2008); McEneaney and Kluberg (2009)]. However, there are still many more classes of optimal control problems that cannot be solved (exactly) using these techniques. For example, optimal control problems with state-dependent running costs or constraints on the control are, in general, difficult to solve without approximations.

In this extended abstract, we summarize our recent works [Chen et al. (2021a,b)], which provide analytical solutions to two classes of high-dimensional optimal control problems. The first class involves certain state-dependent non-smooth running costs and is summarized in Section 2. The second class involves certain state-dependent running costs and control constraints and is summarized in Section 3. For both classes of problems, we also provide efficient numerical solvers that do not rely on approximations of the corresponding optimal control problem and HJ PDE and are numerically shown to overcome the CoD.

2. THE FIRST CLASS OF OPTIMAL CONTROL PROBLEMS

We consider the following high-dimensional optimal control problem with state-dependent non-smooth running cost:

$$V(\boldsymbol{x},t)=\inf\left\{\int_0^t\left(\frac{1}{2}\|\dot{\boldsymbol{x}}(s)\|^2-U(\boldsymbol{x}(s))\right)ds+\Phi(\boldsymbol{x}(0))\colon \boldsymbol{x}(t)=\boldsymbol{x}\right\}, \tag{1}$$

where $\|\cdot\|$ denotes the ℓ^2-norm, $\boldsymbol{x}\in\mathbb{R}^n$ and $t>0$ are the terminal position and time horizon, respectively, the initial cost $\Phi\colon\mathbb{R}^n\to\mathbb{R}$ is a convex function, and the function $U\colon\mathbb{R}^n\to(-\infty,0]$ satisfies $U(\boldsymbol{x})=\sum_{i=1}^n U_i(x_i)$ for any $\boldsymbol{x}=(x_1,\dots,x_n)\in\mathbb{R}^n$, where each function $U_i\colon\mathbb{R}\to(-\infty,0]$ is the 1-homogeneous concave function defined by

$$U_i(x)=\begin{cases}-a_i x & x\geq 0,\\ b_i x & x<0,\end{cases}$$

with positive constants a_i and b_i. In the remainder of this abstract, we use bold characters to denote high-dimensional vectors in $\mathbb{R}^n$, and we use x_i to denote the i-th component of a high-dimensional vector $\boldsymbol{x}\in\mathbb{R}^n$. The corresponding HJ PDE reads:

$$\begin{cases}\dfrac{\partial V}{\partial t}(\boldsymbol{x},t)+\dfrac{1}{2}\|\nabla_{\boldsymbol{x}}V(\boldsymbol{x},t)\|^2+U(\boldsymbol{x})=0 & \boldsymbol{x}\in\mathbb{R}^n, t\in(0,+\infty),\\ V(\boldsymbol{x},0)=\Phi(\boldsymbol{x}) & \boldsymbol{x}\in\mathbb{R}^n,\end{cases} \tag{2}$$

where the initial condition Φ and the potential energy U are the corresponding functions in (1).

In Chen et al. (2021a), we show that under some assumptions, the viscosity solution $V\colon\mathbb{R}^n\times\mathbb{R}\to\mathbb{R}$ is defined by the following Hopf-type formula:

$$V(\boldsymbol{x},t):=\sup_{\boldsymbol{p}\in\mathbb{R}^n}\left\{\sum_{i=1}^n V(x_i,t;p_i,a_i,b_i)-\Phi^*(\boldsymbol{p})\right\}, \tag{3}$$

for any $\boldsymbol{x}\in\mathbb{R}^n$, $t\geq 0$, where the function $(x_i,t)\mapsto V(x_i,t;p_i,a_i,b_i)$ on the right-hand side is a continuously differentiable function defined explicitly in Chen et al. (2021a). Moreover, for a positive time horizon $t>0$, the function value $V(\boldsymbol{x},t)$ defined in (3) is finite, and the maximizer in (3) exists and is unique. We denote the unique maximizer by $\boldsymbol{p}^*=(p_1^*,\dots,p_n^*)\in\mathbb{R}^n$. The optimal trajectory $[0,t]\ni s\mapsto\boldsymbol{\gamma}(s;\boldsymbol{x},t)\in\mathbb{R}^n$ of the optimal control problem (1) is then given by

$$\boldsymbol{\gamma}(s;\boldsymbol{x},t):=\left(\gamma(s;x_1,t,p_1^*,a_1,b_1),\dots,\gamma(s;x_n,t,p_n^*,a_n,b_n)\right), \tag{4}$$

for any $s\in[0,t]$, where the i-th element $\gamma(s;x_i,t,p_i^*,a_i,b_i)$ on the right-hand side is a one-dimensional function whose explicit formula is given in Chen et al. (2021a). Note that the components of $\boldsymbol{\gamma}(s;\boldsymbol{x},t)$ are independent from each other, and hence, they can be computed in parallel as long as $\boldsymbol{p}^*$ is known.

Now, we will present efficient algorithms for solving the optimal control problem (1) and the corresponding HJ PDEs (2). All of the numerical examples for this class of problems were run on an 8th Gen Intel Laptop Core i5-8250U with a 1.60GHz processor. First, consider the quadratic initial condition, i.e., set

$$\Phi(\boldsymbol{x})=\frac{1}{2\lambda}\|\boldsymbol{x}-\boldsymbol{y}\|^2+\alpha\quad\forall\boldsymbol{x}\in\mathbb{R}^n,$$

where $\boldsymbol{y}\in\mathbb{R}^n$, $\lambda>0$, and $\alpha\in\mathbb{R}$ are some known parameters. The i-th component of the maximizer $\boldsymbol{p}^*$ in (3) is the proximal point of $p\mapsto-\frac{1}{\lambda}V(x_i,t;p,a_i,b_i)$ at $-\frac{y_i}{\lambda}$, which can be efficiently computed using the algorithm proposed in Chen et al. (2021a). Then, the solution to the optimal control problem (1) and the corresponding HJ PDE (2) can be computed using (4) and (3), respectively. In Chen et al. (2021a), we see that it takes less than 2×10^{-6} seconds on average to compute the solution at one point in a 16-dimensional problem with quadratic initial condition $\Phi(\boldsymbol{x})=\frac{1}{2}\|\boldsymbol{x}-\mathbf{1}\|^2$, which demonstrates the efficiency of our proposed solver in high dimensions.

Next, consider more general convex initial conditions. Note that (3) can be written as a convex optimization problem and thus can be solved using many proximal point based optimization algorithms. For illustration, we present an ADMM scheme (see Glowinski (2014); Boyd et al. (2011)), whose k-th step contains the updates of $\boldsymbol{v}^{k+1}$, $\boldsymbol{d}^{k+1}$, and $\boldsymbol{w}^{k+1}$. First, we update $\boldsymbol{v}^{k+1}\in\mathbb{R}^n$ by

$$\boldsymbol{v}^{k+1}=\operatorname*{arg\,min}_{\boldsymbol{v}\in\mathbb{R}^n}\left\{\Phi^*(\boldsymbol{v})+\frac{\lambda}{2}\left\|\boldsymbol{v}-\boldsymbol{d}^k+\boldsymbol{w}^k\right\|^2\right\},$$

which can be efficiently computed if there exists an efficient numerical algorithm for computing the proximal point of Φ or Φ^*. Then, we update $\boldsymbol{d}^{k+1}\in\mathbb{R}^n$, where the i-th element d_i^{k+1} is computed by

$$d_i^{k+1}=\operatorname*{arg\,min}_{d_i\in\mathbb{R}}\left\{-V(x_i,t;d_i,a_i,b_i)+\frac{\lambda}{2}(v_i^{k+1}-d_i+w_i^k)^2\right\}. \tag{5}$$

Note that (5) is a one-dimensional convex optimization problem whose objective function has an explicit formula. Therefore, the minimizer d_i^{k+1} can be efficiently computed using the algorithm proposed in Chen et al. (2021a). The last step is to update $\boldsymbol{w}^{k+1}\in\mathbb{R}^n$ by

$$\boldsymbol{w}^{k+1}=\boldsymbol{w}^k+\boldsymbol{v}^{k+1}-\boldsymbol{d}^{k+1}. \tag{6}$$

We set the stopping criteria to be

$$\max\{\|\boldsymbol{v}^{N-1}-\boldsymbol{v}^N\|^2,\|\boldsymbol{d}^{N-1}-\boldsymbol{d}^N\|^2,\|\boldsymbol{v}^N-\boldsymbol{d}^N\|^2\}\leq\epsilon. \tag{7}$$

After N steps when the stopping criteria (7) is met, we set the maximizer of (3) to be $\boldsymbol{p}^N=\boldsymbol{v}^N$, and then output the optimal trajectory by

$$\hat{\boldsymbol{\gamma}}(s;\boldsymbol{x},t)=(\gamma(s;x_1,t,p_1^N,a_1,b_1),\dots,\gamma(s;x_n,t,p_n^N,a_n,b_n)), \tag{8}$$

where the i-th component $\gamma(s;x_i,t,p_i^N,a_i,b_i)$ is defined in Chen et al. (2021a). The numerical solution to the HJ PDE at $(\boldsymbol{x},t)$ is given by

$$\hat{V}(\boldsymbol{x},t)=\sum_{i=1}^n V\left(x_i,t;p_i^N,a_i,b_i\right)-\Phi^*\left(\boldsymbol{p}^N\right), \tag{9}$$

where the i-th component $V\left(x_i,t;p_i^N,a_i,b_i\right)$ in the summation is defined in Chen et al. (2021a). In Chen et al. (2021a), we present several numerical examples that demonstrate the efficiency of our proposed algorithm.

For instance, consider the initial condition given by

$$\Phi(\boldsymbol{x})=\frac{1}{2}\|\boldsymbol{x}-\mathbf{1}\|_1^2, \tag{10}$$

where $\|\cdot\|_1$ denotes the ℓ^1-norm and $\mathbf{1}$ denotes the vector in $\mathbb{R}^n$ whose elements are all one. Then, the average time per call of our algorithm to evaluate the solution of the HJ PDE (2) is summarized below for various dimensions n.

n	4	8	12	16
running time (s)	2.1192e-05	9.4819e-05	2.0531e-04	3.2751e-04

Specifically, we see that our algorithm takes less than 4×10^{-4} seconds on average to compute the solution at one point in 16 dimensions, which demonstrates its efficiency even in high dimensions.

3. THE SECOND CLASS OF OPTIMAL CONTROL PROBLEMS

We consider the following high-dimensional optimal control problem with state-dependent running cost and control constraints:

$$V(\boldsymbol{x},t) = \min\left\{ \int_0^t \frac{\|\boldsymbol{x}(s)\|^2}{2} ds + \Phi(\boldsymbol{x}(0)) \colon \boldsymbol{x}(t) = \boldsymbol{x}, \right. \\ \left. \dot{\boldsymbol{x}}(s) \in \prod_{i=1}^n [-b_i, a_i] \ \forall s \in (0,t) \right\}, \tag{11}$$

where $\boldsymbol{x}$ and t are the terminal position and time horizon, respectively, $\{a_i\}$ and $\{b_i\}$ are positive scalars which provide restrictions on the control (velocity) $\dot{\boldsymbol{x}}$, and the initial cost $\Phi\colon \mathbb{R}^n \to \mathbb{R}$ is a lower semi-continuous function. The corresponding HJ PDE reads:

$$\begin{cases} \dfrac{\partial V}{\partial t}(\boldsymbol{x},t) + \displaystyle\sum_{i=1}^n K_i\left(\frac{\partial V(\boldsymbol{x},t)}{\partial x_i}\right) - \frac{1}{2}\|\boldsymbol{x}\|^2 = 0 & \boldsymbol{x}\in\mathbb{R}^n, t\in(0,+\infty), \\ V(\boldsymbol{x},0) = \Phi(\boldsymbol{x}) & \boldsymbol{x}\in\mathbb{R}^n, \end{cases} \tag{12}$$

where each function $K_i\colon \mathbb{R}\to\mathbb{R}$ is the 1-homogeneous convex function defined by

$$K_i(x) = \begin{cases} a_i x & x \ge 0, \\ -b_i x & x < 0, \end{cases}$$

and the initial condition is given by the initial cost Φ in (11).

In Chen et al. (2021b), we show that under some assumptions, the viscosity solution $V\colon \mathbb{R}^n\times\mathbb{R}\to\mathbb{R}$ is defined by the following Lax-Oleinik-type representation formula:

$$V(\boldsymbol{x},t) := \inf_{\boldsymbol{u}\in\prod_{i=1}^n [x_i - a_i t, x_i + b_i t]} \left\{ \sum_{i=1}^n V(x_i,t;u_i,a_i,b_i) + \Phi(\boldsymbol{u}) \right\}, \tag{13}$$

for all $\boldsymbol{x}\in\mathbb{R}^n, t\ge 0$, where each function $(x_i,t)\mapsto V(x_i,t;u_i,a_i,b_i)$ on the right-hand side is a continuous function defined explicitly in Chen et al. (2021b).

Let $\boldsymbol{u}^* = (u_1^*,\dots,u_n^*)\in\mathbb{R}^n$ be a minimizer in (13). Note that the minimizer $\boldsymbol{u}^*$ exists since the objective function in the minimization problem in (13) is a lower semi-continuous function with compact domain $\prod_{i=1}^n[x_i - a_i t, x_i + b_i t]$ (see (Rockafellar and Wets, 1998, Theorem 1.9)). However, the minimizer may be not unique. When there are multiple minimizers, let $\boldsymbol{u}^*$ be one such minimizer. Define the trajectory $[0,t]\ni s\mapsto \boldsymbol{\gamma}(s;\boldsymbol{x},t)$ using $\boldsymbol{u}^*$ as

$$\boldsymbol{\gamma}(s;\boldsymbol{x},t) := (\gamma(s;x_1,t,u_1^*,a_1,b_1),\dots,\gamma(s;x_n,t,u_n^*,a_n,b_n)), \tag{14}$$

where the i-th component $\gamma(s;x_i,t,u_i^*,a_i,b_i)$ on the right-hand side is defined explicitly in Chen et al. (2021b). Note that the components of $\boldsymbol{\gamma}(s;\boldsymbol{x},t)$ are independent from each other, and hence, they can be computed in parallel as long as $\boldsymbol{u}^*$ is known.

It is shown in (Chen et al., 2021b, Lemma 3) that the function $u_i\mapsto V(x_i,t;u_i,a_i,b_i)$ is strictly convex and twice continuously differentiable in its domain. Hence, if the initial cost Φ is convex, then (13) is a convex optimization problem that can be numerically solved using convex optimization algorithms. Furthermore, if Φ is quadratic, i.e., Φ is of the form

$$\Phi(\boldsymbol{x}) = \frac{\lambda}{2}\|\boldsymbol{x}-\boldsymbol{y}\|^2 + \alpha \quad \forall \boldsymbol{x}\in\mathbb{R}^n, \tag{15}$$

for some parameters $\boldsymbol{y}\in\mathbb{R}^n$, $\lambda>0$, and $\alpha\in\mathbb{R}$, then solving the corresponding optimization problem (13) is equivalent to computing the proximal point of the function $\boldsymbol{u}\mapsto \frac{1}{\lambda}\sum_{i=1}^n V(x_i,t;u_i,a_i,b_i)$; this problem can be split into n one-dimensional subproblems, which, in turn, can be solved in parallel and for which explicit formulas were provided in Chen et al. (2021b). In Chen et al. (2021b), we see that when $\lambda=1, \boldsymbol{y}=\boldsymbol{1}$, and $\alpha=0$, this proximal point can be computed on an 11th Gen Intel Laptop Core i7-1165G7 with a 2.80GHz processor in less than 8×10^{-7} seconds on average at one point in 16 dimensions.

Next, we present an efficient algorithm for solving (13) with general convex initial costs Φ. As noted above, in this case, (13) is a convex optimization problem that can be solved using convex optimization algorithms, and the proximal point of the function $\boldsymbol{u}\mapsto\frac{1}{\lambda}\sum_{i=1}^n V(x_i,t;u_i,a_i,b_i)$ can be computed explicitly and in complexity $\Theta(n)$. Thus, proximal point based methods provide a reasonable approach for solving (13). As a demonstration, we show how ADMM (see Glowinski (2014); Boyd et al. (2011)) can be applied to solve (13) in this case. Here, ADMM consists of iterating the following steps:

$$\boldsymbol{v}^{k+1} = \operatorname*{arg\,min}_{\boldsymbol{v}\in\mathbb{R}^n}\left\{\Phi(\boldsymbol{v}) + \frac{\lambda}{2}\left\|\boldsymbol{v}-\boldsymbol{d}^k+\boldsymbol{w}^k\right\|^2\right\},$$

which is the proximal point of the initial condition,

$$d_i^{k+1} = \operatorname*{arg\,min}_{d_i\in\mathbb{R}}\left\{V(x_i,t;d_i,a_i,b_i) + \frac{\lambda}{2}(v_i^{k+1}-d_i+w_i^k)^2\right\},$$

which is the proximal point of the function $u_i\mapsto\frac{1}{\lambda}V(x_i,t;u_i,a_i,b_i)$, and (6), which is a linear update of coefficients. Once the stopping criteria (7) is met, we set the numerical minimizer to be $\boldsymbol{u}^N = \boldsymbol{d}^N$. We then output the optimal trajectory by:

$$\hat{\boldsymbol{\gamma}}(s;\boldsymbol{x},t) = (\gamma(s;x_1,t,u_1^N,a_1,b_1),\dots,\gamma(s;x_n,t,u_n^N,a_n,b_n)),$$

where the i-th component $\gamma(s;x_i,t,u_i^N,a_i,b_i)$ is defined explicitly in Chen et al. (2021b), and the solution to the HJ PDE by:

$$\hat{V}(\boldsymbol{x},t) = \sum_{i=1}^n V\left(x_i,t;u_i^N,a_i,b_i\right) + \Phi\left(\boldsymbol{u}^N\right),$$

where the i-th component $V\left(x_i,t;u_i^N,a_i,b_i\right)$ in the summation is defined explicitly in Chen et al. (2021b). We note that if $\boldsymbol{v}^{k+1}$ can be computed in complexity $\Theta(n)$, then the overall complexity for each ADMM iteration is also $\Theta(n)$. In other words, using a fixed number of iterations, the curse of dimensionality is avoided in this case. In Chen et al. (2021b), we present several numerical examples that demonstrate the efficiency of our proposed algorithm. As before, all numerical examples were run on an 11th Gen Intel Laptop Core i7-1165G7 with a 2.80GHz processor. For instance, when the initial condition is given by (10), the average time per call of our algorithm to evaluate the solution of the HJ PDE (12) is summarized below for various dimensions n.

n	4	8	12	16
running time (s)	4.6206e-06	3.2871e-05	1.8791e-04	1.9571e-04

Specifically, we see that it takes less than 2×10^{-4} seconds on average to compute the solution at one point in 16 dimensions, which demonstrates that our proposed algorithm can overcome the CoD in this example.

Abstract: The aim of this note is to present two specific constructions of flag codes having maximum distance through the action of Singer groups. To this end, we will make use of their transitive action on lines and hyperplanes.

Keywords: Network coding, orbit codes, flag codes, Singer group actions.

1. INTRODUCTION

Random Network Coding is a method for maximize the information rate of an incoherent network which is a directed graph with possibly several senders and receivers. In Koetter and Kschischang (2008) an algebraic framework for such networks is developed by encoding the information in subspaces of a given ambient space $\mathbb{F}_q^n$ over a finite field $\mathbb{F}_q$. In this setting, the set of all subspaces of $\mathbb{F}_q^n$ is turned into a metric space in which two subspaces are closer the greater their intersection. A *constant dimension code* is a set of subspaces of $\mathbb{F}_q^n$ having the same dimension. Since their definition, research works on these codes have proliferated considerably (see for instance Horlemann-Trautmann and Rosenthal (2018) and the references therein). *Flag codes* can be seen as a generalization of constant dimension codes. In this case, the codewords are flags on $\mathbb{F}_q^n$, that is, tuples of nested vector subspaces of prescribed dimensions (Liebhold et al. (2018)). The aim of this note is to explain how we can construct flag codes having maximum distance through the action of Singer groups. Its content is part of the article Navarro-Pérez and Soler-Escrivà (2022), where the reader can find the required proofs. The structure of the note is the following: In the second section we give some preliminaries. In Section 3 we explain how to construct flag codes with maximum distance through the action of a Singer group.

2. PRELIMINARIES

The set of all subspaces of $\mathbb{F}_q^n$ of dimension k is called the *Grassmann variety*, denoted by $\mathcal{G}_q(k,n)$. Given $\mathcal{U},\mathcal{V}\in\mathcal{G}_q(k,n)$, their *subspace distance* is defined as $d_S(\mathcal{U},\mathcal{V}) = \dim(\mathcal{U}+\mathcal{V}) - \dim(\mathcal{U}\cap\mathcal{V}) = 2(k-\dim(\mathcal{U}\cap\mathcal{V}))$. Then, a *constant dimension code* $\mathcal{C}$ is a nonempty subset of $\mathcal{G}_q(k,n)$ and its minimum distance, $d_S(\mathcal{C})$, is the minimum of the distances between distinct pairs of elements of $\mathcal{C}$. The code $\mathcal{C}$ is said to be a *spread code* if it is a spread in the geometrical sense, that is, its elements pairwise intersect trivially and cover the whole space $\mathbb{F}_q^n$. Spreads of dimension k exist if, and only if, k divides n and, in this case, they have cardinality $(q^n-1)/(q^k-1)$.

We put $\mathbb{F}_q^{k\times n}$ for the set of all $k\times n$ matrices with entries in $\mathbb{F}_q$ and $\mathrm{GL}_n(\mathbb{F}_q)$ for the *general linear group* of degree n over $\mathbb{F}_q$, composed by all invertible matrices in $\mathbb{F}_q^{n\times n}$. Given $\mathcal{U}\in\mathcal{G}_q(k,n)$ and a full-rank matrix $U\in\mathbb{F}_q^{k\times n}$ such that $\mathcal{U}=\mathrm{rowsp}(U)$, the operation $\mathcal{U}\cdot A=\mathrm{rowsp}(UA)$ defines a group action of $\mathrm{GL}_n(\mathbb{F}_q)$ on the Grassmann variety, since it is independent from the choice of U (Trautmann et al. (2010)). This way, for a subgroup $\mathbf{H}$ of $\mathrm{GL}_n(\mathbb{F}_q)$, the *orbit code* $\mathrm{O}_{\mathbf{H}}(\mathcal{U})$ is just the constant dimension code arising as the orbit of $\mathcal{U}$ under the action of $\mathbf{H}$. That is, $\mathrm{O}_{\mathbf{H}}(\mathcal{U})=\{\mathcal{U}\cdot A \mid A\in\mathbf{H}\}\subseteq\mathcal{G}_q(k,n)$.

Given integers $0<t_1<\cdots<t_r<n$, a flag $\mathcal{F}=(\mathcal{F}_1,\ldots,\mathcal{F}_r)$ of type $(t_1,\ldots,t_r)$ on $\mathbb{F}_q^n$ is a sequence of nested subspaces of $\mathbb{F}_q^n$, $\mathcal{F}_1\subseteq\cdots\subseteq\mathcal{F}_r$, with $\mathcal{F}_i\in\mathcal{G}_q(t_i,n)$, for all $i=1,\ldots,r$. We say that $\mathcal{F}_i$ is the *i-th subspace* of the flag $\mathcal{F}$ and when the type vector is $(1,2,\ldots,n-1)$ we speak about *full flags*. The subspace distance defined for the Grassmann variety can be naturally extended to flags as follows. Given $\mathcal{F}=(\mathcal{F}_1,\ldots,\mathcal{F}_r)$ and $\mathcal{F}'=(\mathcal{F}'_1,\ldots,\mathcal{F}'_r)$ two flags of type $(t_1,\ldots,t_r)$, their *flag distance* is $d_f(\mathcal{F},\mathcal{F}')=\sum_{i=1}^r d_S(\mathcal{F}_i,\mathcal{F}'_i)$. A *flag code of type* $(t_1,\ldots,t_r)$ is just a nonempty set $\mathcal{C}$ consisting of flags of this type vector and its *minimum distance* is $d_f(\mathcal{C})=\min\{d_f(\mathcal{F},\mathcal{F}')\mid\mathcal{F},\mathcal{F}'\in\mathcal{C},\ \mathcal{F}\neq\mathcal{F}'\}$. For any $i\in\{1,\ldots,r\}$, the *i-projected code* $\mathcal{C}_i$ of $\mathcal{C}$ is defined in Alonso-González et al. (2020) as the constant dimension code $\mathcal{C}_i=\{\mathcal{F}_i\mid(\mathcal{F}_1,\ldots,\mathcal{F}_r)\in\mathcal{C}\}\subseteq\mathcal{G}_q(t_i,n)$. Notice that $d_f(\mathcal{C})\leq 2\left(\sum_{2t_i\leq n}t_i+\sum_{2t_i>n}(n-t_i)\right)$. We say that $\mathcal{C}$ is an *optimum distance flag code* (ODFC) whenever $d_f(\mathcal{C})$ attains this upper bound. It follows that the projected codes of an ODFC are constant dimension codes of maximum distance. However, this is not a sufficient condition in order to obtain ODFC (Alonso-González et al. (2020)).

Clearly, the action of the general linear group on the Grassmann variety can be extended to flags. Given a flag $\mathcal{F}=(\mathcal{F}_1,\ldots,\mathcal{F}_r)$ and a subgroup $\mathbf{H}$ of $\mathrm{GL}(n,q)$, the *orbit flag code* generated by $\mathcal{F}$ under the action of $\mathbf{H}$ is

$$\mathrm{O}_{\mathbf{H}}(\mathcal{F})=\{\mathcal{F}\cdot A\mid A\in\mathbf{H}\}=\{(\mathcal{F}_1\cdot A,\ldots,\mathcal{F}_r\cdot A)\mid A\in\mathbf{H}\}.$$

⋆ The authors received financial support of Ministerio de Ciencia e Innovación (PID2019-108668GB-I00). The first author is supported by Generalitat Valenciana and Fondo Social Europeo (Grant number: ACIF/2018/196).

Putting $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}) = \{A \in \mathbf{H} \mid \mathcal{F}\cdot A = \mathcal{F}\}$ for the stabilizer subgroup of this action, it holds $|\mathrm{O}_{\mathbf{H}}(\mathcal{F})| = \frac{|\mathbf{H}|}{|\mathrm{Stab}_{\mathbf{H}}(\mathcal{F})|}$. Moreover, the minimum distance of the orbit flag code is

$$d_f(\mathrm{O}_{\mathbf{H}}(\mathcal{F})) = \min\{d_f(\mathcal{F}, \mathcal{F}\cdot A) \mid A \in \mathbf{H} \setminus \mathrm{Stab}_{\mathbf{H}}(\mathcal{F})\}$$

and it holds $d_f(\mathrm{O}_{\mathbf{H}}(\mathcal{F})) = 0$ if, and only if, $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}) = \mathbf{H}$. The projected codes of an orbit flag code are orbit (subspace) codes. More precisely, for every $1 \leq i \leq r$, we have $\mathrm{O}_{\mathbf{H}}(\mathcal{F})_i = \mathrm{O}_{\mathbf{H}}(\mathcal{F}_i) \subseteq \mathcal{G}_q(t_i, n)$. Besides, the stabilizer subgroup of $\mathcal{F}$ is closely related to the ones of its subspaces: $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}) = \bigcap_{i=1}^{r} \mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_i)$ (Alonso-González et al. (2021b)).

Remark that, fixed an acting subgroup $\mathbf{H}$ of $\mathrm{GL}_n(\mathbb{F}_q)$, the cardinality of the flag code $\mathrm{O}_{\mathbf{H}}(\mathcal{F})$ and their projected codes are determined by the orders of the corresponding stabilizer subgroups. Since $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}) = \mathrm{Stab}_{\mathrm{GL}_n(\mathbb{F}_q)}(\mathcal{F}) \cap \mathbf{H}$, one way to construct orbit flag codes is to start from a subspace whose stabilizer in $\mathrm{GL}_n(\mathbb{F}_q)$ is known and consider subgroups $\mathbf{H}$ that trivially intersect it. This is the approach of the constructions given in Liebhold et al. (2018). More generally, we can look for subgroups of $\mathrm{GL}_n(\mathbb{F}_q)$ whose action on certain subspaces of $\mathbb{F}_q^n$ is known and try to extend this action to flags in an appropriate manner. This is our strategy, using classical results about the action of Singer groups on lines and hyperplanes (Theorem 1).

3. ORBIT FLAG CODES FROM SINGER GROUPS

The aim of this section is to present two constructions of ODFC. In Subsection 3.1 we construct ODFCs on $\mathbb{F}_q^n$ having a k-spread as a projected code, for k a divisor of n. To do so, we consider flags of type $(1, \ldots, k, n-k, \ldots, n-1)$. Such a construction leads to full flag codes whenever $n = 2k$ or $k = 1$ and $n = 3$. In Subsection 3.2, we build ODFCs of full type vector for the remaining cases. Both constructions are closely related to Singer groups. A *Singer subgroup* of $\mathrm{GL}_n(\mathbb{F}_q)$ is a cyclic subgroup of the largest possible order, which is $q^n - 1$. Singer subgroups form a conjugacy class of $\mathrm{GL}_n(\mathbb{F}_q)$ and act on the Grassmann varieties of lines and hyperplanes as follow:

Theorem 1. (Beth et al., 1999, Th. 6.2) Any Singer cyclic subgroup $\mathbf{S}$ of $\mathrm{GL}_n(\mathbb{F}_q)$ acts transitively on both $\mathcal{G}_q(1, n)$ and $\mathcal{G}_q(n-1, n)$. Moreover, for any $l \in \mathcal{G}_q(1, n)$ and any $h \in \mathcal{G}_q(n-1, n)$, it holds that $\mathrm{Stab}_{\mathbf{S}}(l) = \mathrm{Stab}_{\mathbf{S}}(h) = \{aI_n \mid a \in \mathbb{F}_q^*\}$, which is the unique cyclic subgroup of $\mathbf{S}$ of order $q-1$.

3.1 Orbit ODFC from spreads

Assume that $n = ks$, for $s \geq 2$, and that $\mathcal{C}$ is an ODFC such that dimension k appears in its type vector. Then $|\mathcal{C}| \leq \frac{q^n-1}{q^k-1}$ and the equality holds if, and only if, the projected code $\mathcal{C}_i$ is a k-spread of $\mathbb{F}_q^n$ (Alonso-González et al. (2020)). Moreover, $(1, \ldots, k, n-k, \ldots, n-1)$ is the largest type vector for an ODFC on $\mathbb{F}_q^n$ having a k-spread as one of its projected codes (Alonso-González et al. (2021a)).

Motivated by these results, we consider for our construction an arbitrary flag of the *full admissible type vector* $(1, \ldots, k, n-k, \ldots, n-1)$. For sake of simplicity, we will denote it by $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_k, \mathcal{F}_{n-k}, \ldots, \mathcal{F}_{n-1})$. Then the following result holds:

Theorem 2. (Navarro-Pérez and Soler-Escrivà, 2022, Th. 4.11) Given a subgroup $\mathbf{H}$ of $\mathrm{GL}_n(\mathbb{F}_q)$ and a flag $\mathcal{F}$ of the full admissible type vector, the following sentences are equivalent:

(*i*) $\mathrm{O}_{\mathbf{H}}(\mathcal{F})$ is an ODFC.
(*ii*) $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_k) = \mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_{n-k}) \subseteq \mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_i)$, for every i and the subspace codes $\mathrm{O}_{\mathbf{H}}(\mathcal{F}_k)$ and $\mathrm{O}_{\mathbf{H}}(\mathcal{F}_{n-k})$ are of maximum distance.

Now, the idea is to use Theorem 1 in order to achieve the condition (*ii*) of Theorem 2. To do so, let ω be a primitive element of the field $\mathbb{F}_{q^k}$ and $M_k \in \mathrm{GL}_k(\mathbb{F}_q)$ the companion matrix associated to the primitive polynomial of ω over $\mathbb{F}_q$. It turns out that $\mathbb{F}_{q^k} \cong \mathbb{F}_q[\omega] \cong \mathbb{F}_q[M_k]$, where the last field isomorphism is given by $\phi(\sum_{i=0}^{k-1} a_i\omega^i) = \sum_{i=0}^{k-1} a_i M_k^i$. In particular $\phi(\omega) = M_k$ and the multiplicative order of M_k is $q^k - 1$. Thus, $\langle M_k \rangle$ is a Singer subgroup of $\mathrm{GL}_k(\mathbb{F}_q)$. Equivalently, M_k is a primitive element of the finite field $\mathbb{F}_q[M_k] \subseteq \mathbb{F}_q^{k\times k}$.

The field isomorphism ϕ is useful to map vector subspaces of $\mathbb{F}_{q^k}^s$ into vector subspaces of $\mathbb{F}_q^n$. For $m \in \{1, \ldots, s\}$, one has the embedding $\varphi : \mathcal{G}_{q^k}(m, s) \longrightarrow \mathcal{G}_q(km, n)$ given by

$$\mathrm{rowsp}\begin{pmatrix} a_{11} & \cdots & a_{1s} \\ \vdots & \ddots & \vdots \\ a_{m1} & \cdots & a_{ms} \end{pmatrix} \longmapsto \mathrm{rowsp}\left(\begin{array}{c|c|c} \phi(a_{11}) & \cdots & \phi(a_{1s}) \\ \hline \vdots & \ddots & \vdots \\ \hline \phi(a_{m1}) & \cdots & \phi(a_{ms}) \end{array}\right),$$

which is called a *field reduction map*. In particular, φ preserves intersections of subspaces, since it is injective. Therefore, an m-spread of $\mathbb{F}_{q^k}^s$ will be mapped into a km-spread of $\mathbb{F}_q^n$. We will use two constant dimension codes of $\mathbb{F}_q^n$ constructed in this way. First, from the spread of lines of $\mathbb{F}_{q^k}^s$, we consider

$$\mathcal{S} = \varphi(\mathcal{G}_{q^k}(1, s)) \subseteq \mathcal{G}_q(k, n),$$

which is a k-spread of $\mathbb{F}_q^n$. Originally, due to Segre, in the network coding setting, this construction appears for the first time in Manganiello et al. (2008). Secondly, from the Grassmannian of hyperplanes of $\mathbb{F}_{q^k}^s$, we obtain

$$\mathcal{H} = \varphi(\mathcal{G}_{q^k}(s-1, s)) \subseteq \mathcal{G}_q(n-k, n),$$

which is a constant dimension code of $\mathbb{F}_q^n$ with maximum distance.

On the other hand, we can also use ϕ to obtain the following group monomorphism:

$$\begin{array}{rccc} \psi: & \mathrm{GL}_s(\mathbb{F}_{q^k}) & \longrightarrow & \mathrm{GL}_{ks}(\mathbb{F}_q) \\ & \begin{pmatrix} a_{11} & \cdots & a_{1s} \\ \vdots & \ddots & \vdots \\ a_{s1} & \cdots & a_{ss} \end{pmatrix} & \longmapsto & \left(\begin{array}{c|c|c} \phi(a_{11}) & \cdots & \phi(a_{1s}) \\ \hline \vdots & \ddots & \vdots \\ \hline \phi(a_{s1}) & \cdots & \phi(a_{ss}) \end{array}\right). \end{array}$$

In this way, we can establish the following relation between the group action of $\mathrm{GL}_s(\mathbb{F}_{q^k})$ on $\mathcal{G}_{q^k}(m, s)$ and the group action of $\mathrm{GL}_n(\mathbb{F}_q)$ on $\mathcal{G}_q(km, n)$:

$$\varphi(\mathcal{V}\cdot A) = \varphi(\mathcal{V})\cdot\psi(A), \tag{1}$$

for all $\mathcal{V} \in \mathcal{G}_{q^k}(m, s)$ and $A \in \mathrm{GL}_s(\mathbb{F}_{q^k})$. In particular, we will use this equality to relate the respective actions of two Singer subgroups in which we are very interested.

Let α be a primitive element of $\mathbb{F}_{q^n}$ and $M_s \in \mathrm{GL}_s(\mathbb{F}q^k)$ the companion matrix of the minimal polynomial of α

over $\mathbb{F}_{q^k}$, then $\mathbb{F}_{q^n} \cong \mathbb{F}_{q^k}[\alpha] \cong \mathbb{F}_{q^k}[M_s]$. Therefore, the multiplicative order of M_s is q^n-1 and $\langle M_s\rangle$ is a Singer subgroup of $\mathrm{GL}_s(\mathbb{F}_{q^k})$. Besides, it turns out that $\psi(\langle M_s\rangle) = \langle \psi(M_s)\rangle$ is a Singer subgroup of $\mathrm{GL}_n(\mathbb{F}_q)$. Given a line $l_0 \in \mathcal{G}_{q^k}(1,s)$, put $\varphi(l_0) = \mathcal{S}_0 \in \mathcal{S}$. In accordance with Theorem 1 and (1) we can write

$$\mathcal{S} = \varphi(\mathcal{G}_{q^k}(1,s)) = \varphi(\mathrm{O}_{\langle M_s\rangle}(l_0)) = \{\varphi(l_0 \cdot A) \mid A \in \langle M_s\rangle\}$$
$$= \{\mathcal{S}_0 \cdot \psi(A) \mid \psi(A) \in \langle \psi(M_s)\rangle\} = \mathrm{O}_{\langle \psi(M_s)\rangle}(\mathcal{S}_0).$$

In an analogous way, given a hyperplane $h_0 \in \mathcal{G}_{q^k}(s-1,s)$, denote $\varphi(h_0) = \mathcal{H}_o \in \mathcal{H}$. Then, we obtain that

$$\mathcal{H} = \varphi(\mathcal{G}_{q^k}(s-1,s)) = \varphi(\mathrm{O}_{\langle M_s\rangle}(h_0)) = \mathrm{O}_{\langle \psi(M_s)\rangle}(\mathcal{H}_0).$$

That is, the transitive action of $\langle M_s\rangle$ on the lines and hyperplanes of $\mathbb{F}_{q^k}^s$ is translated into the transitive action of $\langle \psi(M_s)\rangle$ on the constant dimension codes of maximum distance $\mathcal{S}$ and $\mathcal{H}$. Moreover, for any $\mathcal{S}_0 \in \mathcal{S}$ and $\mathcal{H}_0 \in \mathcal{H}$, Theorem 1 also leads to

$$\mathrm{Stab}_{\langle \psi(M_s)\rangle}(\mathcal{S}_0) = \mathrm{Stab}_{\langle \psi(M_s)\rangle}(\mathcal{H}_0) = \{\psi(aI_s) \mid a \in \mathbb{F}_{q^k}^*\},$$

which has order q^k-1.

With all these ingredients, we can now apply Theorem 2 in order to characterize those subgroups of $\langle \psi(M_s)\rangle$ that are appropriate to construct ODFCs.

Theorem 3. Let $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_k, \mathcal{F}_{n-k}, \ldots, \mathcal{F}_{n-1})$ be a flag of full admissible type vector such that $\mathcal{F}_k \in \mathcal{S}$ and $\mathcal{F}_{n-k} \in \mathcal{H}$. For any positive integer t dividing q^n-1, consider the unique subgroup $\mathbf{T}$ of $\langle \psi(M_s)\rangle$ of order t. Then:

(*i*) $|\mathrm{O}_{\mathbf{T}}(\mathcal{F})| = \frac{t}{\gcd(t,q-1)}$.
(*ii*) $\mathrm{O}_{\mathbf{T}}(\mathcal{F})$ is an ODFC if, and only if, $\gcd(t,q^k-1) = \gcd(t,q-1) \neq t$.

Theorem 3 states which subgroups of $\langle \psi(M_s)\rangle$ allow the construction of ODFCs as a single orbit of them. Notice that bigger subgroups not always will provide bigger orbit flag codes. In addition, it may eventually happen that some subgroup provides an orbit ODFC of the maximum possible size, that is, $\frac{q^n-1}{q^k-1}$. Otherwise, we will consider unions of orbits under the action of that subgroup in order to obtain an optimal construction (Navarro-Pérez and Soler-Escrivà, 2022, Th. 4.13). Clearly, the larger the size of each orbit, the fewer orbits we need to reach the maximum size and vice versa. In particular, the degenerate case where an ODFC is constructed as a union of $\frac{q^n-1}{q^k-1}$ orbits with just one element is also contemplated. All these considerations are reflected in the following examples, in which we apply Theorem 3 for different values of the parameters.

Examples. With the notation of Theorem 3, we consider all the divisors t of q^n-1 such that $\gcd(t,q^k-1) = \gcd(t,q-1)$ and the corresponding subgroup $\mathbf{T}$ of $\langle \psi(M_s)\rangle$ of order t. Consider a flag $\mathcal{F}$ of the full admissible type $(1,\ldots,k,n-k,\ldots,n-1)$ such that $\mathcal{F}_k \in \mathcal{S}$ and $\mathcal{F}_{n-k} \in \mathcal{H}$. Finally, denote by m the number of required orbits of $\mathbf{T}$ to attain the maximum size, $\frac{q^n-1}{q^k-1}$, for an ODFC with these parameters.

(1) Put $q=3$, $k=3$ and $n=6$. Thus, $k=n-k$, $q^n-1=728$, $q^k-1=26$ and $\frac{q^n-1}{q^k-1}=28$. Then

t	1	2	4	7	8	14	28	56
$\lvert\mathrm{O}_{\mathbf{T}}(\mathcal{F})\rvert$	1	1	2	7	4	7	14	28
m	28	28	14	4	7	4	2	1

Notice that, in this case, the subgroup of order $t=56$ allows us to obtain ODFCs of full type vector and having the best possible size, i.e., 28, by using a single orbit. Moreover, remark that the subgroup of order $t=8$ gives an orbit ODFC of smaller size than the obtained with the subgroup of order $t=7$.

(2) Put $q=4$, $k=3$ and $n=9$. Thus, $n-k=6$, $q^n-1=262143$, $q^k-1=63$ and $\frac{q^n-1}{q^k-1}=4161$. Then

t	1	3	19	57	73	219	1387	4161
$\lvert\mathrm{O}_{\mathbf{T}}(\mathcal{F})\rvert$	1	1	19	19	73	73	1387	1387
m	4161	4161	219	219	57	57	3	3

The largest orbit size is 1387 and it is obtained when the acting group has order either 1387 or 4161. On the other hand, the maximum possible size of an ODFC with these parameters is 4161. Hence, in order to achieve that cardinality, we must consider the union of, at least, 3 different orbits.

The orbital constructions of ODFC provided in this section present a restriction on the type vector, coming from the condition of having a spread as a projected code. However, there are two possible situations in which flag codes of full type can be given by using Theorem 3. First, for even values of n, taking the divisor $k=\frac{n}{2}$ leads to a construction of full type in which $k=n-k$. This particular case was first studied in Alonso-González et al. (2021b), where a construction using the action of a Singer subgroup of $\mathrm{SL}_{2k}(\mathbb{F}_q)$ is presented. On the other hand, for $n=3$ and $k=1$, the action of a Singer subgroup of $\mathrm{GL}_3(\mathbb{F}_q)$ on the Grassmannian of lines and hyperplanes gives us a construction of type $(1,2)$. This construction is also known and appears in (Kurz, 2021, Prop. 2.5), where the author shows that it is the one with the biggest cardinality among ODFC of full type when $n=3$. In the following section, we consider the remaining situations, that is, we address the construction of orbit ODFCs of full type vector on $\mathbb{F}_q^n$ for odd values of $n>3$.

3.2 Orbit ODFC of full type vector

In this section, we assume that $n=2k+1$, for some $k>1$. In this case, instead of Theorem 2, the following result is achieved.

Theorem 4. (Navarro-Pérez and Soler-Escrivà, 2022, Th. 4.11) Given a subgroup $\mathbf{H}$ of $\mathrm{GL}_n(\mathbb{F}_q)$ and a full flag $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_{2k})$ on $\mathbb{F}_q^n$, the following sentences are equivalent:

(*i*) $\mathrm{O}_{\mathbf{H}}(\mathcal{F})$ is an ODFC.
(*ii*) $\mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_k) = \mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_{k+1}) \subseteq \mathrm{Stab}_{\mathbf{H}}(\mathcal{F}_i)$, for every i and the subspace codes $\mathrm{O}_{\mathbf{H}}(\mathcal{F}_k)$ and $\mathrm{O}_{\mathbf{H}}(\mathcal{F}_{k+1})$ are of maximum distance.

Our aim is to use the previous theorem in order to obtain a specific construction of orbit ODFC of full type vector. For this, let us consider $M_{k+1} \in \mathrm{GL}_{k+1}(\mathbb{F}_q)$ the companion matrix of a primitive polynomial of degree $k+1$ in $\mathbb{F}_q[x]$. Then $\langle M_{k+1}\rangle$ is a Singer subgroup of $\mathrm{GL}_{k+1}(\mathbb{F}_q)$ and

$\mathbb{F}_q[M_{k+1}]$ is a matrix representation of the finite field of q^{k+1} elements. Let us write

$$g = \left(\begin{array}{c|c} I_k & 0_{k\times(k+1)} \\ \hline 0_{(k+1)\times k} & M_{k+1} \end{array}\right) \in \mathrm{GL}_n(\mathbb{F}_q)$$

and consider the cyclic group

$$\mathbf{G} = \langle g \rangle = \left\{ g^i \mid 0 \le i \le q^{k+1} - 2 \right\}.$$

Clearly, $\mathbf{G}$ is a subgroup of order $q^{k+1}-1$ of $\mathrm{GL}_n(\mathbb{F}_q)$, isomorphic to the Singer subgroup $\langle M_{k+1} \rangle$ of $\mathrm{GL}_{k+1}(\mathbb{F}_q)$. In the rest of this section, the orbit codes considered will be always generated by the action of this specific group $\mathbf{G}$.

We start by characterizing the subspaces of dimensions k and $k+1$ of $\mathbb{F}_q^n$ whose orbits under the action of $\mathbf{G}$ are constant dimension codes of maximum distance. Given arbitrary subspaces $\mathcal{U} = \mathrm{rowsp}(U) \in \mathcal{G}_q(k,n)$ and $\mathcal{V} = \mathrm{rowsp}(V) \in \mathcal{G}_q(k+1,n)$, their respective full-rank generator matrices can split into two blocks as

$$U = (U_1 \mid U_2) \quad \text{and} \quad V = (V_1 \mid V_2), \tag{2}$$

where U_1 (resp. V_1) denotes the first k columns of U (resp. V). Therefore, $U_1 \in \mathbb{F}_q^{k\times k}$, $U_2 \in \mathbb{F}_q^{k\times(k+1)}$, $V_1 \in \mathbb{F}_q^{(k+1)\times k}$ and $V_2 \in \mathbb{F}_q^{(k+1)\times(k+1)}$. Now, consider the orbit codes

$$\mathrm{O}_{\mathbf{G}}(\mathcal{U}) = \{\mathcal{U} \cdot g^i \mid 0 \le i \le q^{k+1} - 2\} \tag{3}$$

and

$$\mathrm{O}_{\mathbf{G}}(\mathcal{V}) = \{\mathcal{V} \cdot g^i \mid 0 \le i \le q^{k+1} - 2\}. \tag{4}$$

With the notation of (2) the following results hold.

Proposition 5. The orbit code $\mathrm{O}_{\mathbf{G}}(\mathcal{U})$ defined in (3) has maximum distance if, and only if, $\mathrm{rk}(U_1) = \mathrm{rk}(U_2) = k$. Its cardinality is $|\mathrm{O}_{\mathbf{G}}(\mathcal{U})| = |\mathbf{G}| = q^{k+1} - 1$.

Proposition 6. The orbit code $\mathrm{O}_{\mathbf{G}}(\mathcal{V})$ defined in (4) has maximum distance if, and only if, $\mathrm{rk}(V_1) = k$ and $\mathrm{rk}(V_2) = k+1$. Its size is $|\mathrm{O}_{\mathbf{G}}(\mathcal{V})| = |\mathbf{G}| = q^{k+1} - 1$.

In the following, we use the previous characterizations for constant dimension codes of maximum distance in order to provide orbit ODFCs of full type on $\mathbb{F}_q^n$. To do so, we need to consider nested subspaces $\mathcal{U} \subsetneq \mathcal{V}$ of dimensions k and $k+1$, respectively. Using the notation of (2), we can formulate the problem in a matrix approach: given a full-rank generator matrix $U = (U_1 \mid U_2) \in \mathbb{F}_q^{k\times n}$ of $\mathcal{U}$, we consider a subspace $\mathcal{V}$ spanned by the rows of a matrix $V \in \mathbb{F}_q^{(k+1)\times n}$, obtained by adding an appropriate row to U. In other words, we choose vectors $\mathbf{v}_1 \in \mathbb{F}_q^k$ and $\mathbf{v}_2 \in \mathbb{F}_q^{k+1}$ such that the matrix

$$V = (V_1 \mid V_2) = \left(\begin{array}{c|c} U_1 & U_2 \\ \hline \mathbf{v}_1 & \mathbf{v}_2 \end{array}\right) \tag{5}$$

has rank equal to $k+1$. Using this notation, we present the next construction of ODFCs arising from the action of the group $\mathbf{G}$ defined in this section.

Theorem 7. Let $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_{2k})$ be a full flag on $\mathbb{F}_q^n$ such that $\mathcal{F}_k = \mathcal{U} = \mathrm{rowsp}(U_1 \mid U_2)$ and $\mathcal{F}_{k+1} = \mathcal{V} = \mathrm{rowsp}(V_1 \mid V_2)$, with generator matrix as in (5). The following statements are equivalent:

(i) The flag code $\mathrm{O}_{\mathbf{G}}(\mathcal{F})$ is an ODFC.
(ii) The matrices $U_1 \in \mathbb{F}_q^{k\times k}$ and $V_2 \in \mathbb{F}_q^{(k+1)\times(k+1)}$ are invertible.

In this situation, $|\mathrm{O}_{\mathbf{G}}(\mathcal{F})| = |\mathbf{G}| = q^{k+1} - 1$.

The ODFC constructed in Theorem 7 contains $q^{k+1} - 1$ flags. It is the largest size for orbits under the action of the group $\mathbf{G}$. On the other hand, as proved in (Kurz, 2021, Prop. 2.4), the maximum possible cardinality for ODFCs of full type on $\mathbb{F}_q^n$ is exactly $q^{k+1}+1$. Consequently, our orbital construction is only two flags away from reaching the mentioned bound. In order to complete this construction into an ODFC with size $q^{k+1}+1$, we form the following subspaces

$$\begin{aligned} &\mathcal{U}' = \mathrm{rowsp}(U_1 \mid 0_{k\times(k+1)}), \ \mathcal{V}' = \mathrm{rowsp}\left(\begin{array}{c|c} U_1 & 0_{k\times(k+1)} \\ \hline \mathbf{v}_1 & \mathbf{v}_2 \end{array}\right), \\ &\mathcal{U}'' = \mathrm{rowsp}(0_{k\times k} \mid U_2), \qquad \mathcal{V}'' = \mathrm{rowsp}\left(\begin{array}{c|c} 0_{k\times k} & U_2 \\ \hline \mathbf{v}_1 & \mathbf{v}_2 \end{array}\right). \end{aligned} \tag{6}$$

With this notation, as long as $\mathrm{rk}(U_1) = \mathrm{rk}(U_2) = k$ and $\mathbf{v}_2 \notin \mathrm{rowsp}(U_2)$, the next result holds.

Theorem 8. Let $\mathcal{F}, \mathcal{F}', \mathcal{F}''$ be full flags on $\mathbb{F}_q^n$ such that $\mathcal{F}_k = \mathcal{U}$ and $\mathcal{F}_{k+1} = \mathcal{V}$ defined as in *Theorem 7* and

$$\mathcal{F}'_k = \mathcal{U}', \ \mathcal{F}'_{k+1} = \mathcal{V}', \ \mathcal{F}''_k = \mathcal{U}'', \ \mathcal{F}''_{k+1} = \mathcal{V}''.$$

Then the flag code $\mathcal{C} = \mathrm{O}_{\mathbf{G}}(\mathcal{F}) \cup \{\mathcal{F}', \mathcal{F}''\}$ is an ODFC with the maximum possible cardinality, i.e., $q^{k+1}+1$, if, and only if, $\mathbf{v}_1 = \mathbf{0}_k$.

Towards a reduction of the public-key size of a Gabidulin codes based encryption scheme

Pierre Loidreau *

* *DGA and Institut de Recherche Mathmatique de Rennes, IRMAR - UMR CNRS 6625*

Abstract: We exhibit a way to reduce the public-key size of a rank metric based public-key cryptosystem. This approach does not use a structural property of the code but exhibit some particular generator matrices that have a quasi-cyclic like structure.

Keywords: Post-Quantum Cryptography, Coding Theory, Rank metric based cryptosystems

1. INTRODUCTION

Code-based cryptography is among the main solutions for post-quantum cryptography together with lattice-based and isogeny-based cryptography. A McEliece type OW-PKE based on Gabidulin codes was proposed in Loidreau (2017). It mimics the McEliece type OW-PKE proposed in Hamming metric, but compared to modern PKE and especially those proposed at the NIST post-quantum standardization process this one has three main advantages.

- Decryption is deterministic. This makes much easier to handle as an IND-CCA version than Lattice based schemes and MDPC codes based schemes.
- Key size is between one and two orders of magnitude smaller than other Hamming metric based cryptosystem. It favourably compares to unstructured lattice-based PKEs such as the one used in `FrodoKEM`.
- The cipher text is small compared to unstructured lattice and compares favourably with structured lattices.

On the other hand, and this forms the main drawback, the security analysis is not yet sufficiently stabilized. The security of the scheme relies on two paradigms:

- The complexity of distinguishing the public code from random
- The complexity of decoding a random code in rank metric.

The latter problem was proven to be a hard problem in the complexity class ZPP Gaborit and Zémor (2015). However, in practice significant recent progresses were made in the computational complexity which makes necessary to reconsider the parameters, Bardet et al. (2020). This implies in particuler increasing the public-key size which is the main drawback in using code-based cryptography in limited resources devices.

In our work we propose a new direction towards the reduction of the public-key.

2. BACKGROUND ON GABIDULIN CODES AND ON RANK METRIC

First we define the rank norm of a vector inducing a metric on a finite field. Let q be the power of some prime number.

Definition 1. (Rank of a vector). Let $\mathbb{F}_{q^m}$ be the finite field with q^m elements. Let $\mathbf{a} = (a_1, \ldots, a_n) \in \mathbb{F}_{q^m}^n$. Then the rank of $\mathbf{a}$ denoted by $\mathrm{Rk}(\mathbf{a})$ is the dimension of the $\mathbb{F}_q$-dimensional vector subspace of $\mathbb{F}_{q^m}$ generated by the components of $\mathbf{a}$, *i.e.*

$$\mathrm{Rk}(\mathbf{a}) \stackrel{def}{=} \dim \langle a_1, \ldots, a_n \rangle_{\mathbb{F}_q}$$

As extremal object in Bose-Mesner algebra Gabidulin codes were first discovered by Delsarte Delsarte (1978). Some years later Gabidulin presented an algebraic theory as well as a polynomial-time decoding algorithm Gabidulin (1985).

Definition 2. Let $0 < k < n \leq m$, and $\mathbf{g} = (g_1, \ldots, g_n) \in \mathbb{F}_{q^m}^n$ of rank n. Then, the k-dimensional Gabidulin code with support vector $\mathbf{g}$ denoted by $\mathcal{G}_k(\mathbf{g})$ is

$$\mathcal{G}_k(\mathbf{g}) = \left\{ \mathbf{x} \left(g_j^{[i]} \right)_{i=0,j=1}^{k-1,n} \mid \mathbf{x} \in \mathbb{F}_{q^m}^k \right\},$$

where $[i] \stackrel{def}{=} q^i$

We consider now more specific Gabidulin codes. Let $u, \lambda, k \in \mathbb{N} \setminus \{0\}$. Let us define $m = \mu u$ and $k = \kappa u$, with $\kappa < \mu$. Let $g_\ell \in \mathbb{F}_{q^m}$, for $\ell = 1, \ldots, u$ such that

$$\mathrm{Rk}(\mathbf{g} = (g_\ell^{[uj]},\ j = 0, \ldots, \mu - 1,\ \ell = 1, \ldots, u)) = m \quad (1)$$

A generator $\mathbf{G}$ matrix of $\mathcal{G}_k(\mathbf{g})$ has the form

$$\mathbf{G} = \begin{pmatrix} \mathbf{G}_{11} & \cdots & \mathbf{G}_{1u} \\ \vdots & \ddots & \vdots \\ \mathbf{G}_{u1} & \cdots & \mathbf{G}_{uu} \end{pmatrix} \quad (2)$$

where

$$\forall \ell, s = 1, \ldots, u,\ \mathbf{G}_{s\ell} = \left(g_\ell^{[(s-1)+u(i+j)]} \right)_{i=0,j=0}^{\kappa-1,\mu-1}$$

In other terms the matrices $\mathbf{G}_{s\ell}$ are submatrices formed by the κ first rows of the circulant $\mu \times \mu$ matrices

$$\left(g_\ell^{[(s-1)+u(i+j)]} \right)_{i=0,j=0}^{\mu-1,\mu-1}$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Definition 3. A generator matrix of a Gabidulin code $\mathcal{G}_k(\mathbf{g})$ under the form (2) is said to be under quasi-cyclic form.

3. CONSTRUCTION OF GABIDULIN CODES UNDER QUASI-CYCLIC FORM

We show how to find a vector $\mathbf{g}$ or rank m as described in equation (1). Let $g \in \mathbb{F}_{2^m}$ and let us define

$$\mathcal{V}_g \stackrel{def}{=} \langle g, g^{[u]}, \ldots, g^{[u(\mu-1)]} \rangle_{\mathbb{F}_2}$$

Note that we can show that if $h \in \mathbb{F}_{2^m}$ and $h \notin \mathcal{V}_g$ then $\mathcal{V}_g \cap \mathcal{V}_h = \{0\}$

(1) Choose $g_1 \in \mathbb{F}_{2^m}$ such that $\dim(\mathcal{V}_{g_1}) = \mu$.
(2) For $\ell = 2, \ldots, u$ choose $g_\ell \in \mathbb{F}_{2^m} \setminus \cup_{i=1}^{\ell-1} \mathcal{V}_{g_i}$ such that $\dim(\cup_{i=1}^{\ell} \mathcal{V}_{g_i}) = \mu$.

Note that we did not check the effective number of such vectors. At least any normal element of the finite field can give rise to such vectors. Our simulations in MAGMA confirm for $q = 2$ that a very small number of tries is necessary to find a target vector (typically less than 10).

The key proposition is:

Proposition 1. Let $\mathbf{G} = (\mathbf{G}_{s\ell})$ be the generator matrix of the Gabidulin code $\mathcal{G}_k(\mathbf{g})$ under quasi-circulant form where $\mathbf{G}_{s\ell} \in \mathbb{F}_{q^m}^{\kappa \times \mu}$ are $\kappa \times \mu$ submatrices of circulant $\mu \times \mu$ matrices. Let $\mathbf{T} = (\mathbf{T}_{s\ell})$ where $\mathbf{T}_{s\ell} \in \mathbb{F}_{q^m}^{\mu \times \mu}$ are circulant $\mu \times \mu$-matrices, then $\mathbf{GT}$ is a generator matrix in quasi-circulant form of the code $\mathcal{G}_k(\mathbf{g})\mathbf{T}$

The proposition implies that

$$\mathbf{GT} = \begin{pmatrix} \mathbf{G'}_{11} & \cdots & \mathbf{G'}_{1u} \\ \vdots & \ddots & \vdots \\ \mathbf{G'}_{u1} & \cdots & \mathbf{G'}_{uu} \end{pmatrix}$$

where $\mathbf{G'}_{s\ell}$ are submatrices of circulant matrices. This in turn implies that the matrix can be regenerated by storing the u^2 rows of size $\mu \log_2(q^m)$ bits which are the first rows of the matrices $\mathbf{G'}_{s\ell}$.

Corollary 2. To generate the matrix $\mathbf{GT}$ one requires $um^2 \log_2(q)$ bits

Without this particular structure, considering the matrix under systematic form would require $mk(m-k)$ bits. In this sense the gain is significant.

4. STRUCTURE OF THE ENCRYPTION SCHEME

Now we design an encryption scheme similar to that in Loidreau (2017), except for the generation of the public-key. The only difference lies in the public-key generation which is a generator matrix under circulant form of the distorted Gabidulin code. First a designer has to select parameters $q, \mu, \kappa, m = \mu u, k = \kappa u$ and the parameter λ in accordance to the security target.

`KeyGen()`

(1) Pick up randomly a vector $\mathbf{g} \in \mathbb{F}_{q^m}^m$ as in equation (1).
(2) Construct the generator matrix $\mathbf{G}$ for the Gabidulin code $\mathcal{G}_k(\mathbf{g})$ under the form (2).
(3) Pick $\mathcal{V} \subset \mathbb{F}_{q^m}$ a randomly chosen λ-dimensional $\mathbb{F}_q$-vector subspace of $\mathbb{F}_{q^m}$.
(4) Construct a matrix $\mathbf{P} = (\mathbf{P}_{s\ell}) \in GL_m(\mathbb{F}_q)$ where $\mathbf{P}_{s\ell} \in \mathcal{V}^{\mu \times \mu}$, are circulant $\mu \times \mu$ matrices with components in $\mathcal{V}$.
(5) **return** $\mathbf{G}_{pub} = \mathbf{GP}^{-1}$, and $\mathbf{sk} = (\mathbf{G}, \mathbf{P})$

sk stands for the secret key and $\mathbf{G}_{pub}$ is a matrix which generates the public-code $\mathcal{G}_k(\mathbf{g})$. Now Suppose that $\mathbf{p} \in \mathbb{F}_{q^m}^k$ is the plaintext, the encryption procedure is

`Encrypt(p,G`$_{pub}$`)`

(1) Pick $\mathbf{e} \in \mathbb{F}_{2^m}^n$ such that $\mathrm{Rk}(\mathbf{e}) \leq \lfloor (n-k)/2\lambda \rfloor$
(2) **return** $\mathbf{c} = \mathbf{p} \cdot \mathbf{G}_{pub} + \mathbf{e}$

And the decryption procedure for the ciphertext $\mathbf{c}$.

`Decrypt(c,sk)`

- **return** `Decode`$(\mathbf{c} \cdot \mathbf{P}, \mathbf{G})$

where `Decode`$(*, \mathbf{G})$ stands for a decoding algorithm for a Gabidulin code with generator matrix $\mathbf{G}$.

Note that from our construction $\mathbf{G}_{pub} = (\mathbf{G'}_{s\ell})$, where $\mathbf{G'}_{s\ell}$ are submatrices of size $\kappa \times \mu$ of $\mu \times \mu$ circulant matrices. Therefore, to store the public-key, it suffices to store the first rows of each matrix $\mathbf{G'}_{s\ell}$.

5. SECURITY OF THE ENCRYPTION SCHEME

The security of the scheme is related to the difficulty of solving the two following problems

(1) Distinguish the public-code $\mathcal{C}_{pub} = \langle \mathbf{G}_{pub} \rangle$ from a random code
(2) Solve the Rank Bounded Distance Decoding problem of a randomly generated code for the parameters given in the design of the encryption scheme. That is decode errors of rank $\lfloor (n-k)/(2\lambda) \rfloor$ in a k-dimensional code of length n with components in $\mathbb{F}_{2^m}$

Compared to the original scheme, our design has an impact on the first item only. Namely, our construction does not select a particular structured code, but only a particular generator matrix. It can be shown that the security rely completely on the fact that $\mathcal{V}$ remains secret.

However, our proposal introduces a new way to *attack* the first problem which needs careful investigation. Without going into too many details idea of the attack relies on the following considerations

(1) By construction we know that $\mathbf{g} \in \mathcal{V}_{g_1} \times \cdots \times \mathcal{V}_{g_u}$.
(2) From the knowledge of $\mathbf{G}_{pub}$ and of any vector in $\mathbf{g'} = (g'_1, \ldots, g'_u) \in \mathbb{F}_{q^m}^{\mu u}$ such that
$$\mathcal{V}_{g'_1} \times \cdots \times \mathcal{V}_{g'_u} = \mathcal{V}_{g_1} \times \cdots \times \mathcal{V}_{g_u},$$
an attacker can construct a decoder for the public-code thus recovering the plaintext.

A trivial way to achieve this goal is to enumerate vectors $\mathbf{g'} = (g'_1, \ldots, g'_u) \in \mathbb{F}_{q^m}^{\mu u}$, until
$$\forall s = 1, \ldots, u, \ \mathcal{V}_{g'_s} = \mathcal{V}_{g_s}.$$
To obtain a simpler analysis, we relax the condition and say that the attack succeds if

$$\forall s = 1, \ldots, u, \ \begin{cases} \mathcal{V}_{g'_s} \subset \mathcal{V}_{g_s} \\ \mathcal{V}_{g'_s} \neq \{0\} \end{cases}$$

Since for any $s = 1, \ldots, \ell$, the vector space $\mathcal{V}_{g_s}$ is closed under the action of $[u]$. This is equivalent to finding $g'_s \in \mathbb{F}_{q^m} \setminus \{0\}$ such that

$$\forall s = 1, \ldots, u, \ g'_s \in \mathcal{V}_{g_s}$$

Now we can establish the following proposition

Proposition 3. Let $\mathbf{g}' = (g'_1, \ldots, g'_u) \in \mathbb{F}_{q^m}^m$ be randomly and uniformly chosen, then

$$\Pr(\forall s = 1, \ldots, u, \ g'_s \in \mathcal{V}_{g_s}) \approx q^{-\frac{(u-1)m}{2}}$$

6. CONCLUSION

In this abstract, we presented a procedure to reduce significantly the public-key size of a distorted Gabidulin code based encryption scheme. It is of importance that different types of attacks be thouroughly considered before claiming security. However, were this approach sound, then this would enable to provide algebraic code-based public-key cryptosystems with public-key size of a few kilo-bytes.

Keywords: Multiobjective Model Predictive Control, Multiobjective Optimal Control

1. INTRODUCTION

In model predictive control, it is a natural idea that not only one but multiple objectives have to be optimized. This leads to the formulation of a multiobjective optimal control problem (MO OCP). In this talk we introduce a multiobjective MPC algorithm, which yields on the one hand performance estimates for all considered objective functions and on the other hand stability results of the closed-loop solution. To this end, we build on the results in Zavala and Flores-Tlacuahuac (2012); Grüne and Stieler (2019) and introduce a simplified version of the algorithm presented in Grüne and Stieler (2019). Compared to Grüne and Stieler (2019), we allow for more general MO OCPs than in Grüne and Stieler (2019) and get rid of restrictive assumption on the existence of stabilizing stage and terminal costs in all cost components. Compared to Zavala and Flores-Tlacuahuac (2012), we obtain rigorous performance estimate for the MPC closed loop.

2. SETTING AND PRELIMINARIES

For a discrete time nonlinear sytem $x(k+1) = f(x(k), u(k))$, $x(0) = x_0$ with continuous $f : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$, we impose nonempty state and input constraint sets $\mathbb{X} \subseteq \mathbb{R}^n$ and $\mathbb{U} \subset \mathbb{R}^m$, respectively, as well as a nonempty terminal constraint set $\mathbb{X}_0 \subseteq \mathbb{R}^n$, and the set of admissible control sequences for $x_0 \in \mathbb{X}$ up to time $N \in \mathbb{N}$ by $\mathbb{U}^N(x_0) := \{\mathbf{u} \in \mathbb{U}^N \,|\, x_\mathbf{u}(k, x_0) \in \mathbb{X} \;\forall\; k = 1, \dots, N-1 \text{ and } x_\mathbf{u}(N, x_0) \in \mathbb{X}_0\}$.

For given stage costs $\ell_i : \mathbb{X} \times \mathbb{U} \to \mathbb{R}$, $i \in \{1, \dots, s\} =: \mathcal{I}$, $s \in \mathbb{N}_{\geq 2}$, and terminal cost $F_1 : \mathbb{X}_0 \to \mathbb{R}_{\geq 0}$ we define the first cost functional $J_1^N : \mathbb{X} \times \mathbb{U}^N \to \mathbb{R}$ by $J_1^N(x_0, \mathbf{u}) := \sum_{k=0}^{N-1} \ell_1(x_\mathbf{u}(k, x_0), u(k)) + F_1(x(N, x_0))$, and for $i \in \{2, \dots, s\}$, we define cost functionals $J_i^N : \mathbb{X} \times \mathbb{U}^N \to \mathbb{R}$ by $J_i^N(x_0, \mathbf{u}) := \sum_{k=0}^{N-1} \ell_i(x(k, x_0), u(k))$ for horizon $N \in \mathbb{N}_{\geq 2}$. Here, F_1 is defined on the terminal constraint set $\mathbb{X}_0 \subseteq \mathbb{X}$ and we need to ensure that $x(N, x_0) \in \mathbb{X}_0$ by imposing suitable terminal constraints.

⋆ The authors are supported by DFG Grant Gr 1569/13-2.

We consider multiobjective optimal control problems with terminal conditions of the form

$$\begin{aligned} \min_{\mathbf{u} \in \mathbb{U}^N(x_0)} \; & J^N(x_0, \mathbf{u}) := \big(J_1^N(x_0, \mathbf{u}), \dots, J_s^N(x_0, \mathbf{u})\big) \\ & x(k+1) = f(x(k), u(k)), \quad k = 0, \dots, N-1 \\ & x(0) = x_0, \quad x(k) \in \mathbb{X} \\ & x(N, x_0) \in \mathbb{X}_0. \end{aligned} \tag{MO OCP}$$

Since we only consider multiobjective optimal control problems with terminal constraint and the terminal constraint $x(N, x_0) \in \mathbb{X}_0$ can generally not be satisfied by all initial values $x_0 \in \mathbb{X}$, we define the feasible set $\mathbb{X}_N := \{x_0 \in \mathbb{X} \mid \exists\; \mathbf{u} \in \mathbb{U}^N : x_\mathbf{u}(k, x_0) \in \mathbb{X},\; k = 1, \dots, N-1,\; x(N, x_0) \in \mathbb{X}_0\} \neq \emptyset$. Further, a pair $(x^e, u^e) \in \mathbb{X} \times \mathbb{U}$ is called equilibrium if $x^e = f(x^e, u^e)$ holds.

In the context of multiobjective optimization we need an appropriate notion of optimality namely the formalization of efficient points and nondominated sets, see, for instance, Ehrgott (2005). Here we denote the set of all efficient solutions of length N for initial value $x_0 \in \mathbb{X}$ by $\mathbb{U}_\mathcal{P}^N(x_0)$. Further, we use the notion of strict dissipativity and some stability results from Grüne and Pannek (2017).

3. A NEW MULTIOBJECTIVE MPC ALGORITHM

In this talk, we combine multiobjective optimization and model predictive control. Thus, we use the MPC theory to solve a multiobjective optimal control problem. Since in the multiobjective case there are several "optimal" (efficient) solutions we have to adapt the "standard" MPC. To this end, we analyze the case of (MO OCP), building on the results in Stieler (2018); Grüne and Stieler (2019), particularly on Algorithm 2 from this last reference. For some theoretical results such as trajectory convergence, performance estimates and stability results, we can use a simplified version of this algorithm, in which we allow for more general MO OCPs. More precisely, we only require that the first stage cost ℓ_1 is strictly dissipative and has a Lyapunov function terminal cost and a corresponding local feedback $\kappa : \mathbb{X}_0 \to \mathbb{U}$, since the first stage cost determine the closed-loop behavior. In contrast we do not require the disappearance or optimality of the other stage costs at

the equilibrium and, thus, the other cost criteria and the selection of the efficient solution determine the transient behavior.

This simplified version is Variant A of the following algorithm, whereas Variant B is Algorithm 2 from Grüne and Stieler (2019).

Algorithm 1 MO MPC with terminal conditions

for $k = 0, \dots, K$:

0. If $k = 0$, set $x(0) = x_0$ and choose an efficient solution $\mathbf{u}^\star_{x(0)} \in \mathbb{U}^N_{\mathcal{P}}(x(0))$ of (MO OCP). Go to 2.
1. **Variant A:**
   If $k \geq 1$, choose a efficient solution $\mathbf{u}^\star_{x(k)}$ of (MO OCP) with $x_0 = x(k)$ so that the inequality
   $$J_1^N(x(k), \mathbf{u}^\star_{x(k)}) \leq J_1^N(x(k), \mathbf{u}_{x(k)}) \tag{1}$$
   holds.
   Variant B:
   If $k \geq 0$, choose a efficient solution $\mathbf{u}^\star_{x(k)}$ of (MO OCP) with $x_0 = x(k)$ so that the inequalities
   $$J_i^N(x(k), \mathbf{u}^\star_{x(k)}) \leq J_i^N(x(k), \mathbf{u}_{x(k)}) \quad \forall i \in \mathcal{I} \tag{2}$$
   hold.
2. For $x := x_{u^*_{x(k)}}(N, x(k))$ set
   $$\mathbf{u}_{x(k+1)} := \left(u^*_{x(k)}(1), \dots, u^*_{x(k)}(N-1), \kappa(x)\right).$$
3. Apply the feedback $\mu^N(k, x(k)) := u^*_{x(k)}(0)$, i.e., evaluate $x(k+1) = f(x(k), \mu^N(k, x(k)))$, set $k = k+1$ and go to 1.

4. RESULTS

For Variant A of Algorithm 1, under the assumption of strict dissipativity of the first stage cost ℓ_1 at an equilibrium (x^e, u^e) for all $(x, u) \in \mathbb{X} \times \mathbb{U}$, we can prove feasibility, trajectory convergence to the equilibrium and a performance estimate for the first cost criterion J_1^N analogously to Stieler (2018); Grüne and Stieler (2019). More precisely, we obtain a bound on the infinite-horizon closed-loop performance of the first cost function of the form
$$J_1^\infty(x_0, \mu^N) \leq J_1^N(x_0, \mathbf{u}^\star_{x_0}). \tag{3}$$
Inequality (3) gives an a-priori bound on the performance only in dependence of the MPC-horizon N, the initial value x_0 and the efficient solution $\mathbf{u}^\star_{x_0}$ chosen in step (0) of Algorithm 1. Further, by using the continuity of the stage costs ℓ_i, $i \in \mathcal{I}$, and the trajectory convergence, we can bound the averaged performance
$$\begin{aligned} \bar{J}_i^\infty(x_0, \mu^N) &:= \limsup_{K\to\infty} \frac{1}{K} \sum_{k=0}^{K-1} \ell_i(x(k), \mu^N(x(k))) \\ &\leq \ell_i(x^e, u^e) \end{aligned} \tag{4}$$
for all $i \in \mathcal{I}$ by the corresponding stage cost at the considered equilibrium $\ell_i(x^e, u^e)$.

Moreover, we are interested in stability results. Assuming strict dissipativity of the first stage cost ℓ_1 and some technical inequalities to hold we can prove local asymptotic stability for the MPC closed-loop defined in Algorithm 1, Variant A. To this end, we only use the properties of the first cost function J_1^N and the trajectory convergence. Thus, we can adapt the proof of the single-objective case, see e.g. Grüne and Pannek (2017), and show that the rotated cost function $\widetilde{J}_1^N$ is a time varying Lyapunov function. In our talk we will give insights into the technical assumptions and a sketch of this proof.

Besides the performance of J_1 we are also interested in a non-averaged performance result for J_i^N, $i \in \{2, \dots, s\}$. For this purpose we will use the previous results and combine them with the idea of the performance of single-objective economic MPC without terminal conditions, see Grüne and Pannek (2017). To this end, we consider the trajectories x, which are driven by the efficient solution $\mathbf{u}^\star_{x_0}$. First, we show that the end points of the efficient trajectories are close to the equilibrium because of the stability and the strict dissipative stage cost ℓ_1. Next, in order to establish a performance estimate on J_i, $i \in \{2, \dots, s\}$, we extend the constraint (1) to all $i \in \mathcal{I}$. This way we end up with Algorithm 1 Variant B — an algorithm originally proposed in Grüne and Stieler (2019). However, we still do not require additional properties, such as dissipativity, of the stage cost ℓ_i for $i \geq 2$. Thus, under some technical assumptions we can show that for any $C > 0$ there is a function $\delta \in \mathcal{L}$ such that the performance estimates
$$J_i^K(x_0, \mu^N) \leq J_i^N(x_0, \mathbf{u}^\star_{x_0}) + (K-N)\ell_i(x^e, u^e) + K\delta(N), \tag{5}$$
hold for all $i \in \{2, \dots, s\}$, $N, K \in \mathbb{N}$ with $K \geq N$ and all $x_0 \in \mathbb{X}_N$ with $\|x_0 - x^e\| \leq C$. We remark that for all sufficiently large K the relative error in the estimation above is proportional to $\delta(N)$ and thus decreases to 0 as N tends to infinity. Hence, in terms of the relative error the estimate gives a perfectly useful estimate.

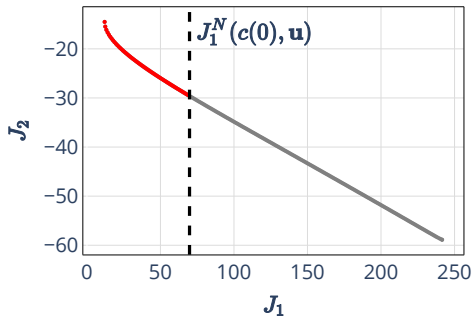
The proofs for all these results will appear in Eichfelder et al. (2022).

5. NUMERICAL SIMULATIONS

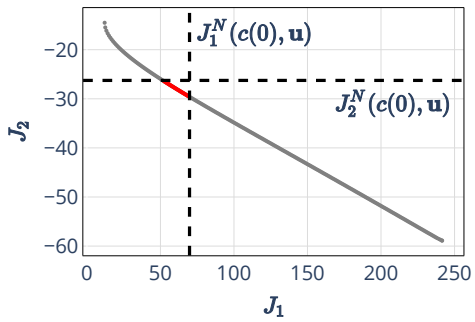
Next, we illustrate the theoretical results of the previous section by numerical simulations. For verifying the theoretical results we use the example of an isothermal chemical reactor, see Diehl et al. (2011); Zavala (2015).

Example 1. We consider a single first-order, irreversible chemical reaction in an isothermal continuous stirred-tank reactor (CSTR). The material balances and the system data are provided in Diehl et al. (2011) and given by
$$\begin{aligned} c_A(k+1) &= c_A(k) + \frac{1}{2}\left(\frac{u(k)}{V}(c_{A_f} - c_A(k)) - k_r c_A(k)\right), \\ c_B(k+1) &= c_B(k) + \frac{1}{2}\left(\frac{u(k)}{V}(c_{B_f} - c_B(k)) + k_r c_B(k)\right), \\ c(0) &= c_0 = (0.4, 0.2) \end{aligned}$$
whereas the stage costs—a tracking type cost forcing the solutions to a desired equilibrium and an economic stage cost maximizing the yield (by minimizing the negative yield) of the reaction—are introduced in Zavala (2015) and given by
$$\begin{aligned} \ell_1(c, u) &= \frac{1}{2}(c_A - \frac{1}{2})^2 + \frac{1}{2}(c_B - \frac{1}{2})^2 + \frac{1}{2}(u - 12)^2, \\ \ell_2(c, u) &= -2uc_B + \frac{1}{2}u. \end{aligned}$$

By setting $\mathbb{X} = [0, 20]$, $\mathbb{U} = [0, 20]$ and $\mathbb{X}_0 = \{(c^e, u^e)\} = \{(\frac{1}{2}, \frac{1}{2}, 12)\}$ we can formulate a multiobjective optimal control problem with terminal constraints of the type (MO OCP). This way, all theoretical assumptions are fulfilled since stabilizing stage cost are a special case of strictly dissipative costs and by setting $\kappa = u^e$ there exists a local feedback with the desired properties. In Figure 1,



Variant A



Variant B

Figure 1. Visualization of step (1) of Algorithm 1

step (1) is visualized for both versions of Algorithm 1 for MPC-horizon $N = 5$. Hence, in Variant A on the left-hand side, only the first cost function J_1^N is restricted whereas on the right-hand side both cost functions are restricted by the additional inequalities (2). Thus, after the first iteration there is still a degree of freedom in choosing the efficient solution. Further, using Variant A of Algorithm 1, we observe trajectory convergence, see Figure 2, and the performance estimate on J_1^N in Figure 3 for MPC-horizon $N = 5$ where the theoretical bound – in dependence of the first chosen efficient solution – is complied.

6. CONCLUSION

We have introduced a new multiobjective MPC algorithm by adapting the algorithm from Grüne and Stieler (2019) and require strong assumptions, namely strict dissipativity and a Lyapunov function terminal cost, only of the first stage cost. For this setting we show that this MOMPC algorithm has the certain desirable properties: feasibility, convergence and stability, and performance results. Finally, we illustrate our theoretical results by means of numerical examples.

Systems theoretic properties of linear RLC circuits

Timo Reis

Institut für Mathematik, Technische Universität Ilmenau, Weimarer Straße 25, 98693 Ilmenau, Germany (e-mail: timo.reis@tu-ilmenau.de).

Abstract: We consider the differential-algebraic systems obtained by modified nodal analysis of linear RLC circuits from a systems theoretic viewpoint. We derive expressions for the set of consistent initial values and show that the properties of controllability at infinity and impulse controllability do not depend on parameter values but rather on the interconnection structure of the circuit. We further present circuit topological criteria for behavioral stabilizability.
This extended abstract is a shortened version of the full paper Glazov and Reis (2020) which has been accepted for the cancelled MTNS 2020 in Cambridge.

Keywords: electrical circuits, stabilizability, system space, consistent initial values, controllability at infinity, impulse controllability

1. INTRODUCTION

Modified nodal analysis (MNA) is a widely used technique for modelling RLC circuits. It has been first introduced in Ho et al. (1975). It is based on regarding a circuit as a graph, and results in a differential-algebraic model. This model provides a structure which allows a mathematically elegant analysis of essential properties and their physical interpretation. Among these properties is the *index*, i.e., the order of smoothness of perturbations entering the solution of the differential-algebraic equation, see Lamour et al. (2013); Kunkel and Mehrmann (2006); it is shown in Estévez Schwarz and Tischendorf (2000); Günther and Feldmann (1999a,b) that the index is not dependent on system parameters (such as values of resistances, capacitances and inductances), but rather on the interconnection structure, i.e., the topology, of the circuit. Further important possible properties of the circuit system are *stability* and *asymptotic stability*. Whereas MNA models of RLC circuits are always stable as long as the parameter values of resistances, capacitances and inductances are positive, asymptotic stability requires some further conditions. It is shown in Riaza and Tischendorf (2010, 2007); Riaza (2006) that asymptotical stability is guaranteed, if certain parameter-independent criteria on the circuit interconnection structure are fulfilled. The general idea of these articles is used in Berger and Reis (2014), where topological criteria for asymptotic stability and autonomy of the zero dynamics are presented for the purpose of adaptive tracking control of circuits.

In this article, we analyse further systems theoretic properties of the MNA equations. Besides presenting sufficient topological criteria for behavioral stabilizability, we derive the space of consistent initial values, and conclude topological conditions for controllability at infinity and impulse controllability. The key ingredient are the results (Estévez Schwarz and Tischendorf, 2000, Lem. 2.1&2.3) & (Riaza and Tischendorf, 2007, Prop. 4.4&4.5), which give direct links between graph theoretical properties of the circuit to linear algebraic conditions on the involved incidence matrices.

2. CIRCUIT EQUATIONS

The MNA of a linear RLC circuit is given by

$$\tfrac{\mathrm{d}}{\mathrm{d}t}Ex(t) = Ax(t) + Bu(t) \tag{1}$$

with state being composed of vertex potentials, inductive currents, and currents through voltage sources, i.e., $x = (\eta^\top i_\mathcal{L}^\top i_\mathcal{V}^\top)^\top$ and input consisting of voltages at voltage sources and currents at current sources, i.e., $u = (v_\mathcal{V}^\top i_I^\top)^\top$. The matrices E, A, B in (1) are given by

$$sE - A = \begin{bmatrix} sA_\mathcal{C}\mathcal{C}A_\mathcal{C}^\top + A_\mathcal{R}\mathcal{G}A_\mathcal{R}^\top & A_\mathcal{L} & A_\mathcal{V} \\ -A_\mathcal{L}^\top & s\mathcal{L} & 0 \\ -A_\mathcal{V}^\top & 0 & 0 \end{bmatrix},\ B = \begin{bmatrix} -A_I & 0 \\ 0 & 0 \\ 0 & -I_{n_\mathcal{V}} \end{bmatrix}, \tag{2}$$

where s has to be regarded as a formal variable. The expression $sE - A$ is called a *matrix pencil*. Here, $\mathcal{G} \in \mathbb{R}^{n_\mathcal{G}\times n_\mathcal{G}}$, $\mathcal{L} \in \mathbb{R}^{n_\mathcal{L}\times n_\mathcal{L}}$, $\mathcal{C} \in \mathbb{R}^{n_\mathcal{C}\times n_\mathcal{C}}$ are the conductance, inductance and capacitance matrix, and

$$A_\mathcal{R} \in \mathbb{R}^{n_e\times n_\mathcal{R}}, \quad A_\mathcal{L} \in \mathbb{R}^{n_e\times n_\mathcal{L}}, \quad A_\mathcal{C} \in \mathbb{R}^{n_e\times n_\mathcal{C}},$$
$$A_\mathcal{V} \in \mathbb{R}^{n_e\times n_\mathcal{V}}, \quad A_I \in \mathbb{R}^{n_e\times n_I}$$

are the element-specific incidence matrices with sizes $n = n_e + n_\mathcal{L} + n_\mathcal{V}$, $m = n_I + n_\mathcal{V}$. The matrices $\mathcal{G}$, $\mathcal{L}$, $\mathcal{C}$ contain the parameters of capacitances, resistances, and inductances. Further, $A_\mathcal{R}$ is an incidence matrix of the spanning subgraph consisting of all edges that contain resistances. Similarly, the incidence matrices $A_\mathcal{L}, A_\mathcal{C}, A_\mathcal{V}, A_I$ then resp. correspond to the spanning subgraphs with the edges to inductances, capacitances, voltage and current source. An incidence matrix of the finite and loop-free directed graph modeling the circuit is consequently given by $A = [A_\mathcal{R}\ A_\mathcal{L}\ A_\mathcal{C}\ A_\mathcal{V}\ A_I]$. It is also reasonable to assume

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

that the circuit graph is connected, as any connected component corresponds to a subcircuit which does not physically interact with the remaining components, so one may simply consider the connected components separately. It can be inferred from (Estévez Schwarz and Tischendorf, 2000, Lem. 2.1&2.3) that connectedness of a circuit is equivalent to

$$\operatorname{rk}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}\ A_I] = n_e. \tag{3a}$$

We consider circuits with *passive* devices. This leads to the assumption that the conductance matrix is dissipative, whereas the inductance and capacitance matrices are positive definite, i.e.,

$$\mathcal{G} + \mathcal{G}^\top > 0, \quad \mathcal{L} = \mathcal{L}^\top > 0, \quad \mathcal{C} = \mathcal{C}^\top > 0. \tag{3b}$$

3. REGULARITY AND STABILITY

We take a closer look at the properties of the properties of the pencil $sE - A$ with matrices as in (2). First we recall some results from Berger and Reis (2014).

Proposition 1. Let $E, A \in \mathbb{R}^{n\times n}$ as in (2) and assume that (3) holds. Then there exist invertible $W, T \in \mathbb{R}^{n\times n}$ with

$$W(sE - A)T = \operatorname{diag}(sI - \tilde{A}, sN - I, 0_{n_0,n_0}), \tag{4}$$

where $n_0 \in \mathbb{N}_0$, N is nilpotent with $N^2 = 0$, and $\tilde{A}$ is a square matrix with the property that all its eigenvalues have nonpositive real part. Further, all eigenvalues of $\tilde{A}$ on the imaginary axis are semi-simple (i.e., their respective geometric and algebraic multiplicities coincide). The pencil $sE - A$ further fulfills

$$\begin{aligned} &\ker_{\mathbb{R}(s)}(sE - A) \\ &= \ker_{\mathbb{R}(s)}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top \times \{0\} \times \ker_{\mathbb{R}(s)} A_{\mathcal{V}}, \\ &\operatorname{im}_{\mathbb{R}(s)}(sE - A) \\ &= \operatorname{im}_{\mathbb{R}(s)}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}] \times \mathbb{R}(s)^{n_{\mathcal{L}}} \times \operatorname{im}_{\mathbb{R}(s)} A_{\mathcal{V}}^\top. \end{aligned} \tag{5}$$

A direct consequence of Prop. 1 is that

$$\begin{aligned} \forall \lambda \in \mathbb{C}_+ :\ &\ker_{\mathbb{C}}(\lambda E - A) \\ &= \ker_{\mathbb{C}}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top \times \{0\} \times \ker_{\mathbb{C}} A_{\mathcal{V}}, \\ \forall \lambda \in \mathbb{C}_+ :\ &\operatorname{im}_{\mathbb{C}}(\lambda E - A) \\ &= \operatorname{im}_{\mathbb{C}}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}] \times \mathbb{R}^{n_{\mathcal{L}}} \times \ker_{\mathbb{C}} A_{\mathcal{V}}^\top. \end{aligned} \tag{6}$$

We further characterize *regularity*, i.e., the invertibility of $sE - A$ in $\mathbb{R}(s)^{n\times n}$. Note that regularity translates to the property of a differential-algebraic equation having a solution for all smooth right hand sides, which is moreover unique by specification of the initial condition, see Kunkel and Mehrmann (2006). (Estévez Schwarz and Tischendorf, 2000, Lem. 2.1&2.3) and Prop. 1 allow to characterize regularity in terms of the circuit topology.

Corollary 2. Let $E, A \in \mathbb{R}^{n\times n}$ as in (2) and assume that (3) holds. Then the pencil $sE - A$ is regular, if and only if, the underlying circuit neither contains $\mathcal{V}$-cycles nor I-cuts; equivalently,

$$\ker[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top = \{0\} \ \wedge\ \ker A_{\mathcal{V}} = \{0\}.$$

Next we consider *generalized eigenvalues* of $sE - A$. This is a complex number λ with $\operatorname{rk}_{\mathbb{C}} \lambda E - A < \operatorname{rk}_{\mathbb{R}(s)} sE - A$. We see from Prop. 1 that all generalized eigenvalues of $sE - A$ have nonpositive real part. In the following we discuss the possible absence of purely imaginary generalized eigenvalues. The absence of generalized eigenvalues on $\overline{\mathbb{C}_+}$ corresponds to stabilizability of the circuit equation $\frac{\mathrm{d}}{\mathrm{d}t}Ex(t) = Ax(t)$. The latter refers to the properties that for all $x_0 \in \mathbb{R}^n$ such that there exists a solution x of $\frac{\mathrm{d}}{\mathrm{d}t}Ex(t) = Ax(t)$ with $Ex(0) = Ex_0$, there also exists a solution x of $\frac{\mathrm{d}}{\mathrm{d}t}Ex(t) = Ax(t)$ with $Ex(0) = Ex_0$ which vanishes at infinity, see (Berger and Reis, 2013, Sec. 5).

Proposition 3. [(Berger and Reis, 2014, Thm. 4.6)] Let $E, A \in \mathbb{R}^{n\times n}$ as in (2) and assume that (3) holds. Then all generalized eigenvalues of $sE - A$ have negative real part, if at least one of the following two assertions holds:

(i) The circuit neither contains $\mathcal{LV}$-cycles except for $\mathcal{V}$-cycles, nor $\mathcal{LCI}$-cuts except for $\mathcal{L}I$-cuts; equivalently,

$$\begin{aligned} \ker[A_{\mathcal{L}}\ A_{\mathcal{V}}] &= \{0\} \times \ker A_{\mathcal{V}}, \\ \wedge\ \ker[A_{\mathcal{R}}\ A_{\mathcal{V}}]^\top &= \ker[A_{\mathcal{R}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top. \end{aligned}$$

(ii) The circuit neither contains $\mathcal{C}I$-cuts except for I-cuts, nor $\mathcal{LCV}$-cycles except for $\mathcal{CV}$-cycles; equivalently,

$$\begin{aligned} \ker[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top &= \ker[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{V}}]^\top, \\ \wedge\ \ker[A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}] &= \{0\} \times \ker[A_{\mathcal{C}}\ A_{\mathcal{V}}]. \end{aligned}$$

Prop. 3 slightly generalizes (Riaza and Tischendorf, 2007, Thm. 5.2), where regularity (i.e., the absence of $\mathcal{V}$-cycles and I-cuts) is presumed. Now we combine Prop. 1 with Prop. 3 to show a condition for $\ker_{\mathbb{C}} \lambda E - A = \{0\}$ for all $\lambda \in \overline{\mathbb{C}_+}$. The latter refers to *asymptotic stability*, i.e., all solutions of $\frac{\mathrm{d}}{\mathrm{d}t}Ex(t) = Ax(t)$ vanish at infinity.

Proposition 4. Let $E, A \in \mathbb{R}^{n\times n}$ as in (2) and assume that (3) holds. Then $\ker_{\mathbb{C}} \lambda E - A = \{0\}$ for all $\lambda \in \overline{\mathbb{C}_+}$, if at least one of the following two assertions holds:

(i) The circuit neither contains $\mathcal{LV}$-cycles, nor $\mathcal{LCI}$-cuts except for $\mathcal{L}I$-cuts which are no I-cuts; equivalently

$$\begin{aligned} \ker[A_{\mathcal{L}}\ A_{\mathcal{V}}] &= \{0\}, \\ \wedge\ \ker[A_{\mathcal{R}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top &= \ker[A_{\mathcal{R}}\ A_{\mathcal{V}}]^\top, \\ \wedge\ \ker[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}]^\top &= \{0\}. \end{aligned}$$

(ii) The circuit neither contains $\mathcal{C}I$-cuts, nor $\mathcal{LCV}$-cycles except for $\mathcal{CV}$-cycles which are no $\mathcal{V}$-cycles; equivalently,

$$\begin{aligned} \ker[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{V}}]^\top &= \{0\}, \\ \wedge\ \ker[A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}] &= \{0\} \times \ker[A_{\mathcal{C}}\ A_{\mathcal{V}}], \\ \wedge\ \ker A_{\mathcal{V}} &= \{0\}. \end{aligned}$$

4. BEHAVIORAL STABILIZABILITY

Loosely speaking, behavioral stabilizability of a differential-algebraic control system (1) means that x can always be asymptotically steered to zero by a suitable choice of the input u. More precisely, for any $x_0 \in \mathbb{R}^n$ for which there exists a control u such that a solution x of (1) with initial condition $Ex(0) = Ex_0$ exists, there especially exists some control u such that a solution x of (1) with $Ex(0) = Ex_0$ exists which vanishes at infinity. It is proven in (Berger and Reis, 2013, Sec. 5) that this is equivalent to

$$\forall\, \lambda \in \overline{\mathbb{C}_+} : \quad \operatorname{rk}_{\mathbb{C}}[\lambda E - A\ B] = \operatorname{rk}_{\mathbb{C}}[\lambda E - A\ B]. \tag{7}$$

Now consider the circuit model $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Then

$$\begin{aligned} & \operatorname{im}_{\mathbb{R}(s)}[sE - A\ B] = \operatorname{im}_{\mathbb{R}(s)}(sE - A) \ + \ \operatorname{im}_{\mathbb{R}(s)} B \\ \overset{\text{Prop.1}}{=} \ & \operatorname{im}_{\mathbb{R}(s)}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}] \times \mathbb{R}^{n_{\mathcal{L}}} \times \operatorname{im}_{\mathbb{R}(s)} \\ & \quad + \operatorname{im}_{\mathbb{R}(s)} A_I \times \{0\} \times \mathbb{R}^{n_{\mathcal{L}}} \\ = \ & \operatorname{im}_{\mathbb{R}(s)}[A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}\ A_I] \times \mathbb{R}^{n_{\mathcal{L}}} \times \mathbb{R}^{n_{\mathcal{V}}} \overset{\text{(3a)}}{=} \mathbb{R}(s)^n. \end{aligned}$$

Likewise, by using (6), the circuit model (2) with assumption (3) fulfills

$$\forall \lambda \in \overline{\mathbb{C}_+} : \ \operatorname{im}_{\mathbb{C}}[\lambda E - A\ B] = \mathbb{C}^n. \tag{8}$$

As a consequence, the circuit model is behaviorally stabilizable if, and only if, $\operatorname{rk}_{\mathbb{C}}[\imath\omega E - A\ B] = n$ for all $\omega \in \mathbb{R}$. This is used in the following result, where we present sufficient conditions for behavioral stabilizability in terms of the circuit topology.

Proposition 5. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Then (1) is behaviorally stabilizable, if at least one of the below two statements holds:

(i) The circuit neither contains $\mathcal{L}$-cycles, nor $\mathcal{LC}$-cuts except for $\mathcal{L}$-cuts; equivalently,

$$\begin{aligned} \ker A_{\mathcal{L}} \ &= \{0\}, \\ \wedge \ \ker [A_{\mathcal{R}}\ A_{\mathcal{C}}\ A_{\mathcal{V}}\ A_I]^\top \ &= \ker [A_{\mathcal{R}}\ A_{\mathcal{V}}\ A_I]^\top . \end{aligned}$$

(ii) The circuit neither contains $\mathcal{C}$-cuts, nor $\mathcal{LC}$-cycles except for $\mathcal{C}$-cycles; equivalently,

$$\begin{aligned} \ker [A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{V}}\ A_I]^\top \ &= \{0\}, \\ \wedge \ \ker [A_{\mathcal{L}}\ A_{\mathcal{C}}] \ &= \{0\} \times \ker A_{\mathcal{C}}. \end{aligned}$$

Remark 1. Behavioral stabilizability is implied by *behavioral controllability*, which is defined by concatenation of trajectories (Polderman and Willems, 1998, Def. 5.2.2), and it is algebraically characterized by

$$\forall \lambda \in \mathbb{C} : \ \operatorname{rk}_{\mathbb{C}} [\lambda E - A\ B] = \operatorname{rk}_{\mathbb{R}(s)} [sE - A\ B],$$

see (Berger and Reis, 2013, Cor. 4.3). Note that this property is parameter dependent, as it can be seen from (Polderman and Willems, 1998, Ex. 5.2.13).

5. SYSTEM SPACE

A useful space to understand differential-algebraic systems is the *system space*, which is the minimal subspace $V \subset \mathbb{R}^{n+m}$ in which all solutions $(x(t)^\top u(t)^\top)^\top$ of (1) evolve pointwisely. This space plays a crucial role, for instance in optimal control and dissipativity analysis of differential-algebraic systems, see Reis and Voigt (2015, 2019).

The main result in this section is an expression for the system space of the MNA equations (2).

Theorem 6. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Let $Z_{\mathcal{C}}$ and $Z_{\mathcal{RCVI}}$ be basis matrices of $\ker A_{\mathcal{C}}^\top$ and, resp., $\ker[A_{\mathcal{C}}\ A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{V}}\ A_I]^\top$. Then the system space of (1) is given by

$$\ker \begin{bmatrix} Z_{\mathcal{C}}^\top A_{\mathcal{R}} \mathcal{G} A_{\mathcal{R}}^\top & Z_{\mathcal{C}} A_{\mathcal{L}} & Z_{\mathcal{C}}^\top A_{\mathcal{V}} & Z_{\mathcal{C}}^\top A_I & 0 \\ A_{\mathcal{V}}^\top & 0 & 0 & 0 & -I_{n_{\mathcal{V}}} \\ Z_{\mathcal{RCVI}}^\top A_{\mathcal{L}} \mathcal{L}^{-1} A_{\mathcal{L}}^\top & 0 & 0 & 0 & 0 \end{bmatrix}.$$

Thm. 6 means that a vector $(x_1^\top\ x_2^\top\ x_3^\top\ u_1^\top\ u_2^\top)^\top$ partitioned according to the blocks in $[A\ B]$ as in (2) is in the system space of (1) if, and only if, it satisfies

$$\begin{aligned} Z_{\mathcal{C}}^\top (A_{\mathcal{R}} \mathcal{G} A_{\mathcal{R}}^\top x_1 + A_{\mathcal{L}} x_2 + A_{\mathcal{V}} x_3 + A_I u_1) &= 0, \\ A_V^\top x_1 - u_2 &= 0, \\ Z_{\mathcal{RCVI}}^\top A_{\mathcal{L}} \mathcal{L}^{-1} A_{\mathcal{C}}^\top x_1 &= 0. \end{aligned}$$

6. CONSISTENT INITIAL VALUES AND CONTROLLABILITY AT INFINITY

Here we analyze the space of consistent initial values, which is the space of all $x_0 \in \mathbb{R}^n$ for which there exists some control u for which there is a weakly differentiable solution x of (1) with initial condition $x(0) = x_0$. If this space is the entire $\mathbb{R}^n$, then the system (1) is called *controllable at infinity*. It is proven in (Berger and Reis, 2013, Sec. 5) that controllability at infinity is equivalent to $\operatorname{rk}[E\ B] = \operatorname{rk}[E\ A\ B]$. For $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in the circuit model (2) with assumption (3), we can conclude from (8) that $\operatorname{rk}[E\ A\ B] = n$, whence the analysis of controllability at infinity for MNA equations reduces to check whether $\operatorname{rk}[E\ B] = n$. By using $\mathcal{C} > 0$, $\mathcal{L} > 0$, we obtain that $\operatorname{im} E = \operatorname{im} A_{\mathcal{C}} \times \mathbb{R}^{n_{\mathcal{L}}} \times \{0\}$, whence

$$\operatorname{im}[E\ B] = \operatorname{im} A_{\mathcal{C}} \times \mathbb{R}^{n_{\mathcal{L}}} \times \{0\} + \operatorname{im} A_I \times \{0\} \times \mathbb{R}^{n_{\mathcal{V}}}.$$

Controllability at infinity is therefore guaranteed if, and only if, $\operatorname{im}[A_{\mathcal{C}}\ A_I] = \mathbb{R}^{n_e}$ or, equivalently, $\ker[A_{\mathcal{C}}\ A_I]^\top = \{0\}$. We summarize these findings in the following result.

Proposition 7. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Then the system (1) is controllable at infinity if, and only if, the underlying circuit does not contain any $\mathcal{RLV}$-cuts; equivalently,

$$\ker [A_{\mathcal{C}}\ A_I]^\top = \{0\}.$$

It can be concluded from (Reis and Voigt, 2019, Lem. 3.7) that the system space $\mathcal{V}_{\text{sys}}$ and the space $\mathcal{V}_{\text{init}}$ of consistent initial values of the system (1) fulfill the identity

$$\mathcal{V}_{\text{init}} = \{x \in \mathbb{R}^n \ : \ \exists u \in \mathbb{R}^m \text{ s.t. } \left(\begin{smallmatrix} x \\ u \end{smallmatrix}\right) \in \mathcal{V}_{\text{sys}}\}. \tag{9}$$

This identity is the essential ingredient in the proof of the following result which contains an expression of the space of consistent initial values for the MNA system.

Theorem 8. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Let $Z_{\mathcal{RCVI}}$ and $Z_{\mathcal{CI}}$ be basis matrices of $\ker[A_{\mathcal{C}}\ A_{\mathcal{R}}\ A_{\mathcal{L}}\ A_{\mathcal{V}}\ A_I]^\top$ and, resp., $\ker[A_{\mathcal{C}}\ A_I]^\top$. Then the space of consistent initial values of (1) is given by

$$\ker \begin{bmatrix} Z_{\mathcal{RCVI}}^\top A_{\mathcal{L}} \mathcal{L}^{-1} A_{\mathcal{L}}^\top & 0 & 0 \\ Z_{\mathcal{CI}}^\top A_{\mathcal{R}} \mathcal{G} A_{\mathcal{R}}^\top & Z_{\mathcal{CI}}^\top A_{\mathcal{L}} & Z_{\mathcal{CI}}^\top A_{\mathcal{V}} \end{bmatrix}.$$

In the case where there are no $\mathcal{RLV}$-cuts, we can conclude from (Estévez Schwarz and Tischendorf, 2000, Lem. 2.1&2.3) that both Z_{IC} and $Z_{\mathcal{RCVI}}$ are trivial, i.e., these matrices have zero columns. Consequently, we also obtain from Thm. 8 that the absence of $\mathcal{RLV}$-cuts causes that any vector in $\mathbb{R}^n$ is a consistent initial value for the MNA system (cf. Prop. 7).

7. CONSISTENT INITIAL DIFFERENTIAL VALUES AND IMPULSE CONTROLLABILITY

We now consider another type of initialization, namely (1) with initial condition $Ex(0) = Ex_0$. $x_0 \in \mathbb{R}^n$ is called a *consistent initial differential value*, if there exists a control u for which a solution x of (1) with initial condition $Ex(0) = Ex_0$ exists. If this space equals to $\mathbb{R}^n$,

then the system (1) is called *impulse controllable*. It is proven in (Berger and Reis, 2013, Sec. 5) that impulse controllability is equivalent to $\operatorname{rk}[E\ AZ\ B] = \operatorname{rk}[E\ A\ B]$ for some (and hence any) basis matrix Z of $\ker E$. By again using that the circuit model (2) with assumption (3) has the property $\operatorname{rk}[E\ A\ B] = n$, it is impulse controllable if, and only if, $\operatorname{rk}[E\ AZ\ B] = n$. By using that $\mathcal{C} > 0$ and $\mathcal{L} > 0$ by (3b), we obtain that a basis matrix of $\ker E$ is given by $Z = \operatorname{diag}(Z_C, 0, I)$, where Z_C is a basis matrix of $\ker A_C^\top$. Then

$$\begin{aligned}\operatorname{rk}[E\ AZ\ B] &= \operatorname{rk}\begin{bmatrix} A_C\mathcal{C}A_C^\top & 0 & A_\mathcal{R}\mathcal{G}A_C^\top Z_C & A_\mathcal{V} & A_I & 0 \\ 0 & \mathcal{L} & -A_\mathcal{L}^\top Z_C & 0 & 0 & 0 \\ 0 & 0 & -A_\mathcal{V}^\top Z_C & 0 & 0 & I_{n_\mathcal{V}} \end{bmatrix} \\ &= \operatorname{rk}[A_C\ A_\mathcal{R}\mathcal{G}A_\mathcal{R}^\top Z_C\ A_\mathcal{V}\ A_I] + n_\mathcal{L} + n_\mathcal{V}. \end{aligned} \tag{10}$$

If $\ker[A_C\ A_\mathcal{R}\ A_\mathcal{V}\ A_I]^\top \neq \{0\}$, (10) implies $\operatorname{rk}[E\ AZ\ B] < n$. Conversely, if $\ker[A_C\ A_\mathcal{R}\ A_\mathcal{V}\ A_I]^\top = \{0\}$ and $x_1 \in \ker[A_C\ A_\mathcal{R}\mathcal{G}A_\mathcal{R}^\top Z_C\ A_\mathcal{V}\ A_I]^\top$, then $x_1 \in \ker A_C$, i.e., $x_1 = Z_C z_1$ for a vector z_1, and thus $Z_C^\top A_\mathcal{R}\mathcal{G}A_\mathcal{R}^\top Z_C z_1 = 0$. Then $\mathcal{G} + \mathcal{G} > 0$ leads to $A_\mathcal{R}^\top x_1 = A_\mathcal{R}^\top Z_C z_1 = 0$, whence $x_1 \in \ker[A_C\ A_\mathcal{R}\ A_\mathcal{V}\ A_I]^\top = \{0\}$. We summarize these findings in the following result.

Proposition 9. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Then the system (1) is impulse controllable if, and only if, the underlying circuit does not contain any $\mathcal{L}$-cuts; equivalently,

$$\ker\left[A_\mathcal{R}\ A_C\ A_\mathcal{V}\ A_I\right]^\top = \{0\}.$$

Theorem 10. Let $E, A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$ as in (2) and assume that (3) holds. Let $Z_{\mathcal{RCVI}}$ be a basis matrix of $\ker[A_C\ A_\mathcal{R}\ A_\mathcal{L}\ A_\mathcal{V}\ A_I]^\top$. Then the space of consistent initial differential values of (1) is given by

$$\ker\left[0\ Z_{\mathcal{RCVI}}^\top A_\mathcal{L}\ 0\right].$$

In the case where the circuit does not contain any $\mathcal{L}$-cuts, we can conclude from (Estévez Schwarz and Tischendorf, 2000, Lem. 2.1&2.3) that $Z_{\mathcal{RCVI}}$ are trivial, i.e., it has zero columns. As a consequence, we also obtain from Thm. 10 that in the case of absence of $\mathcal{L}$-cuts, any vector in $\mathbb{R}^n$ is a consistent initial differential value for the MNA system (cf. Prop. 9).

CONCLUSION

We have analyzed the MNA equations of linear time-invariant RLC circuits by using linear algebraic and graph theoretical techniques. Circuit topological criteria for regularity, stability, and behavioral stabilizability, controllability at infinity and impulse controllability have been derived. Moreover, our approach leads to explicit expressions for the system space and for the space of consistent initial (differential) values.

Moment based parametrization of higher order stochastic models

Patrick Dewilde

TUM-IAS, (email: p.dewilde at me.com)

Paper accepted for presentation at MTNS 2020 in Cambridge.
AMS classification: 60G25, 37M05, 30E05

Abstract: The paper reports results on the modeling of related stochastic variables, based on a finite fully ordered sequence of higher order moments (or correlations), and using mutually independent parameters that characterize all solutions that interpolate the given (or measured) data. The results are obtained by determining properties of the hierarchical generalized Hankel matrix of the moments. A system theoretic approach is used to derive the results. It appears that an extension of the related Hamburger-Jacobi orthogonal polynomials to the multivariate case does not suffice to yield a parametrization, but a further reduction of the recursive Cholesky factorization of the moment matrix does.

Keywords: parametrization, multivariate moments, stochastic models

1. INTRODUCTION

Modeling stochastic variables has been a central piece of endeavor in signal processing, leading in particular to the famous Levinson model filters [Kailath (1976)], and their Schur parameter implementation [Dewilde et al. (1978)], in which a (zero means) stochastic process for which n specific covariance data items have been measured is modeled by an artificial linear filter of order n driven by (artificial) white noise. This order n stochastic modeling is known to provide a 'best' possible model when the original process is known to be zero mean Gaussian, where 'best' can be understood as reproducing (interpolating) the measured covariance data and being as unspecified as possible concerning unspecified covariances (i.e., maximum entropy for the unknown parameters, while satisfying the positivity of the covariance matrix). From the model a predictor or estimator can be derived, which, in the specific Gaussian case, is both the conditional expectation as well as the maximum likelihood estimate. It may be remarked that the coefficients of the Levinson polynomials do not form an independent parametrization, but the Schur coefficients do. (The Levinson coefficients have potentially very sensitive internal relations!)

However, many processes are highly non-Gaussian so that non-linear moment information is needed if any modeling accuracy is to be obtained for them [Zarzycki (2004)]. The modeling filter (also to be driven by an artificially constructed process) will have to be non-linear if any accuracy (preferably interpolation of the known data) is to be obtained. Needless to say, the problem just stated is not solvable in all generality, but with the condition of a fully ordered sequence of moments starting at zero it is. This parametrization problem for one variable is fully solved by using the classical Hamburger theory and the parametrization implicit in the related orthogonal polynomial Jacobi recursion [Hamburger (1920-21)]. In this paper, we show how Hamburger's results extend to multiple variables (as they occur in a stochastic process), for as far as independent parametrization is concerned. The general aim is to generate an interpolating pdf of the variables present, i.e., a pdf that is as simple as possible while matching the known data. The present paper expands on the recent publication of the basic theory in [Dewilde (2020)]. In particular, extensions to the nD case as summarized is new.

Notation: I use MATLAB indexing notation, with some abbreviations: $A_{i:j}^{k:l}$ form a (sub)matrix of the (block) matrix A with (block) rows i to j and columns k to l; A' is the transpose of A. A fat index $\underline{\imath}$ indicates a generic order. Expectation is abbreviated by an overline: $\overline{X} = \mathbf{E}X$.

Modeling principle: Given a multidimensional pdf for a joint process involving $n+1$ stochastic variables $Y_0, \cdots, Y_n$, then the best possible model in the pdf sense, is a set of artificial stochastic variables $X_{0:n}$ with the same overall distribution, and the best model for X_0, assuming the $[X_i]_{i=1:n}]$ known, is the conditional probability $\widehat{X}_0 = X_0|_{[X_i]_{i=1:n}]}$. When not the original multidimensional pdf is known, but only some data related to it, then the modeling problem is to find a parametrization of all possible pdf's that match the given data, so that the most adequate solution (for example: the least complex one, or a solution that matches other criteria) can be found. Under *parametrization* we understand a characterization that uses a set of *independent* parameters, i.e., parameters that can be chosen independently from each other and still produce a solution that matches the original data. In our case, the data that we shall match will be a fully ordered set of moments.

The conditional probability is a stochastic variable in one dimension, with a specific pdf for each value of the n-tuple $X_{1:n}$. In the Gaussian case, this pdf is Gaussian as well and its argument is $x - \mu$ with $\mu = -\sum_{i=1:n} a_i x_i$, which is linearly dependent on the $x_{1:n}$ with Levinson coefficients a_i

and a related variance. In the general case the statistics of the estimate is non-Gaussian. The method proposed here determines a discretized version of the pdf, which matches the desired moments exactly. In case not a model is needed, but an estimation or prediction, some strategy is needed to select one representative value. This can be a mean, a median, maximum likelihood or any desirable average.

It has been thought that the moment modeling problem can be solved using an extended version of the classical Schur-Levinson recursion. That is pertinently (but perhaps unfortunately) not true. The modeling problem based on second order covariances in the scalar time invariant case consists in parametrizing positive definite Toeplitz matrices and is essentially different from the moment problem, which consists in characterizing positive definite Hankel matrices. The characteristics, symmetries and number of parameters involved are different, and the resulting models are correspondingly different.

Nonetheless, the solution of both problems uses recursive orthogonalizations of a growing sequence of positive-definite matrices, different in each case. This can already be illustrated on a 2 by 2 positive definite matrix. In the Schur case, three independent numbers $a > 0$, $b > 0$ and $\rho : |\rho < 1|$ parametrize a (non-singular) positive definite matrix as $\begin{bmatrix} a & \rho\sqrt{ab} \\ \rho\sqrt{ab} & b \end{bmatrix}$ while in the moment case (which will be discussed further), the parametrization consists of two positive numbers a, c and an arbitrary number b: $\begin{bmatrix} a & b \\ b & \frac{b^2}{a} + c \end{bmatrix}$ (in both instances, the singular case is a bit more complex.)

The problem to be considered in this paper is the extension of moment parametrization to higher dimensions. Orthogonal polynomials can be extended to the block matrix or multivariable case, as is done for the Levinson case in [Vieira (1977)] and for the moment case in [Arizn-Abarreta and Mañas (2014)]. However, the generalized Jacobi parameters in the multivariate moment case do not amount to a parametrization (nor do Levinson parameters do in the Gaussian estimation case, only Schur parameters are independent [Dewilde and Deprettere (1987)].) A further refinement is needed, and that is the main result of this paper.

The presentation starts out with a brief review of the classical (scalar) Hamburger-Jacobi moment matching case first, but then concentrates on the multivariable stochastic modeling problem given a coherent set of higher order correlation data. Since the matrices to be handled are 'Hankel-like', and Hankel matrices play a key role in system theory, a system-theoretic approach is called for and will be used throughout. Such an approach matches well with the central role played by Cholesky factorization and Schur complementation in the theory.

2. THE 1-D MOMENT MATCHING PROBLEM

Given a required set of moments $\mu_{0:2n}$, can we find a stochastic variable X of minimal complexity that matches them (i.e., $\mu_k = \overline{X^k}$) and find parametrizations for the solutions (notice that, in contrast with the Schur case, one needs $2n$ values for an order n problem)? This question has been very beautifully resolved by Hamburger and Akhiezer, see [Hamburger (1920-21); Akhiezer (1965)], in which the connection between Hankel matrices and Jacobi matrices is exploited to build polynomials that are orthogonal with respect to a positive measure on the real line. Such measures correspond to pdf's (probability density functions) of a stochastic variable. A pdf can only consist of a measurable positive function and positive Dirac impulses. We do not repeat the Akhiezer theory here, but build on it by making the connection with dynamical system theory, in which Hankel matrices play a central role.

A *Jacobi matrix* is by definition a symmetric, tridiagonal matrix, in which the main diagonal is a sequence $\{a_k\}_{k=0:}$ of arbitrary coefficients, and the first off diagonal is a sequence of positive coefficients $\{b_k\}_{k=0:}$, with the termination rule: either all $b_n > 0$ or the series terminate at the first n for which $b_n = 0$. The relation between a positive definite Hankel matrix $H_{\mathbf{n}}$ of dimension $(n+1)^2$ and a related Jacobi matrix can be understood in various ways. Akhiezer uses orthogonal polynomials, with $H_{\mathbf{n}}$ as the Gramian defining the inner product. Here we follow a somewhat different (but of course equivalent) path, based on Cholesky factorization. Let $H_{\mathbf{n}} = L_{\mathbf{n}} L'_{\mathbf{n}}$ be a Cholesky factorization (i.e., $L_{\mathbf{n}}$ is lower triangular).

Case 1: $H_{\mathbf{n}}$ is non-singular. Then $L_{\mathbf{n}}^{-1}$ exists as a lower triangular matrix, and let the rows of $L_{\mathbf{n}}^{-1}$ be defined as $p_{k,:} := [L_{\mathbf{n}}^{-1}]_{k,:}]$. Next we define the k^{th} polynomial $P_k(z) := p_{k,0} + p_{k,1}z + \cdots + p_{k,k}z^k$. It follows immediately that $p_{k,:} H_{\mathbf{n}} p'_{\ell,:} = \delta(k-\ell)$, which is also the usual definition of orthonormality for the $P_k(z)$ with respect to the Gramian $H_{\mathbf{n}}$ (the *inner product* $(P_k(z), P_\ell(z))$ being defined as $p_{k,:} H_{\mathbf{n}} p'_{\ell,:}$). Next, $p_{k,:} H_{\mathbf{n}} e_\ell = 0$ (with $[e_\ell]_j := \delta(\ell - j)$ the ℓ^{th} natural base vector) for $\ell < k$, hence $P_k(z) \perp z^\ell$ for $\ell < k$, and this just because $L_{\mathbf{n}}^{-1} H_{\mathbf{n}} = L_{\mathbf{n}}^{-\prime}$ is upper triangular. It follows that the $P_k(z)$ satisfy a three term recursion

$$zP_k(z) = b_k P_{k-1}(z) + a_k P_k(z) + b_{k+1} P_{k+1}(z) \qquad (1)$$

because 1., both $\{[z^\ell]_{\ell=0:k}\}$ and $\{[P_\ell]_{\ell=0:k}\}$ form bases for the same space and 2., the inner products $(zP_k(z), P_\ell(z)) = (P_k(z), zP_\ell(z))$ are equal, due to the Hankel symmetry.

Infinite non-singular positive definite Hankel matrices can be Cholesky factorized for as much as one wants to go, just by extending the Cholesky factorization of finite restrictions. So, when $H_{\mathbf{m}} = L_{\mathbf{m}} L'_{\mathbf{m}}$ and similarly $H_{\mathbf{n}}$ with $m > n$ are Cholesky factorizations, then $L_{\mathbf{m}}$ is a submatrix of $L_{\mathbf{n}}$, which can be obtained recursively by just extending $H_{\mathbf{m}}$ and $L_{\mathbf{m}}$ recursively (as is usually done in Cholesky factorization). In this way we may consider the infinite Hankel H and its Cholesky factoriztion $H = LL'$, although these infinite matrices are only defined numerically and will typically be very much unbounded. Calculus on such matrices is allowed so long as it remains unilateral, meaning: recursively increasing. This works for the determination of orthonormal polynomials, and the inner products on which they depend, for as long as one works on finitely supported vectors. Let then $[\sigma]_{k,\ell} = \delta(k+1-\ell)$ be the infinitely supported upper shift matrix then the Hankel symmetry on the global Hankel series is

equivalent to $\sigma H = H\sigma'$. Suppose now that $H = LL'$ and L, being lower triangular, is recursively invertible.

Proposition 1. A recursively invertible L is the lower Cholesky factor of a strictly positive definite Hankel matrix iff $J = L^{-1}\sigma L$ is a Jacobi matrix. J characterizes L (and H) uniquely.

Proof One checks that the equations $JL^{-1} = L^{-1}\sigma$ are exactly those that define the three terms recursion. Uniqueness of the solution does the rest.□

The merit of the proposition (and equivalently, the three term recursion) is that it characterizes 'Hankelness' in terms of the Cholesky factor L. The case for a non-singular but finite Hankel matrix is similar, but a bit involved due to the singularity of the finite shift matrix. We shall soon see that it can be derived from a step one extension, which we discuss now.

Case 2: let us assume the positive definite $H_{\mathbf{n}}$ non-singular, and search for a one-step augmentation of $H_{\mathbf{n}}$ to a singular $H_{\mathbf{n+1}} = \begin{bmatrix} H_{\mathbf{n}} & \mu_{n+1:2n+1} \\ \mu'_{n+1:2n+1} & \mu_{2n+2} \end{bmatrix}$. μ_{2n+1} can be chosen arbitrarily, and next $\mu_{2n+2} = \mu'_{n+1:2n+1} H_{\mathbf{n}}^{-1} \mu_{n+1:2n+1}$ must be the Schur complement of μ_{2n+2} if $H_{\mathbf{n+1}}$ is to be singular. From system theory (realizations), we now know that there exist an $(n+1)\times(n+1)$ matrix A and (n+1)-vectors B and C' so that $\mu_k = CA^kB$. Additionally, because $H_{\mathbf{n+1}}$ is symmetric, one can choose A symmetric and $C' = B$. It follows that the eigenvalues of A are all real and there shall exist a unitary state transformation matrix U so that $UAU' = \mathrm{diag}[\alpha_i]$ is diagonal. Redefining the realization $A \leftarrow UAU', B \leftarrow \beta = Ub, C' \leftarrow Uc' = \beta'$ then produces $\mu_k = \sum_{i=0:n} \beta_i^2 \alpha_i^k$. It follows that the moments $\mu_{0:2n+2}$ can be generated by an *atomic* pdf $p(x) = \sum_{i=0:n} \beta_i^2 \delta(x-\alpha_i)$. To this there corresponds a rational *generating function* $G_X(z) = 1 + \mu_1 z + \mu_2 z^2 + \cdots = \sum_{i=1:n} \frac{b_i^2}{1-za_i}$ and we have that $G_X(z)$ matches the $2n+2$ first moments of $G_Y(z)$.

Remark 1: once $H_{\mathbf{n+1}}$ is singular of rank n, then all subsequent H_k $(k > n)$ are singular of rank n as well, and all moments are given by $\mu_k = \beta' A^k \beta$. Every given partial series $\mu_{0:2n}$ with $H_{\mathbf{n}}$ non-singular has a rational generating function of degree n, and can be continued with all subsequent $H_{\mathbf{k}}$, $k > n$, singular.

Remark 2: the generating function $G(z)$ is generally highly unstable, and should be handled using polynomial calculus on unilateral series.

Remark 3: the generating function corresponding to a zero means Gaussian variable of variance σ has $\mu_k = (k-1)!!\sigma^k$, where $(k-1)!!$ equals 0 when k is odd and otherwise $1\cdot 3\cdots(k-1)$. Hence, it converges nowhere in the complex plane (except at zero).

A further observation leads to another interesting result connecting realization theory with Jacobi matrices:

Proposition 2. The realization for $G(z) = \sum_{k=0:} B'A^kBz^k$ based on a Cholesky factorization of the non-singular $H_{\mathbf{n}} = L_{\mathbf{n}} L'_{\mathbf{n}}$ is given by $\{A, B, B'\} \leftarrow \{J_n, e_0, e'_0\}$, in which $[e_0]_k = \delta(k)$ and $J_{\mathbf{n}}$ is the n^{th} order Jacobi matrix related to the singular $H_{\mathbf{n+1}}$. Conversely, any such realization produces a moment series μ_k with non-singular positive $H_{\mathbf{n}}$ and singular $H_{\mathbf{n+1}}$.

Proof (sketch) The Cholesky factorization produces the relation, for $1 < k \le n$,

$$p_k^{\rightarrow} = b_{k-1}p_{k-1} + a_k p_k + b_k p_{k+1}, \tag{2}$$

with $p_k^{\rightarrow}$ a right shift version of p_k. This relation is equivalent to (1).

3. GENERALIZED HANKELS IN TWO AND N VARIABLES

Two stochastic variables (2D). A full moment matrix in two dimensions is $\overline{\mathbf{X}\mathbf{X}'}$ for $\mathbf{X}' := \left[1 \middle| X\ Y \middle| X^2\ XY\ Y^2 \middle| \cdots\right]$. Such matrices (also for more variables) have a *hierarchical* Hankel structure, in the sense that blocks on anti-diagonals contain the same elements and are internally Hankel as well, with compatible ordering structures. Connected to the

Fig. 1. The 2D Hankel structure in H_3

2D case we can define a 2D generating function, very much in the same way as in the 1D case, but now introducing two variables z_1 and z_2, summed by order and then as $\mu(I-i,i)_{i=0:I} = (\overline{X^{I-i}Y^i})_{i=0:I}$ within order I: $G(z_1,z_2) = \sum_{I=0:,(i=I:0,j=I-i)} \mu_{i,j} z_1^i z_2^j$, which can also be seen as the unilateral expansion in 2D of $\mathbf{E}\frac{1}{(1-z_1X)(1-z_2Y)}$. We now have almost immediately:

Theorem 1. A rational generating function $G(z_1,z_2)$ corresponds to a 2D atomic distribution.

The **proof** is based on considering marginals and applying the 1D theory on them.

Orthogonalization of the non-singular $\mathbf{X}$ series in order produces a 2D orthogonal sequence and corresponding block tri-diagonal Jacobi matrix of the form

$$\begin{bmatrix} P_{00}X \\ P_{00}Y \\ \hline P_{10}X \\ P_{01}X \\ P_{01}Y \\ \hline P_{20}X \\ P_{11}X \\ P_{02}X \\ P_{02}Y \end{bmatrix} = \left[\begin{array}{cc|ccc|ccc|cccc} * & a & & & & & & & & & & \\ * & * & c & & & & & & & & & \\ \hline a & * & h & d & & & & & & & & \\ 0 & h & * & e & f & & & & & & & \\ c & * & * & * & * & g & & & & & & \\ \hline 0 & d & e & * & i & j & * & & & & & \\ 0 & 0 & f & i & * & k & * & * & & & & \\ 0 & 0 & 0 & j & k & * & * & * & * & & & \\ 0 & 0 & g & * & * & * & * & * & * & * & * \end{array}\right] \begin{bmatrix} P_{00} \\ \hline P_{10} \\ P_{01} \\ \hline P_{20} \\ P_{11} \\ P_{02} \\ \hline P_{30} \\ P_{21} \\ P_{12} \\ P_{03} \end{bmatrix} \tag{3}$$

in which the upper block diagonal is non-singular and redundancies are indicated with like literals. Unlike in the 1D case, the orthogonalization does not deliver a full parametrization. The coefficients on the rightmost diagonal can be chosen independently, but not the others, and there are more hidden dependencies than indicated by

the literals. Let us therefore consider a full order update of the 2D hierarchical Hankel matrix, namely $H_{\mathbf{i}} \Rightarrow H_{\mathbf{i+1}}$. $H_{\mathbf{i+1}}$ inherits $H_{\mathbf{i}}$ and $H_{0:i}^{i+1}$ from the previous step, only H_i^{i+1} and H_{i+1}^{i+1} are new. H_i^{i+1} is Hankel and of odd order: its entries may be chosen arbitrarily. H_{i+1}^{i+1} has to be Hankel and such that the whole $H_{\mathbf{i+1}}$ is positive definite, which will be the case iff $H_{i+1}^{i+1} \geq S_{i+1}$, for the *Schur residue* $S_{i+1} := L_{i+1}^{0:i}(L_{i+1}^{0:i})'$ (notice: $L_{i+1}^{0:i}$ is known at this point.) The Schur residue itself is not Hankel, but the following holds:

Proposition 3. A non-singular L_{i+1}^{i+1} can be fully parametrized by arbitrary strictly positive numbers on the main diagonal, and arbitrary numbers on the first lower diagonal.

This solves the 2D parametrization problem for the non-singular case.

The singular case. Any discretized pdf as final result of a parametrization, must involve steps that finally make the full moment matrix singular. This is done by deciding on the maximal degree of one of the variables, making the column corresponding to that variable singular, and deleting all columns corresponding to monomials having that power as a factor. The non-singular proceeding can then be continued on the pruned system. For 1D systems, one can just puts the last Jacobi coefficient $b_n = 0$, and the Hankel remains singular and fully determined from that point on. This produces a (non-uniform) discretization of the pdf. For 2D systems, the progressive order can be reduced in two steps: a first reduction produces a polynomial algebraic relation between X and Y, and a second reduction makes the complete system redundant from that order on, resulting in a 2D discretization of the pdf. These two steps can be combined in one. It turns out that this generalizes to nD systems, which can be reduced in n steps, using linear dependencies and generalized Hankel symmetries. Each time a singularity is introduced in a column corresponding to a monomial, say M, then all rows and columns corresponding to monomials that have M as a factor are determined, and the characterization can be continued on a reduced set of moments.

The nD case: The procedure described for the 2D case generalizes to n variables, with mostly technical complications, due to the increased hierarchy. Keeping the reverse lexicographic order at each degree we now have as global stochastic vector

$$\mathbf{X}' := [1|X, Y, Z, \cdots|X^2, XY, XZ, \cdots]. \tag{4}$$

The basic principles remain: (1) odd orders can be chosen arbitrarily (in the non-singular case, in the singular cases many are determined by singularity reductions), and (2) only the central order update block has to be parametrized further recursively so that it becomes larger than the Schur residue, and this is achieved again by specifying its diagonal and subdiagonal entries, in a recursive way corresponding to a one-order lower update. Fig. 2 shows the order of parameter determination for order 4 in the 3D case, starting form the left upper corner: regular Jacobi for the first block, the next two blocks are odd and free, the next diagonal block requires an application of proposition 3 etc. It follows that recursive applications of filling in odd blocks followed by applications of proposition 3 lead to the solution for the 3D case. Likewise, the nD case reduces to recursive applications of the (n-1)D case etc. Only blocks

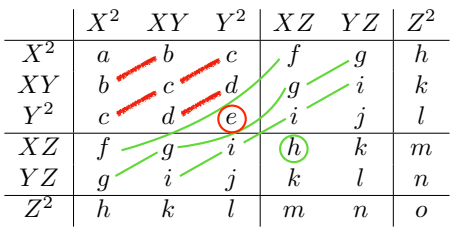

Fig. 2. The order update illustrated on order 4 in the 3D case.

on main diagonals specify free positive entries on top of Schur residues, while odd blocks can be chosen at will at all levels.

The considerations given so far lead to general extensions as well: assuming non-singularity up to some level n, obtained by adding central $[H_{\mathbf{k}}]_{k,k}$'s which are strictly larger that the k^th order Schur complement S_k for $k < n$, when a sufficient level of n of sampling accuracy is obtained, a new $[H_{\mathbf{n}}]_{n,n}$ has to be added for which $[H_{\mathbf{n}}]_{n,n} - S_{\mathbf{n}}$ is rank deficient of order 2. When that is the case, then all subsequent Hankels will be rank deficient, which, after at most n such steps, leads to an atomic distribution that meets the moment data up to order n.

So far for the basic parametrization. The method can be refined considerably by using the connection between Cholesky factors and Jacobi parameters in scalar cases or Jacobi blocks in higher order cases. How this works is beyond the present paper.

Abstract: Hamilton's principle is one of the most fundamental principle in physics. Incorporating the principle into data-driven models of dynamical systems guarantees that motions share important qualitative properties with the real system, such as energy or momentum conservation. To learn Lagrangian dynamics, we propose to learn inverse modified Lagrangians related to variational integrators instead of attempting to learn an exact Lagrangian, as is typically done in the literature. The key advantage is that inverse modified Lagrangians can be learned from snapshots of position data of observed trajectories directly without approximating velocities or acceleration data. This is beneficial when snapshot times are large. Moreover, when inverse modified Lagrangians are integrated using a variational method, discretisation errors are compensated for. Therefore, large step-sizes can be used while maintaining high accuracy and tiny energy errors.

Keywords: Hamilton's principle, variational integrators, backward error analysis

1. INTRODUCTION

Physics informed learning describes the incorporation of prior physical knowledge into machine learning based models for unknown dynamical systems to improve accuracy and reliability of predicted motions. One of the most fundamental physical principles is *Hamilton's principle*. It states that a motion $q\colon [t_0, t_1] \to Q$ of a dynamical system connecting two points q_0 and q_1 in a manifold Q extremises an action

$$S(q) = \int_{t_0}^{t_1} L(t, q(t), \dot{q}(t)) \tag{1}$$

for some $L\colon \mathbb{R} \times TQ \to \mathbb{R}$ called *Lagrangian*. From the stationarity condition on S, *Euler–Lagrange equations* $0 = \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}}(t,q,\dot{q}) - \frac{\partial L}{\partial q}(t,q,\dot{q})$ can be derived.

A typical strategy to incorporate variational structure into learned models of dynamical systems is to learn the Lagrangian L using neural networks (LNN – see Cranmer et al. (2020)) or Gaussian Processes (LGP – see Ober-Blöbaum and Offen (2022)). In a second step, motions are predicted by integrating the learned dynamical system using a numerical method.

Existing approaches such as LNN assume the availability of trajectory data consisting of position data, velocity data, and acceleration data to learn the Lagrangian L. Refinements such as in Takehiro Aoshima (2021) have been introduced to eliminate some of the data requirements but these assume further prior knowledge about the form of L. In the general case and if only snapshots of positions of trajectories are available, velocity and acceleration data need to be approximated to learn L. We will show that if snapshot times are large, this can cause unacceptably large and biased errors in predicted motions. Further discretisation errors occur when the learned dynamical system is integrated. If step-size adaptive methods are employed, this will come at the cost of not preserving variational structure during integration. Numerical motions then show unphysical behaviour, such as dissipating energy even though the exact system might be energy conserving, which is problematic in long-term simulations or when periodic orbits should be detected. If, on the other hand, variational integrators are used, such that the numerical motions inherit the variational structure and thus much of the qualitative properties of the system (1) (such as energy conservation for autonomous L), error tolerances might require tiny step-sizes.

As a remedy, we introduce *Lagrangian Shadow Integrators* (LSI) which learn an *inverse modified Lagrangian* L_{imd} instead of L. Inverse modified Lagrangians can be learned directly from position data of trajectories such that there is no need to approximate velocity data or acceleration data for the training process. Moreover, inverse modified Lagrangians compensate for discretisation errors in the integration step. In this way, no artificial errors are introduced into the predictions while incorproating variational structure at the same time. We can, therefore, handle snapshot data of trajectories which relate to moderate to large snapshot times. The step-size selection for the integration becomes independent of accuracy requirements, which is beneficial in long-term simulations. Additionally, the Lagrangian L can be computed from L_{imd} using variational backward error analysis.

Extending our framework developed in Ober-Blöbaum and Offen (2022), we will incorporate noise in the derivation of Gaussian Processes based LSI, explain how to handle data with inconsistent snapshot times, provide an analysis employing the generalised midpoint rule, and point out new directions of our research.

2. THE LSI FRAMEWORK

2.1 Overview of the LSI procedure

Let us give an overview of the steps involved in Lagrangian Shadow Integration (LSI). We will restrict ourself to autonomous Lagrangians.

- Preparation and learning:
  (1) A variational integrator and a step-size h are selected.
  (2) An inverse modified Lagrangian L_{imd} is learned directly from position data of trajectories.
  (3) A formula for the Lagrangian L is computed from L_{imd} using variational backward error analysis.
- Computation of a motion to initial data $(q_0, \dot{q}_0)$:
  (1) Compute the conjugate momentum at time $t = 0$ as $p_0 = \frac{\partial L}{\partial \dot{q}}(q_0, \dot{q}_0)$.
  (2) Solve $\nabla_1 L_{\mathrm{imd}\,\Delta}(q_0, q_1) + p_0 = 0$ for q_1.
  (3) Solve for q_{j+1} iteratively
  $$\nabla_2 L_{\mathrm{imd}\,\Delta}(q_{j-1}, q_j) + \nabla_1 L_{\mathrm{imd}\,\Delta}(q_j, q_{j+1}) = 0.$$
- Post-processing (optional):
  (1) If velocity data is required at step q_j, solve for $\dot{q}_j$
  $$\nabla_2 L_{\mathrm{imd}\,\Delta}(q_{j-1}, q_j) = \frac{\partial L}{\partial \dot{q}}(q_j, \dot{q}_j). \qquad (2)$$

Above, $L_{\mathrm{imd}\,\Delta}$ denotes the discrete Lagrangian obtained from L_{imd} using the selected variational integrator. The expressions $\nabla_1 L_{\mathrm{imd}\,\Delta}$ and $\nabla_2 L_{\mathrm{imd}\,\Delta}$ denote partial derivatives with respect to the first or second argument of $L_{\mathrm{imd}\,\Delta}$, respectively. In conclusion, the computation of motions of the learned system proceeds like applying the variational integrator to the inverse modified Lagrangian L_{imd}. Whenever velocity data needs to be related to conjugate momenta, the computed formula for L is used. This computed formula can be derived once and for all for each variational integrator.

In the following, we will introduce the notion of inverse modified Lagrangians and provide details on the preparation and learning steps of LSI.

2.2 Modified and inverse modified Lagrangians

If $L\colon TQ \to \mathbb{R}$ is a regular Lagrangian, the *exact discrete Lagrangian* to a step-size h is given as $L_{\Delta}^{\mathrm{exact}}(q_0, q_1) = \int_{t_0}^{t_0+h} L(q(t), \dot{q}(t))\,\mathrm{d}t$, where $q\colon [t_0, t_0 + h] \to Q$ fulfils the Euler–Lagrange equations and the boundary conditions $q(t_0) = q_0$, $q(t_1) = q_1$. $L_{\Delta}^{\mathrm{exact}}(q_0, q_1)$ exists, provided that $q_0, q_1 \in Q$ are sufficiently close to one another.

The notion of inverse modified Lagrangians is illustrated in Fig. 1: let L be a regular Lagrangian. A variational integrator translates a continuous action functional $S(q) = \int_{t_0}^{t_1} L(q(t), \dot{q}(t))$ to a discrete action functional $S_{\Delta}(q) = \sum_{j=0}^{N-1} L_{\Delta}(q_j, q_{j+1})$. A *modified Lagrangian* L_{md} is a Lagrangian such that its exact discrete Lagrangian $L_{\mathrm{md}\,\Delta}^{\mathrm{exact}}$ coincides with L_{Δ}.

Remark 1. Modified Lagrangians L_{md} exist as formal power series in the step-size h and can be computed by *variational backward error analysis (BEA)*, see Vermeeren (2017).

We introduce an inverse version of modified Lagrangians.

Theorem 2. (Ober-Blöbaum and Offen (2022)). For a regular Lagrangian L and a consistent variational integrator there exists a formal power series L_{imd} in h such that the discrete Lagrangian $L_{\mathrm{imd}\,\Delta}$ coincides with the exact discrete Lagrangian $L_{\Delta}^{\mathrm{exact}}$ up to any order in h.

Example 3. The generalised variational midpoint rule assigns to a Lagrangian L the discrete Lagrangian

$$L_{\Delta}(q_0, q_1) = L\left((1-a)q_1 + aq_0, (q_1 - q_0)/h\right) \qquad (3)$$

with a parameter $a \in \mathbb{R}$. The standard midpoint rule uses $a = 1/2$ and is second order accurate. Using variational backward error analysis, we compute the differential operator

$$\Lambda = \mathrm{Id} + \frac{h}{2}(1-2a)\dot{q}\frac{\partial}{\partial q} + \frac{h^2}{24}\Big(\Big(\frac{\partial}{\partial q} - \dot{q}\frac{\partial^2}{\partial q \partial \dot{q}}\Big)^2 \Big/ \frac{\partial^2}{\partial \dot{q}^2} + 2(1 + 6a(a-1))\dot{q}^2\frac{\partial^2}{\partial q^2}\Big) + \mathcal{O}(h^3).$$

The modified Lagrangian is given as $L_{\mathrm{md}} = \Lambda(L)$. If L_{imd} is the inverse modified Lagrangian, then $\Lambda(L_{\mathrm{imd}}) = L$ to all orders in h. A derivation of Λ and Λ^{-1} including higher order terms can be found in the Mathematica script of the accompanying source code. [1]

2.3 Learning of L_{imd}

We now show how to learn L_{imd} from position data of trajectories. In contrast to the theoretical considerations in the previous section, here L_{imd} is *not* a formal power series but a function $L_{\mathrm{imd}} : TQ \to \mathbb{R}$ represented by either an artificial neural network (ANN) or a Gaussian Process and corresponds to a fixed step-size h.

Preparation of training data Before we start learning, we need to make sure that all observed discrete trajectories have consistent snapshot times h_{snap} compatible with h.

Method 1. If the snapshot times of l observed discrete trajectories $(q_j^{(1)})_j, \ldots, (q_j^{(l)})_j$ are in a rational relation such that $h_{\mathrm{snap}} = r_1/m, r_2/m, \ldots, r_l/m$ with (lowest) common denominator m, then the trajectories can be split up such that they all refer to the same snapshot time: if r is the least common multiple of $r_1, \ldots, r_l$, we split the ith trajectory into $(q^{(i)}_{(r/r_i)j})_j$, $(q^{(i)}_{(r/r_i)j+1})_j, \ldots, (q^{(i)}_{(r/r_i)j+(r/r_i)-1})_j$

[1] https://github.com/Christian-Offen/LagrangianShadowIntegration

for $i = 1, \dots, l$. The snapshot times of the new trajectories are $h_{\text{snap}} = r/m$.

Method 2. An alternative to method 1 is to introduce dummy variables for missing observations into the trajectories such that all trajectories have snapshot time $h_{\text{snap}} = 1/m$. The values of the dummy variables will be interpreted as additional parameters in the learning process and will be subject to the optimisation procedure.

Method 3. If all trajectories have snapshot time h_{snap} and $h = kh_{\text{snap}}$ for $k \in \mathbb{N}$, then each trajectory $(q_j)_j$ is split up into k discrete trajectories $(q_{kj})_j$, $(q_{kj+1})_j$, …, $(q_{kj+k-1})_j$ which correspond to a snapshot time of h.

Method 4. As in method 2, if $h = h_{\text{snap}}/k$ for $k \in \mathbb{N}$ we can fill up missing observations with dummy variables which are interpreted as parameters subject to the learning process.

Any rational snapshot time can be obtained with a combination of the above methods. However, methods 1 and 3 cause a loss of training data, since some interrelations of points are forgotten. Methods 2 and 4, however, introduce more parameters that need to be fitted. In the following, we assume that $h = h_{\text{snap}}$.

Training an ANN Let $L_{\text{imd}\,\Delta}$ denote the discrete Lagrangian assigned to L_{imd} by the integrator. For a weighting factor $\theta > 0$, we employ the loss function $\ell = \ell_{\text{data}} + \theta\ell_{\text{normal}}$ with

$$\ell_{\text{data}} = \sum\nolimits_{(q_j)_j \in \text{trj}} \sum\nolimits_{j=2}^{m-1} \|\text{DEL}_{\text{imd}}\,(q_{j-1}, q_j, q_{j+1})\|^2.$$

The sum is taken over all discrete observations of trajectories $(q_j)_j = (q_1, \dots, q_m)$. DE denotes the discrete Euler–Lagrange operator, i.e. $\text{DEL}_{\text{imd}}\,(q_{j-1}, q_j, q_{j+1})$ denotes $\nabla_2 L_{\text{imd}\,\Delta}(q_{j-1}, q_j) + \nabla_1 L_{\text{imd}\,\Delta}(q_j, q_{j+1})$. Minimisation of ℓ_{data} seeks to fulfil the discrete Euler–Lagrange equations (DELs) on all triples (q_{j-1}, q_j, q_{j+1}) in the trajectory data. To avoid learning a constant L_{imd} (whose DELs are trivial), we consider the normalisation

$$\ell_{\text{normal}} = \Big| c - \frac{1}{2^{2n}} \sum\nolimits_{\text{corners of } E^{2n}} \frac{\partial L_{\text{imd}}}{\partial \dot{q}^1} \cdot \ldots \cdot \frac{\partial L_{\text{imd}}}{\partial \dot{q}^n} \Big|^2$$

for $c \in \mathbb{R} \setminus \{0\}$. The parameter c controls the scaling of the identified symplectic structure and Hamiltonian that can be obtained via Legendre transform of L_{imd}. The condition $\ell_{\text{normal}} = 0$ corresponds to fixing the oriented volume of a $2n$-dimensional hypercube $E^{2n} \subset TQ$ to be c. It enforces regularity of the learned Lagrangian. As ℓ_{normal} mostly acts as a non-triviality condition, the weighting θ will typically be small.

Gaussian Processes As an alternative to ANNs, we can fit a Gaussian Process (GP) modelling L_{imd} such that $\text{DEL}_{\text{imd}}\,(q_{j-1}, q_j, q_{j+1}) = 0$ holds on all triples (q_{j-1}, q_j, q_{j+1}) in the training data.

If values $L_{\text{imd}}\,(Z) = (L_{\text{imd}}\,(z_1), \dots, L_{\text{imd}}\,(z_M))$ of a quantity L_{imd} are known at points $Z = (z_1, \dots, z_M) \in TQ^M$ with i.i.d. Gaussian noise at each observation with mean 0 and standard deviation $\sigma \geq 0$, then $L_{\text{imd}}\,(y)$ can be predicted as

$$L_{\text{imd}}\,(y) = k(y, Z)^\top B, \tag{4}$$

where $B = (k(Z, Z) + \sigma I_M)^{-1} L_{\text{imd}}\,(Z)$. Here the prior is a GP with mean 0 and kernel function $k\colon TM \times TM \to \mathbb{R}$, $k(y, Z) = (k(y, z_j))_{j=1}^M$, $k(Z, Z) = (k(z_i, z_j))_{i,j=1}^M$ (see Rasmussen and Williams (2005)).

In case of the midpoint rule, for each pair of consecutive observations of position data (q_a, q_b) in the training data, we form $z = \text{mp}(q_a, q_b) := ((q_b + q_a)/2, (q_b - q_a)/h)$ and collect all such points in the variable $Z \in TQ^M$, where M is the number of pairs. We determine $L_{\text{imd}}\,(Z)$ by imposing that $\text{DEL}_{\text{imd}}\,(q_{j-1}, q_j, q_{j+1}) = 0$ holds on all triples (q_{j-1}, q_j, q_{j+1}) in the training data. For each triple we get the equation

$$\big[\big(\nabla_{\dot{x}} k\,(\text{mp}(q_{j-1}, q_j), Z)^\top - \nabla_{\dot{x}} k\,(\text{mp}(q_j, q_{j+1}), Z)^\top\big)/h + \big(\nabla_x k\,(\text{mp}(q_{j-1}, q_j), Z)^\top - \nabla_x k\,(\text{mp}(q_j, q_{j+1}), Z)^\top\big)/2\big] \cdot B = 0.$$

The normalising condition discussed for ANN is

$$\Big(\frac{1}{2^{2n}} \sum\nolimits_{v \in \text{corners}(E^{2n})} \mathbf{1}_n^\top \nabla_{\dot{q}} k(v, Z)^\top\Big) B = c,$$

where $\mathbf{1}_n$ is a vector of ones. The equations for the triples and the normalising condition yield a linear system of equations for $B = (k(Z, Z) + \sigma I_M)^{-1} L_{\text{imd}}\,(Z)$ whose minimal norm solution is computed. Once B is determined, L_{imd} can be evaluated using (4) and derivatives via automatic differentiation.

Remark 4. Notice that it is not necessary to explicitly perform the inversion $(k(Z, Z) + \sigma I_M)^{-1}$ or to estimate the noise level σ to learn B or to predict L_{imd}. Moreover, assuming correlated noise instead of i.i.d. noise, i.e. replacing the noise matrix σI_M in B with a more complicated matrix, leaves predicted values for L_{imd} invariant.

3. NUMERICAL EXPERIMENTS

In the following experiments, GPs are employed with squared exponential kernel $k(x, y) = \exp(-\|x - y\|^2/\epsilon)$. The parameter ϵ is related to the typical length scale of the problem. As a variational integrator we use the second order accurate midpoint rule.

3.1 Mathematical pendulum

The mathematical pendulum is described by the Lagrangian $L_{\text{ref}} = \frac{1}{2}\dot{q}^2 - \cos(q)$. The energy $H_{\text{ref}} = \frac{1}{2}\dot{q}^2 + \cos(q)$ is conserved along motions. As described in section 2.3, we train the model on position data of 400 trajectories of length 6 and consider the (relatively large) step-size and snapshot time $h = 0.5$.

For comparison, we learn the Lagrangian L directly (rather than L_{imd}): for this, velocity data is approximated using second-order accurate central finite differences. Then a GP is trained using the same technique as in section 2.3, where L_{imd} is replaced by L in the formulas and instances of $\text{mp}(q_j, q_{j+1})$ are replaced by (q_j, v_j), where v_j is the approximated velocity at position q_j. This is referred to as LGP (Lagrangian Gaussian Process) as it constitutes a GP version of Cranmer et al. (2020)'s LNN. For further comparison and an analysis of the different discretisation errors, we also train with exact velocity data for v_j (LGPExact).

Figure 2 shows the first 13 points of a discrete trajectory and its long-term energy behaviour computed with LSI,

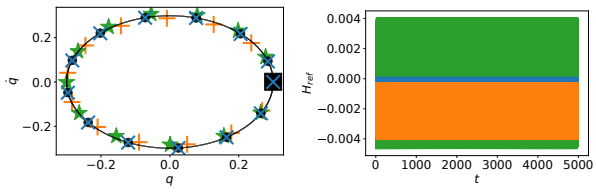

Fig. 2. Left: Pendulum trajectory for LSI (blue, ×), LGP (orange, +), LGPExact (green, ⋆), reference (black, solid). Only the new scheme LSI is accurate since discretisation errors are compensated. Right: Energy along trajectory (colouring as on left hand side).

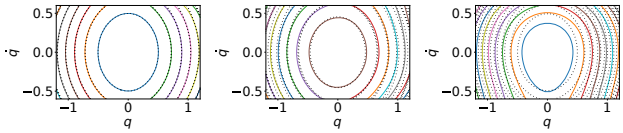

Fig. 3. Left to right: Energy detected by LSI, LGP, and LGPExact. Matching contours of H_{ref} are dotted.

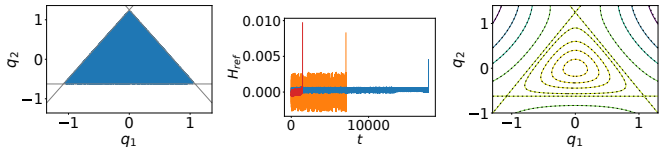

Fig. 4. Left: Position data of an LSI trajectory in a Henon–Heiles system correctly shows a dense orbit. Centre: Energy plots for LSI (blue), LGP (orange), GPFlow (red), Right: Contour plot of the numerical potential and V_{ref} (dashed).

LGP, and LGPExact. As the step-size is quite large, the compensation of discretisation error of the LSI scheme greatly improves accuracy and energy behaviour over methods which try to learn L directly. Even providing exact velocity data does not help as sizeable discretisation errors are introduced when the system is integrated. Interestingly, the energy plot suggests that providing averaged velocity data used to train LGP is better than using exact velocity data in LGPExact: the averaging appears to compensate some of the discretisation errors in the integration step, however not as successfully as our systematic approach LSI.

From the identified L (either computed as $\Lambda(L_{\text{imd}})$ or learned directly) we can calculate the conserved quantity H via Legendre transform of L as $H = q\frac{\partial L}{\partial \dot{q}} - L$. Figure 3 compares the contours of H to the contours of H_{ref}. Clearly, the LSI prediction matches the reference contours best. The computed energy H corresponds to the Hamiltonian of the system which governs the numerical motion. Phase plots of this kind can, therefore, conveniently be used to verify the validity of computations with LSI. Moreover, it shows that LSI can be used for system identification.

3.2 Hénon–Heiles system

The Hénon–Heiles system is governed by $L_{\text{ref}} = \frac{1}{2}\|\dot{q}\|^2 - V_{\text{ref}}(q)$ with potential $V_{\text{ref}}(q) = \frac{1}{2}\|q\|^2 + \mu(q_1^2 q_2 - q_2^3/3)$. We set $\mu = 0.8$, use a step-size and snap-shot time $h = h_{\text{snap}} = 0.1$, and train on 200 trajectories of length 5.

We compare again to LGP with approximated velocities by central finite differences and additionally to a GP representing the flow map on TQ (GPFlow). GPFlow is fitted directly to the position data and the approximated velocity data. GPFlow avoids discretisation errors in the integration step but does not incorporate variational structure. A trajectory and an energy plot of LSI, LGP, and GPFlow is provided in Figure 4. While all trajectories erroneously diverge eventually, LSI's excellent energy preservation properties make the trajectory escape much later. Interestingly, the energy drift of GPFLow causes an early blow-up although at first its absolute energy errors are much smaller than those of LGP which diverges later. This confirms that preservation of variational structure is important. When the potential is computed from $L = \Lambda(L_{\text{imd}})$ its contours match the reference V_{ref} nicely. This verifies the behaviour of numerical solutions of LSI and shows that LSI succeeds in system identification tasks.

4. FUTURE WORK

LSI successfully incorporates variational structure into learning processes of dynamical systems without introducing (biased) discretisation errors. We would like to incorporate symmetries into the learned dynamical system as well, for instance by using symmetric neural network architectures or symmetric kernel functions with Gaussian Processes. In combination with a symmetric variational integrator, the symmetry and variational structure is passed on to the discrete system such that numerical motions conserve the quantities given by Noether's theorem. In this way, completely integrable structure can be preserved under discretisation such that this important structural property is shared by the numerical system.

High order integrators simplify the computation of $L = \Lambda(L_{\text{imd}})$ as correction terms only occur to higher order. However, complicated integrators yield more complicated loss functions ℓ_{data} (ANN) or more involved linear systems (GP based method). We would like to investigate these trade-offs and the potential of using different variational integrators within LSI. Another direction of research is to incorporate external forces into the considered systems.

Moreover, we would like to employ the statistical framework of Gaussian Processes to investigate how uncertainty in the training data relates to model uncertainty in the learned Lagrangian and in the computed trajectories.

Maximum Entropy Optimal Density Control of Discrete-time Linear Systems

Kaito Ito * **Kenji Kashima** *

k *k* *; kk* *k*

Abstract: Entropy regularization, or a maximum entropy method for optimal control has attracted much attention especially in reinforcement learning due to its many advantages such as a natural exploration strategy and robustness against disturbances. Nevertheless, for safety-critical applications, it is crucial to suppress state uncertainty due to the stochasticity of high-entropy control policies and dynamics to an acceptable level. To achieve this, we consider the problem of steering a state distribution of a deterministic discrete-time linear system to a specified one at final time with entropy-regularized minimum energy control. We show that this problem boils down to solving coupled Lyapunov equations. Based on this, we derive the existence, uniqueness, and explicit form of the optimal policy.

Optimal control, stochastic control, maximum entropy, discrete-time linear system

1. INTRODUCTION

Optimal control theory is a powerful mathematical tool for achieving control objectives while considering, for example, energy efficiency (Lewis et al., 2012). Recently, there has been considerable interest in maximum entropy optimal control (MaxEnt OC) especially in reinforcement learning (RL) (Haarnoja et al., 2017, 2018; Levine, 2018; Ho and Ermon, 2016). MaxEnt OC seeks to optimize an objective function which includes an additional entropy regularization term for control policies. This framework offers many advantages such as performing good exploration for RL (Haarnoja et al., 2017), robustness against disturbances (Eysenbach and Levine, 2021), and equivalence between MaxEnt OC and an inference problem (Levine, 2018), to name a few.

On the other hand, in many safety-critical applications, it is important to limit state uncertainty due to the stochasticity of high-entropy policies and dynamics to an acceptable level. A straightforward approach to achieve this is to impose a hard constraint in the state distribution at a specified time. Steering the state of a dynamical system to a desired distribution without entropy regularization has been addressed in the literature. In (Chen et al., 2016), the problem of steering a Gaussian initial density of a continuous-time linear system to a final one with minimum energy is considered, and the optimal policy is derived in explicit form. In (Goldshtein and Tsiotras, 2017), the above problem for a discrete-time linear system is investigated, and the optimality condition for a linear controller gain is derived. See also (Chen et al., 2021) for an extensive review of this area.

In this paper, we tackle the entropy-regularized minimum energy density control problem for deterministic discrete-time linear systems. We reveal that this problem boils down to solving two Lyapunov difference equations coupled through their boundary values. Our main contribution is to show the existence and uniqueness of the optimal policy and then derive its explicit form.

This paper is organized as follows: In Section 2, we provide the problem formulation and derive the coupled Lyapunov equations. The existence, uniqueness, and explicit form of the optimal policy are given in Section 3. Some concluding remarks are given in Section 4.

Let $\mathbb{R}$ denote the set of real numbers and $\mathbb{Z}_{>0}$ denote the set of positive integers. The set of integers $\{k, k+1, \dots, l\}$ $(k < l)$ is denoted by $[\![k, l]\!]$. Denote by $\mathcal{S}^n$ the set of all real symmetric $n \times n$ matrices. For a matrix $A \in \mathcal{S}^n$, we write $A \succ 0$ (resp. $A \prec 0$) if A is positive (resp. negative) definite. For $A \succ 0$, $A^{1/2}$ denotes the unique positive definite square root. The identity matrix is denoted by I, and its dimension depends on the context. The Euclidean norm is denoted by $\|\cdot\|$. Let $(\Omega, \mathscr{F}, \mathbb{P})$ be a complete probability space and $\mathbb{E}$ be the expectation with respect to $\mathbb{P}$. For an $\mathbb{R}^n$-valued random vector w, $w \sim \mathcal{N}(\mu, \Sigma)$ means that w has a multivariate Gaussian distribution with mean $\mu \in \mathbb{R}^n$ and covariance matrix Σ. When $\Sigma \succ 0$, the density function of $w \sim \mathcal{N}(\mu, \Sigma)$ is denoted by $\mathcal{N}(\cdot|\mu, \Sigma)$.

2. PROBLEM FORMULATION AND PRELIMINARY ANALYSIS

In this paper, we consider the following optimal control problem.

Given a finite horizon $N \in \mathbb{Z}_{>0}$, find a policy $\pi = \{\pi_k\}_{k=0}^{N-1}$ that solves

$$\underset{\pi}{\text{minimize}} \quad \mathbb{E}\left[\sum_{k=0}^{N-1}\left(\frac{1}{2}\|u_k\|^2 - \varepsilon \mathrm{H}(\pi_k(\cdot|x_k))\right)\right] \tag{1}$$

$$\text{subject to} \quad x_{k+1} = A_k x_k + B_k u_k, \tag{2}$$

$$u_k \sim \pi_k(\cdot|x_k), \tag{3}$$

$$x_0 \sim \mathcal{N}(0, \bar{\Sigma}_0),\ x_N \sim \mathcal{N}(0, \bar{\Sigma}_N), \tag{4}$$

where $\varepsilon > 0,\ \bar{\Sigma}_0, \bar{\Sigma}_N \succ 0,\ x_k \in \mathbb{R}^n, u_k \in \mathbb{R}^m$. A stochastic policy $\pi_k(\cdot|x)$ denotes the conditional density of u_k given $x_k = x$, and $\mathrm{H}(\pi_k(\cdot|x)) := -\int_{\mathbb{R}^m} \pi_k(u|x) \log \pi_k(u|x) \mathrm{d}u$ denotes the entropy of $\pi_k(\cdot|x)$. ♢

To tackle the above problem, let us start by introducing the auxiliary problem.

Given a finite horizon $N \in \mathbb{Z}_{>0}$, find a policy $\pi = \{\pi_k\}_{k=0}^{N-1}$ that solves

$$\begin{aligned} \underset{\pi}{\text{minimize}} \quad & \mathbb{E}\left[\frac{1}{2} x_N^\top \Pi_N x_N \right. \\ & \left. + \sum_{k=0}^{N-1} \left(\frac{1}{2}\|u_k\|^2 - \varepsilon \mathrm{H}(\pi_k(\cdot|x_k))\right)\right] \quad (5) \\ \text{subject to} \quad & x_{k+1} = A_k x_k + B_k u_k,\ u_k \sim \pi_k(\cdot|x_k), \\ & x_0 \sim \mathcal{N}(0, \bar{\Sigma}_0), \end{aligned}$$

where $\Pi_N \in \mathcal{S}^n$. ♢

Problem 2 has a terminal cost instead of a constraint on the density of the final state. Similarly to the conventional LQR problem (Lewis et al., 2012), we can obtain the optimal policy for Problem 2 explicitly. Due to the limited space, we omit the proof.

Assume that $\Pi_k \in \mathcal{S}^n$ satisfies $I + B_k^\top \Pi_{k+1} B_k \succ 0$ for any $k \in [\![0, N-1]\!]$ and is a solution of the following Riccati difference equation:

$$\begin{aligned} \Pi_k = A_k^\top \Pi_{k+1} A_k - A_k^\top \Pi_{k+1} B_k (I + B_k^\top \Pi_{k+1} B_k)^{-1} \\ \times B_k^\top \Pi_{k+1} A_k,\ k \in [\![0, N-1]\!]. \quad (6) \end{aligned}$$

Then, the unique optimal policy for Problem 2 is given by

$$\begin{aligned} \pi_k^*(u|x) = \mathcal{N}\big(u \big| -(I + B_k^\top \Pi_{k+1} B_k)^{-1} B_k^\top \Pi_{k+1} A_k x, \\ \varepsilon (I + B_k^\top \Pi_{k+1} B_k)^{-1}\big), \\ x \in \mathbb{R}^n, u \in \mathbb{R}^m, k \in [\![0, N-1]\!]. \quad (7) \end{aligned}$$

♢

The system (2) driven by the policy (7) is given by

$$x_{k+1}^* = \bar{A}_k x_k^* + B_k w_k^*,\ w_k^* \sim \mathcal{N}(0, \varepsilon (I + B_k^\top \Pi_{k+1} B_k)^{-1}), \quad (8)$$

$$\bar{A}_k := A_k - B_k (I + B_k^\top \Pi_{k+1} B_k)^{-1} B_k^\top \Pi_{k+1} A_k \quad (9)$$

where $\{w_k^*\}$ is an independent sequence. Suppose that $\Sigma_k := \mathbb{E}\left[x_k^* (x_k^*)^\top\right]$ satisfies $\Sigma_0 = \bar{\Sigma}_0, \Sigma_N = \bar{\Sigma}_N$. Then, from Proposition 1, the policy (7) is the unique optimal solution of Problem 1. This is because for any policy satisfying (4), the terminal cost $\mathbb{E}[x_N^\top \Pi_N x_N/2]$ takes the same value. From (8), Σ_k evolves as

$$\Sigma_{k+1} = \bar{A}_k \Sigma_k \bar{A}_k^\top + \varepsilon B_k (I + B_k^\top \Pi_{k+1} B_k)^{-1} B_k^\top. \quad (10)$$

Note that

$$\begin{aligned} \bar{A}_k \Sigma_k \bar{A}_k^\top = (I + B_k B_k^\top \Pi_{k+1})^{-1} A_k \Sigma_k A_k^\top \\ \times (I + B_k B_k^\top \Pi_{k+1})^{-\top}. \quad (11) \end{aligned}$$

Therefore, if $\Sigma_0 \succ 0$ and A_k is invertible for any $k \in [\![0, N-1]\!]$, it holds $\Sigma_k \succ 0$ for any $k \in [\![1, N]\!]$. Henceforth, we assume the invertibility of A_k.

Now, inspired by (Chen et al. (2016)), we introduce $H_k := \varepsilon \Sigma_k^{-1} - \Pi_k$. Assume that Π_k and H_k are invertible on the time interval $[\![0, N]\!]$. Noting that

$$(\Pi_k + H_k)^{-1} = \Pi_k^{-1} - \Pi_k^{-1} (H_k^{-1} + \Pi_k^{-1})^{-1} \Pi_k^{-1},$$

we obtain

$$\Pi_k^{-1} + H_k^{-1} = \left(\Pi_k - \frac{1}{\varepsilon} \Pi_k \Sigma_k \Pi_k\right)^{-1}. \quad (12)$$

In addition, a straightforward calculation with (6) and (10) shows that

$$\begin{aligned} & A_k^{-1} (\Pi_{k+1}^{-1} + H_{k+1}^{-1}) A_k^{-\top} \\ & = \left(A_k^\top \left(\Pi_{k+1} - \frac{1}{\varepsilon} \Pi_{k+1} \Sigma_{k+1} \Pi_{k+1}\right) A_k\right)^{-1} \\ & = \left(\Pi_k - \frac{1}{\varepsilon} \Pi_k \Sigma_k \Pi_k\right)^{-1} = \Pi_k^{-1} + H_k^{-1}. \quad (13) \end{aligned}$$

Hence, we have

$$\Pi_{k+1}^{-1} + H_{k+1}^{-1} = A_k (\Pi_k^{-1} + H_k^{-1}) A_k^\top. \quad (14)$$

Moreover, the Riccati equation (6) can be rewritten as

$$\Pi_{k+1}^{-1} = A_k \Pi_k^{-1} A_k^\top - B_k B_k^\top. \quad (15)$$

From (14) and (15), it holds

$$H_{k+1}^{-1} = A_k H_k^{-1} A_k^\top + B_k B_k^\top. \quad (16)$$

Therefore, $P_k := H_k^{-1}$ and $Q_k := \Pi_k^{-1}$ satisfy the Lyapunov difference equations

$$P_{k+1} = A_k P_k A_k^\top + B_k B_k^\top, \quad (17)$$

$$Q_{k+1} = A_k Q_k A_k^\top - B_k B_k^\top \quad (18)$$

for $k \in [\![0, N-1]\!]$, and the boundary conditions $\Sigma_0 = \bar{\Sigma}_0, \Sigma_N = \bar{\Sigma}_N$ are written as

$$\varepsilon \bar{\Sigma}_0^{-1} = P_0^{-1} + Q_0^{-1}, \quad (19)$$

$$\varepsilon \bar{\Sigma}_N^{-1} = P_N^{-1} + Q_N^{-1}. \quad (20)$$

In summary, we obtain the following proposition.

Assume that for any $k \in [\![0, N-1]\!]$, A_k is invertible. Assume further that P_k and Q_k satisfy the equations (17), (18) with the boundary conditions (19),(20) and are invertible on $[\![0, N]\!]$, and that it holds $I + B_k^\top Q_{k+1}^{-1} B_k \succ 0$ for any $k \in [\![0, N-1]\!]$. Then, the policy (7) with $\Pi_k = Q_k^{-1}$ is the unique optimal policy for Problem 1. ♢

3. SOLUTION OF MAXIMUM ENTROPY OPTIMAL DENSITY CONTROL PROBLEM

In this section, we analyze the Lyapunov equations (17),(18) with the boundary conditions (19),(20). Under the invertibility of A_k, define the state-transition matrix

$$\Phi(k, l) := \begin{cases} A_{k-1} A_{k-2} \cdots A_l, & k > l \geq 0 \\ I, & k = l \geq 0 \\ A_k^{-1} A_{k+1}^{-1} \cdots A_{l-1}^{-1}, & 0 \leq k < l \end{cases}, \quad (21)$$

and introduce the reachability Gramian

$$G_{\mathrm{r}}(k_1, k_0) := \sum_{k=k_0}^{k_1-1} \Phi(k_1, k+1) B_k B_k^\top \Phi(k_1, k+1)^\top,\ k_0 < k_1, \quad (22)$$

and the controllability Gramian

$$G_{\mathrm{c}}(k_1, k_0) := \sum_{k=k_0}^{k_1-1} \Phi(k_0, k+1) B_k B_k^\top \Phi(k_0, k+1)^\top,\ k_0 < k_1. \quad (23)$$

Note that since $G_{\mathrm{c}}(k_1, k_0) = \Phi(k_0, k_1) G_{\mathrm{r}}(k_1, k_0) \Phi(k_0, k_1)^\top$, if $G_{\mathrm{r}}(k_1, k_0)$ is invertible, $G_{\mathrm{c}}(k_1, k_0)$ is also invertible. Now, we provide the solutions of (17),(18) with (19),(20).

Assume that for any $k \in [\![0, N-1]\!]$, A_k is invertible, and there exists $k_{\mathrm{r}} \in [\![1, N-1]\!]$ such that $G_{\mathrm{r}}(k,0)$ is invertible for any $k \in [\![k_{\mathrm{r}}, N]\!]$ and $G_{\mathrm{r}}(N,k)$ is invertible for any $k \in [\![0, k_{\mathrm{r}}-1]\!]$. Assume further that for

$$S_0 := \frac{1}{\varepsilon} G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \bar{\Sigma}_0 G_{\mathrm{c}}(N,0)^{-\frac{1}{2}}, \tag{24}$$

$$S_N := \frac{1}{\varepsilon} G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \Phi(0,N) \bar{\Sigma}_N \Phi(0,N)^\top G_{\mathrm{c}}(N,0)^{-\frac{1}{2}}, \tag{25}$$

the following two matrices are invertible.

$$\mathcal{F}(S_0, S_N) := S_0 + \frac{1}{2} I - \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}}, \tag{26}$$

$$\mathcal{B}(S_0, S_N) := -S_0 + \frac{1}{2} I + \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}}. \tag{27}$$

Then, the equations (17),(18) with the boundary conditions (19),(20) have two sets of solutions $(P_{\pm,k}, Q_{\pm,k})$, $k \in [\![0, N]\!]$ specified by

$$Q_{\pm,0} = G_{\mathrm{c}}(N,0)^{\frac{1}{2}} S_0^{\frac{1}{2}} \left(S_0 + \frac{1}{2} I \pm \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} \right)^{-1} \times S_0^{\frac{1}{2}} G_{\mathrm{c}}(N,0)^{\frac{1}{2}}, \tag{28}$$

$$P_{\pm,0} = (\varepsilon \bar{\Sigma}_0^{-1} - Q_{\pm,0}^{-1})^{-1}. \tag{29}$$

In addition, the two sets of solutions $(P_{\pm,k}, Q_{\pm,k})$ have the following properties.

(i) $P_{-,k}$ and $Q_{-,k}$ are both invertible on $[\![0, N]\!]$, and for any $k \in [\![0, N-1]\!]$, it holds $I + B_k^\top Q_{-,k+1}^{-1} B_k \succ 0$;

(ii) If $Q_{+,k}$ is invertible on $[\![0, N]\!]$, there exists $s \in [\![0, N-1]\!]$ such that $I + B_s^\top Q_{+,s+1}^{-1} B_s$ is not positive definite.

Proof. First, introduce the change of variables $\xi_k := G_{\mathrm{c}}(N,0)^{-1/2} \Phi(0,k) x_k$. Then the system (2) is transformed into

$$\xi_{k+1} = \xi_k + \underbrace{G_{\mathrm{c}}(N,0)^{-1/2} \Phi(0,k+1) B_k}_{=: B_{\mathrm{new},k}} u_k. \tag{30}$$

We will prove the statement in this new set of coordinates and then turn back to the original set of coordinates at the end. The Lyapunov equations associated with the transformed system (30) are given by

$$P_{\mathrm{new},k+1} = P_{\mathrm{new},k} + B_{\mathrm{new},k} B_{\mathrm{new},k}^\top, \tag{31}$$

$$Q_{\mathrm{new},k+1} = Q_{\mathrm{new},k} - B_{\mathrm{new},k} B_{\mathrm{new},k}^\top. \tag{32}$$

The relationship between $Q_{\mathrm{new},k}$ and Q_k is as follows.

$$Q_{\mathrm{new},k} = G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \Phi(0,k) Q_k \Phi(0,k)^\top G_{\mathrm{c}}(N,0)^{-\frac{1}{2}}. \tag{33}$$

Indeed, substituting (33) into $Q_{\mathrm{new},k+1} - Q_{\mathrm{new},k}$ yields

$$\begin{aligned} Q_{\mathrm{new},k+1} - Q_{\mathrm{new},k} &= G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \Phi(0,k) \\ &\quad \times (A_k^{-1} Q_{k+1} A_k^{-\top} - Q_k) \Phi(0,k)^\top G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \\ &= -G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \Phi(0,k+1) B_k B_k^\top \Phi(0,k+1)^\top G_{\mathrm{c}}(N,0)^{-\frac{1}{2}} \\ &= -B_{\mathrm{new},k} B_{\mathrm{new},k}^\top, \end{aligned} \tag{34}$$

which coincides with (32). The controllability Gramian and the reachability Gramian corresponding to ξ_k are given by

$$G_{\mathrm{c,new}}(k_1, k_0) = G_{\mathrm{r,new}}(k_1, k_0) := \sum_{k=k_0}^{k_1-1} B_{\mathrm{new},k} B_{\mathrm{new},k}^\top \tag{35}$$

satisfying $G_{\mathrm{c,new}}(N,0) = G_{\mathrm{r,new}}(N,0) = I$. The initial and final covariance matrices for ξ_0 and ξ_N are given by

$$\bar{\Sigma}_{\mathrm{new},0} := G_{\mathrm{c}}(N,0)^{-1/2} \bar{\Sigma}_0 G_{\mathrm{c}}(N,0)^{-1/2} = \varepsilon S_0, \tag{36}$$

$$\begin{aligned} \bar{\Sigma}_{\mathrm{new},N} &:= G_{\mathrm{c}}(N,0)^{-1/2} \Phi(0,N) \bar{\Sigma}_N \Phi(0,N)^\top G_{\mathrm{c}}(N,0)^{-1/2} \\ &= \varepsilon S_N. \end{aligned} \tag{37}$$

In what follows, to simplify notation, we omit the subscript "new." First, by substituting

$$P_N = P_0 + I, \ Q_N = Q_0 - I$$

into the boundary conditions (19),(20), similarly to the proof of (Chen et al., 2016, Proposition 4), we obtain the two sets of initial values

$$\begin{aligned} Q_{\pm,0} &= S_0^{\frac{1}{2}} \left(S_0 + \frac{1}{2} I \pm \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} \right)^{-1} S_0^{\frac{1}{2}}, \\ P_{\pm,0} &= (S_0^{-1} - Q_{\pm,0}^{-1})^{-1} \end{aligned}$$

under the invertibility of $\mathcal{F}(S_0, S_N)$ and $\mathcal{B}(S_0, S_N)$. Next, we show that $Q_{-,k} = Q_{-,0} - G_{\mathrm{r}}(k,0)$ is invertible on $[\![0, N]\!]$. Note that formally

$$\begin{aligned} &(Q_{-,0} - G_{\mathrm{r}}(k,0))^{-1} = -G_{\mathrm{r}}(k,0)^{-1} \\ &\quad - G_{\mathrm{r}}(k,0)^{-1} (Q_{-,0}^{-1} - G_{\mathrm{r}}(k,0)^{-1})^{-1} G_{\mathrm{r}}(k,0)^{-1} \\ &= -G_{\mathrm{r}}(k,0)^{-1} - G_{\mathrm{r}}(k,0)^{-1} S_0^{\frac{1}{2}} \Bigg[S_0 + \frac{1}{2} I \\ &\quad - \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} - S_0^{\frac{1}{2}} G_{\mathrm{r}}(k,0)^{-1} S_0^{\frac{1}{2}} \Bigg]^{-1} S_0^{\frac{1}{2}} G_{\mathrm{r}}(k,0)^{-1}. \end{aligned} \tag{38}$$

By assumption, for any $k \in [\![k_{\mathrm{r}}, N]\!]$, $G_{\mathrm{r}}(k,0)$ is invertible. The term in the square brackets obviously attains its maximum at $k = N$

$$\frac{1}{2} I - \left(S_0^{1/2} S_N S_0^{1/2} + \frac{1}{4} I \right)^{1/2} \prec 0.$$

Therefore the term in the brackets is invertible for any $k \in [\![k_{\mathrm{r}}, N]\!]$. This implies that $Q_{-,k}$ has the inverse matrix (38). On the other hand, $Q_{-,k}$ also admits the expression $Q_{-,k} = Q_{-,N} + G_{\mathrm{r}}(N,k)$. Hence, the inverse matrix is formally

$$\begin{aligned} &(Q_{-,N} + G_{\mathrm{r}}(N,k))^{-1} = G_{\mathrm{r}}(N,k)^{-1} \\ &\quad - G_{\mathrm{r}}(N,k)^{-1} (Q_{-,N}^{-1} + G_{\mathrm{r}}(N,k)^{-1})^{-1} G_{\mathrm{r}}(N,k)^{-1} \\ &= G_{\mathrm{r}}(N,k)^{-1} - G_{\mathrm{r}}(N,k)^{-1} ((Q_{-,0} - I)^{-1} + G_{\mathrm{r}}(N,k)^{-1})^{-1} \\ &\quad \times G_{\mathrm{r}}(N,k)^{-1} \\ &= G_{\mathrm{r}}(N,k)^{-1} - G_{\mathrm{r}}(N,k)^{-1} S_0^{\frac{1}{2}} \Bigg[-S_0 + \Bigg(-\frac{1}{2} I + \Bigg(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} \\ &\quad + \frac{1}{4} I \Bigg)^{\frac{1}{2}} \Bigg)^{-1} + S_0^{\frac{1}{2}} G_{\mathrm{r}}(N,k)^{-1} S_0^{\frac{1}{2}} \Bigg]^{-1} S_0^{\frac{1}{2}} G_{\mathrm{r}}(N,k)^{-1}. \end{aligned} \tag{39}$$

Then by the same argument as for the time interval $[\![k_{\mathrm{r}}, N]\!]$, $Q_{-,k}$ is also invertible on $[\![0, k_{\mathrm{r}}-1]\!]$. Similarly, it can be shown that $P_{-,k}$ is invertible on $[\![0, N]\!]$.

Next, we prove that $I + B_k^\top Q_{-,k+1}^{-1} B_k \succ 0$ for any $k \in [\![0, N-1]\!]$. Note that

$$\begin{aligned} (I + B_k^\top Q_{-,k+1}^{-1} B_k)^{-1} &= I - B_k^\top (Q_{-,k+1} + B_k B_k^\top)^{-1} B_k \\ &= I - B_k^\top Q_{-,k}^{-1} B_k. \end{aligned}$$

Hence, we show $I - B_k^\top Q_{-,k}^{-1} B_k \succ 0$. From (38), for $k \in [\![k_\mathrm{r}, N-1]\!]$, we have

$$\begin{aligned} I - B_k^\top Q_{-,k}^{-1} B_k &= I + B_k^\top G_\mathrm{r}(k,0)^{-1} B_k \\ &\quad + B_k^\top G_\mathrm{r}(k,0)^{-1} S_0^{\frac{1}{2}} \Bigg[S_0 + \frac{1}{2} I - \left(S_0^{\frac{1}{2}} S_N S_0^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} \\ &\quad - S_0^{\frac{1}{2}} G_\mathrm{r}(k,0)^{-1} S_0^{\frac{1}{2}} \Bigg]^{-1} S_0^{\frac{1}{2}} G_\mathrm{r}(k,0)^{-1} B_k. \end{aligned} \tag{40}$$

Since the expression in the square brackets is negative definite on $[\![k_\mathrm{r}, N-1]\!]$, it holds for sufficiently small $\delta \in (0,1)$,

$$\begin{aligned} &I - B_k^\top Q_{-,k}^{-1} B_k \succ I + B_k^\top G_\mathrm{r}(k,0)^{-1} B_k + B_k^\top G_\mathrm{r}(k,0)^{-1} S_0^{\frac{1}{2}} \\ &\times \left[S_0 - \delta S_0 - S_0^{\frac{1}{2}} G_\mathrm{r}(k,0)^{-1} S_0^{\frac{1}{2}} \right]^{-1} S_0^{\frac{1}{2}} G_\mathrm{r}(k,0)^{-1} B_k. \end{aligned}$$

Hence, we get

$$\begin{aligned} &I - B_k^\top Q_{-,k}^{-1} B_k \succ I + B_k^\top (G_\mathrm{r}(k,0) - (1-\delta)^{-1} I)^{-1} B_k \\ &= I - B_k^\top \left(\sum_{s=k}^{N-1} B_s B_s^\top + \left((1-\delta)^{-1} - 1 \right) I \right)^{-1} B_k. \end{aligned} \tag{41}$$

In addition, it holds that

$$\begin{aligned} &\left(I - B_k^\top \left(\sum_{s=k}^{N-1} B_s B_s^\top + \left((1-\delta)^{-1} - 1 \right) I \right)^{-1} B_k \right)^{-1} \\ &= I + B_k^\top \left(\sum_{s=k+1}^{N-1} B_s B_s^\top + \left((1-\delta)^{-1} - 1 \right) I \right)^{-1} B_k \succ 0. \end{aligned}$$

Consequently, we obtain $I + B_k^\top Q_{-,k+1}^{-1} B_k \succ 0$ for $k \in [\![k_\mathrm{r}, N-1]\!]$. Noting also that $Q_{-,k}^{-1}$ is given by (39) for $k \in [\![0, k_\mathrm{r}-1]\!]$, by the same argument above, it can be shown that $I + B_k^\top Q_{-,k+1}^{-1} B_k \succ 0$ for $k \in [\![0, k_\mathrm{r}-1]\!]$.

Next, we show the property (ii). Note that since $0 \prec Q_{+,0} \prec I$, it holds $Q_{+,N} \prec 0$, and thus there exists $s \in [\![0, N-1]\!]$ such that $Q_{+,s} \succ 0$ and $Q_{+,s+1}$ is not positive definite. By assumption, $Q_{+,s+1}$ is invertible and

$$\begin{aligned} Q_{+,s+1}^{-1} &= (Q_{+,s} - B_s B_s^\top)^{-1} \\ &= Q_{+,s}^{-1} + Q_{+,s}^{-1} B_s (I - B_s^\top Q_{+,s}^{-1} B_s)^{-1} B_s^\top Q_{+,s}^{-1}. \end{aligned} \tag{42}$$

Now assume $I - B_s^\top Q_{+,s}^{-1} B_s \succ 0$. Then by $Q_{+,s}^{-1} \succ 0$ and (42), we have $Q_{+,s+1}^{-1} \succ 0$, which contradicts the fact that $Q_{+,s+1}$ is not positive definite. Combining this with $I + B_s^\top Q_{+,s+1}^{-1} B_s = (I - B_s^\top Q_{+,s}^{-1} B_s)^{-1}$, we obtain (ii).

Finally, by employing the relationship (33), we obtain the desired result. □

Note that the corresponding result (Chen et al., 2016, Proposition 4) for the continuous-time system also requires the invertibility of $\mathcal{F}(S_0, S_N)$ and $\mathcal{B}(S_0, S_N)$, which is not mentioned in the statement.

By Propositions 2 and 3, we come to the main result of this paper.

Suppose that the assumptions of Proposition 3 are satisfied. Then, the unique optimal policy for Problem 1 is given by

$$\begin{aligned} \pi_k(u|x) = \mathcal{N}\Big(&u \,|\, -(I + B_k^\top Q_{-,k+1}^{-1} B_k)^{-1} B_k^\top Q_{-,k+1}^{-1} A_k x, \\ &\varepsilon (I + B_k^\top Q_{-,k+1}^{-1} B_k)^{-1} \Big), \\ &x \in \mathbb{R}^n, u \in \mathbb{R}^m, k \in [\![0, N-1]\!], \end{aligned} \tag{43}$$

where $Q_{-,k}$ is a solution of (18) with the initial value $Q_{-,0}$ in (28). ♢

4. CONCLUSION

In this paper, we analyzed maximum entropy optimal density control of deterministic discrete-time linear systems. In particular, we revealed the existence and uniqueness of the optimal solution, and provided the explicit construction of the optimal policy. Future work includes removing or relaxing the invertibility assumption on $A_k, \mathcal{F}(S_0, S_N), \mathcal{B}(S_0, S_N)$ and exploring the connection between our result and Schrödinger bridges (Beghi, 1996). Another direction of future work is to extend the result to the case where a quadratic state cost is also present.

INTERPOLATING MATRICES

ALBERTO DAYAN - EXTENDED ABSTRACT

This talk is based on the works in [5], [6] and [7], and it aims to extend some well known results on interpolating sequences to sequences of matrices of arbitrary dimensions. First, we will consider the case of a sequence of square matrices with spectra in the unit disc, and we will obtain an analogue of Carleson's interpolation Theorems, [3] and [4], to this setting. The second part of the talk will consider the case of interpolating d-tuples of matrices: the main difference with the scalar setting is that the components of a d-tuple of matrices need not, in general, to commute. We will see how an analogue of the Pick property enjoyed by the NC (non commutative) Drury-Arveson space allows one to characterize interpolating sequences on the NC unit ball in terms of some Riesz system-type conditions on NC kernels. We will discuss examples, and some possible directions for some future research in the topic.

The one variable case

The first step is to define what an interpolating sequence of matrices is. Since we evaluate an H^∞ function at a matrix via the Riesz-Dunford functional calculus, the first requirement for a sequences $A = (A_n)_{n\in\mathbb{N}}$ of matrices to be interpolating is that their spectra lie in the unit disc. As for a concrete definition for A to be interpolating, a rather versatile choice is the following:

Definition 1 (Interpolating Matrices)**.** *A sequence of matrices $(A_n)_{n\in\mathbb{N}}$ with spectra in the unit disc is interpolating if, for any bounded sequence $(\phi_n)_{n\in\mathbb{N}}$ in H^∞, there exists a function ϕ in H^∞ so that $\phi(A_n) = \phi_n(A_n)$, for any n in $\mathbb{N}$.*

If we chose $(\phi_n)_{n\in\mathbb{N}}$ to be made of constant functions it is immediate to see that this extends the classic definition of interpolating sequences of scalars.
In order to characterize interpolating sequences of matrices, one has to be able to *separate* them. This can be done by using the Hardy space H^2, the reproducing kernel Hilbert space of holomorphic functions on the unit disc with square summable Taylor coefficients. Given a sequence of matrices A, one can define, for any n in $\mathbb{N}$,

$$H_n := \{f \in \mathrm{H}^2 \mid f(A_n) = 0\}^\perp.$$

Each H_n is, in fact, a **model space** in H^2. In particular, it is the orthogonal complement in H^2 of the set of all multiples of a finite Blaschke product B_n. If A was a sequence of scalars $(\lambda_n)_{n\in\mathbb{N}}$, each H_n would be a one dimensional subspace of H^2 spanned by s_λ, the normalized Szegö kernel at λ_n. Looking for a way to separate the sequence $H = (H_n)_{n\in\mathbb{N}}$, we say that H is

- **strongly separated** if the sine of the angle between an element of H and the closure of the span of all the others subspaces in H is uniformly bounded below;
- **weakly separated** if the sine of the angle between any two distinct elements of H is uniformly bounded below;

Date: July 14, 2022.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

- a **Riesz system** if there exists a $C \geq 1$ so that, however we choose a sequence of unit vectors $(x_n)_{n\in\mathbb{N}}$ so that x_n belongs to H_n for any n in $\mathbb{N}$, then for any $a = (a_n)_{n\in\mathbb{N}}$ in l^2

$$\frac{1}{C}||a||_{l^2} \leq \left|\left|\sum_{n\in\mathbb{N}} a_n x_n\right|\right|_{\mathrm{H}^2} \leq C||a||_{l^2}.$$

  The least constant C for which this holds is called the *Riez bound*. If the right inequality holds, then H is a **Bessel system**.

In [1, Ch. 9] one can find a re-statement of the celebrated characterization of interpolating sequences due to Carleson in a operator theoretical language: in [3] he proved that a sequence of scalars $\Lambda = (\lambda_n)_{n\in\mathbb{N}}$ is interpolating if and only if $(s_{\lambda_n})_{n\in\mathbb{N}}$ is strongly separated. Later on, [4], he proved that Λ is interpolating if and only if $(s_{\lambda_n})_{n\in\mathbb{N}}$ is a weakly separated Bessel system in H^2. Moreover, Shapiro and Shields showed in [9] that Λ is interpolating if and only if $(s_{\lambda_n})_{n\in\mathbb{N}}$ is a Riesz system. The first main result of this talk reads as follow:

Theorem 1. *Let A be a sequence of matrices with spectra in the unit disc, and let H be the associated sequence of model spaces in H^2. Then the following are equivalent:*

(i): *A is interpolating;*
(ii): *H is strongly separated;*
(iii): *H is a Riesz system in H^2.*
(iv): *H is a weakly separated Bessel system.*

Interpolating d-tuples

Interpolating sequences are significantly less understood in the multi-variable setting. Looking for extending some of the few known results on the topic to sequences of *d-tuples* of matrices, a first crucial observation is that the components of such d-tuples might not commute, unless they are one-dimensional. Therefore, one has to work with the well developed theory of *noncommutative analytic functions*, and in particular with the nc (non commutative) reproducing kernel Hilbert spaces defined in [2]. We can think of an nc analytic function as a *noncommuative power series*

$$f(z) = \sum_{k\in\mathbb{W}_d} a_k z^k,$$

where $z = (z_1, \ldots, z_d)$ is a d-tuple of non commuting variables, and $\mathbb{W}_d$ is the set of all free words with d generators. In [8] Salomon, Shalit and Shamovich considered the *noncommutative unit ball* $\mathcal{B}_d$, that is, the set of all d-tuples of matrices $(X_1, \ldots, X_d)$ of arbitrary dimensions so that $||\sum_{i=1}^d X_i X_i^*|| < 1$, and they showed that the algebra

$$\mathrm{H}^\infty(\mathcal{B}_d) := \left\{ f \quad \text{nc function} \;\middle|\; \sup_{X\in\mathcal{B}_d} ||f(X)|| < \infty \right\}$$

is the multiplier algebra of a suitable nc reproducing kernel Hilbert space, defined as the *nc Drury-Arveson space* $\mathrm{H}^2(\mathcal{B}_d)$. The nc kernel that defines $\mathrm{H}^2(\mathcal{B}_d)$ is called the *nc Szegö kernel*, and it has a noncommutative version of the complete Pick property, [8]. Definition 1 extends naturally to the nc setting as well: we say that a sequence $A = (A_n)_{n\in\mathbb{N}}$ in $\mathcal{B}_d$ is interpolating if given any bounded sequence $(\phi_n)_{n\in\mathbb{N}}$ in $\mathrm{H}^\infty(\mathcal{B}_d)$ there exists a function ϕ in $\mathrm{H}^\infty(\mathcal{B}_d)$ so that $\phi(A_n) = \phi_n(A_n)$, for any n in $\mathbb{N}$. The second main result of this talk is a characterization of interpolating sequences in this nc setting, stated in terms of separation conditions in the nc Drury Arveson space $\mathrm{H}^2(\mathcal{B}_d)$:

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Theorem 2. *A is interpolating if and only if the sequence of subspaces*

$$\mathcal{H}_n := \{f \in \mathrm{H}^2(\mathcal{B}_d) | f(A_n) = 0\}^{\perp} \tag{1}$$

is a Riesz system.

In order to extend all points of Theorem 1 to this NC setting, it would be interesting to determine whether Carleson's interpolation theorems, [3] and [4], extend to the nc unit ball:

Question 3. *Let A be a sequence of d-tuples of matrices in $\mathcal{B}_d$. Is A interpolating, provided that the associated sequence $(\mathcal{H}_n)_{n\in\mathbb{N}}$ defined in* (1) *is strongly separated?*

Question 4. *Let A be a sequence of d-tuples of matrices in $\mathcal{B}_d$. Is A interpolating, provided that the associated sequence $(\mathcal{H}_n)_{n\in\mathbb{N}}$ defined in* (1) *is a weakly separated Bessel system?*

Abstract: Ando's classical characterization of the unit ball in the numerical radius norm was generalized by Farenick, Kavruk, and Paulsen using the free joint numerical radius of a tuple of Hilbert space operators $(X_1, \dots, X_m)$. In particular, the characterization leads to a positive definite completion problem. In this paper, we study various aspects of Ando's result in this generalized setting. Among other things, this leads to the study of finding a positive definite solution L to the equation

$$L = I + \sum_{j=1}^{m} \left[\left(L^{\frac{1}{2}} X_j^* L X_j L^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} + \left(L^{\frac{1}{2}} X_j L X_j^* L^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} \right],$$

which may be viewed as a fixed point equation. Once such a fixed point is identified, the desired positive definite completion is easily obtained. Along the way we derive other related results including basic properties of the free joint numerical radius and an easy way to determine the free joint numerical radius of a tuple of generalized permutations. Finally, we present some open problems.

Keywords: Free joint numerical radius, Matrix completion, Fixed point, Generalized permutation

1. EXTENDED ABSTRACT

For a bounded Hilbert space operator $X \in B(\mathcal{H})$, the *numerical radius* is defined by

$$w(X) = \sup\{|\langle Xh, h\rangle| : \ h \in \mathcal{H}, \ \|h\| = 1\}.$$

The numerical radius corresponds to the radius of the smallest circle centered at 0 that contains the *numerical range*

$$W(X) = \{\langle Xh, h\rangle : \ h \in \mathcal{H}, \ \|h\| = 1\}.$$

The well known characterization by Ando (1973) of operators whose numerical radius is at most 1 states that $w(X) \leq 1$ if and only if there exists $Z = Z^* \in B(\mathcal{H})$ so that

$$\begin{bmatrix} I - Z & X \\ X^* & I + Z \end{bmatrix} \geq 0,$$

where $T \geq 0$ is shorthand for T being a positive semidefinite operator. Equivalently, $w(X) \leq 1$ if and only if there exist $A_1, A_2 \in B(\mathcal{H})$ with $A_1 + A_2 = I$ so that

$$\begin{bmatrix} A_1 & X/2 \\ X^*/2 & A_2 \end{bmatrix} \geq 0. \tag{1}$$

One way to prove Ando's result is to observe that $w(X) \leq 1$ if and only if

$$Q(e^{i\theta}) = I - \mathrm{Re}(e^{i\theta} X) \geq 0, \ \text{for all } \theta \in [0, 2\pi],$$

and subsequently use Fejér-Riesz factorization

$$\begin{aligned} I - zX/2 - \overline{z}X^*/2 &= Q(z) \\ &= (P_0 + P_1 z)^*(P_0 + P_1 z), \ |z| = 1. \end{aligned}$$

Now $P_0^* P_0 + P_1^* P_1 = I$ and $P_0^* P_1 = -X/2$ and thus

$$0 \leq \begin{bmatrix} P_0^* \\ -P_1^* \end{bmatrix} [P_0 \ -P_1] =: \begin{bmatrix} A_1 & X/2 \\ X^*/2 & A_2 \end{bmatrix}$$

where $A_1 = P_0^* P_0$ and $A_2 = P_1^* P_1$ satisfy $A_1 + A_2 = I$.

There are different ways to find A_1 and A_2 so that (1) holds. In finite dimensions, one can find A_1 and A_2 numerically by using semidefinite programming, as a block matrix (1) is in the intersection of the cone of positive semidefinite matrices and the affine space

$$\left\{ \begin{bmatrix} I & X/2 \\ X^*/2 & 0 \end{bmatrix} + \begin{bmatrix} -Z & 0 \\ 0 & Z \end{bmatrix} : Z = Z^* \right\}.$$

Semidefinite programming is exactly designed to handle such a situation.

An alternative process to arrive at (1), which was used by Ando in his original paper, is to consider $Z_k = Z_k^*$ defined via $\langle Z_k h, h\rangle$

$$\inf_{h_1, \dots, h_k} \left\langle \begin{bmatrix} I & X/2 & \cdots & 0 \\ X^*/2 & I & \ddots & \vdots \\ \vdots & \ddots & \ddots & X/2 \\ 0 & \cdots & X^*/2 & I \end{bmatrix} \begin{bmatrix} h \\ h_1 \\ \vdots \\ h_k \end{bmatrix}, \begin{bmatrix} h \\ h_1 \\ \vdots \\ h_k \end{bmatrix} \right\rangle.$$

Then Z_k converges decreasingly to Z, say; and we obtain

Bayreuth, Germany, 12-16 September 2022

$$\begin{bmatrix} I - Z & X/2 \\ X^*/2 & Z \end{bmatrix} \geq 0 \tag{2}$$

yielding representation (1). In fact, this process yields the maximal Z in (2) (and gives a co-outer factorization of $Q(z)$). In the case when $w(X) < 1$, this leads to the iterative scheme

$$Z_1 = I \text{ and } Z_{k+1} = I - (X/2)Z_k^{-1}(X^*/2) \text{ for } k \in \mathbb{N},$$

which monotonically decreases; see Algorithm 4.1 in Engwerda et al. (1993).

Farenick et al. (2013) generalized Ando's result to the multivariable setting as follows.

Theorem 1. (Farenick et al., 2013, Theorem 3.4) Let $X_1, \ldots, X_m \in B(\mathcal{H})$. The following are equivalent:

(i) $w(X_1, \ldots, X_m) < 1/2$.
(ii) There exist $A_1, \ldots, A_{m+1} \in B(\mathcal{H})$ so that $A_1 + \cdots + A_{m+1} = I$ and

$$\begin{bmatrix} A_1 & X_1 & 0 & \cdots & 0 \\ X_1^* & A_2 & X_2 & & \vdots \\ 0 & X_2^* & \ddots & \ddots & 0 \\ \vdots & & \ddots & A_m & X_m \\ 0 & \cdots & 0 & X_m^* & A_{m+1} \end{bmatrix} > 0. \tag{3}$$

In (3), $T > 0$ is shorthand for T being a positive definite operator. Condition (i) in Theorem 1 concerns the *free joint numerical radius* of a tuple of m Hilbert space operators $X_1, \ldots, X_m \in B(\mathcal{H})$, defined as

$$w(X_1, \ldots, X_m) = \sup \{ w (X_1 \otimes U_1 + \cdots + X_m \otimes U_m) \},$$

where the supremum is taken over every Hilbert space $\mathcal{K}$, every choice of m unitaries $U_1, \ldots, U_m \in B(\mathcal{K})$, and the tensor product is *spatial*, which can be defined as follows. Consider an inner product on the algebraic tensor of $\mathcal{H}$ and $\mathcal{K}$ by letting $\langle h_1 \otimes k_1, h_2 \otimes k_2 \rangle := \langle h_1, h_2 \rangle_{\mathcal{H}} \cdot \langle k_1, k_2 \rangle_{\mathcal{K}}$ for all $h_1, h_2 \in \mathcal{H}$, $k_1, k_2 \in \mathcal{K}$, and then extending linearly. Denote by $\mathcal{H} \otimes \mathcal{K}$ the resulting Hilbert space after completion. For $R \in B(\mathcal{H})$ and $S \in B(\mathcal{K})$, consider defining a map $(R \otimes S)(h \otimes k) := (Rh) \otimes (Sk)$ for all $h \in \mathcal{H}$ and $k \in \mathcal{K}$, and then extending linearly. The resulting operator $R \otimes S$ has the property that $\|R \otimes S\| = \|R\| \cdot \|S\|$. Hence, the algebraic tensor of $B(\mathcal{H})$ and $B(\mathcal{K})$ naturally inherits a norm (called the *spatial tensor norm*) as a subset of $B(\mathcal{H} \otimes \mathcal{K})$. Taking the closure with respect to the spatial tensor norm yields a C^*-subalgebra of $B(\mathcal{H} \otimes \mathcal{K})$.

The free joint numerical radius coincides with the classical numerical radius when there is only one operator ($m = 1$), and Theorem 1 reduces to Ando's classical result. The objective of this paper is to pursue the different aspects of Ando's result in this more general setting. This includes (i) finding a solution using semidefinite programming; (ii) finding a solution via an iterative scheme (which may have the potential to generalize to the infinite dimensional case); and (iii) exploring the connection with factorization. As we will see, along the way we derive other related results including basic properties of the free joint numerical radius and an easy way to determine the free joint numerical radius of a tuple of generalized permutations.

Our approach to solve for $A_1, \ldots, A_{m+1}$ in (3) will be different than Ando's. We will show, in finite dimensions, that a solution $A_1, \ldots, A_{m+1}$ in (3) exists exactly when the function $f_{X_1,\ldots,X_m}$ defined below has a positive definite fixed point. For a given tuple $X_1, \ldots, X_m \in B(\mathcal{H})$ and for any $Z \geq 0$, define $f_{X_1,\ldots,X_m}(Z)$ as

$$I + \sum_{j=1}^{m} \left[\left(Z^{\frac{1}{2}} X_j^* Z X_j Z^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} + \left(Z^{\frac{1}{2}} X_j Z X_j^* Z^{\frac{1}{2}} + \frac{1}{4} I \right)^{\frac{1}{2}} \right]. \tag{4}$$

Operator monotonicity of $t^{\frac{1}{2}}$ implies

$$f_{X_1,\ldots,X_m}(Z) \geq (m+1)I > 0 \text{ for any } Z \geq 0.$$

Theorem 2. Let $X_1, \ldots, X_m \in B(\mathcal{H})$. Consider the following statements:

(i) There exists positive definite $L \in B(\mathcal{H})$ for which

$$f_{X_1,\ldots,X_m}(L) = L. \tag{5}$$

(ii) $w(X_1, \ldots, X_m) < \frac{1}{2}$.

Then (i)→(ii). If $\dim(\mathcal{H}) < \infty$, then (ii)→(i).

Corollary 3. Let $X_1, \ldots, X_m \in B(\mathcal{H})$ with $\dim(\mathcal{H}) < \infty$. Then (i) and (ii) in Theorem 2 are equivalent.

We prove Theorem 2 using matrix completion techniques. We will discuss the difficulties encountered in generalizing $(ii) \to (i)$ to the infinite dimensional case. Once a positive definite fixed point for $f_{X_1,\ldots,X_m}$ is identified, we show that there is an easy construction for the unknowns $A_1, \ldots, A_{m+1}$ in (3) (which works in all dimensions).

In order to find a solution L to (5), one can use well known iterative schemes to find such a fixed point, with the iterative scheme $L_{k+1} = f_{X_1,\ldots,X_m}(L_k)$ being the standard choice. The choice of a starting point is of course important, and we have found that the choice $L_1 = (m+1)I$ (which is the fixed point when $X_1 = \cdots = X_m = 0$) works perfectly numerically, and in fact we find that the corresponding sequence $\{L_k\}_{k \in \mathbb{N}}$ is monotonically nondecreasing in the Loewner partial ordering. Recall that the Loewner partial ordering on Hermitian operators is given by $R \leq S$ if and only if $S - R \geq 0$. This leads to the following conjecture.

Conjecture 4. Let $X_1, \ldots, X_m \in B(\mathcal{H})$. Consider the recurrence

$$L_1 = (m+1)I \text{ and } L_{k+1} = f_{X_1,\ldots,X_m}(L_k) \text{ for } k \in \mathbb{N}, \tag{6}$$

where $f_{X_1,\ldots,X_m}$ is defined in (4). Then

(i) $L_k \leq L_{k+1}$ for all $k \in \mathbb{N}$.
(ii) If $w(X_1, \ldots, X_m) < 1/2$, then $\{L_k\}_{k \in \mathbb{N}}$ converges in the weak operator topology to a fixed point $L \in B(\mathcal{H})$ of $f_{X_1,\ldots,X_m}$.

In general, $L_1 = (m+1)I \leq f(L_1) = L_2$. We will prove Conjecture 4 in the case when $X_1, \ldots, X_m$ are generalized permutations, i.e., each X_j is the product of a permutation matrix and a diagonal matrix. It is worthwhile to observe that our iterative scheme has a different origin than the iterative scheme from Ando's work. Indeed, in Ando's approach one maximizes A_2 in (1) (in the Loewner partial order) while our approach is based on maximizing the determinant of (1). Even though our approach is based on finite dimensional considerations, the iteration scheme can also be defined in infinite dimensional settings. It is our hope that a convergence proof for that case can be obtained in the future.

Aside from the results mentioned above, we will also cover the following. We will show some basic properties

of the free joint numerical radius. We will prove a closed formula for the free joint numerical radius of a tuple of n-by-n generalized permutations. We will describe how to use semidefinite programming to numerically compute $w(X_1, \ldots, X_m)$ for a tuple of n-by-n matrices. We will prove a limit formula for the free joint numerical radius of a tuple of generalized permutations on infinite dimensional separable Hilbert spaces. We will discuss the connection with factorization of Hermitian pencils.

Abstract: We study the optimal design of numerical integrators for dissipative systems, for which there exists an underlying thermodynamic structure known as GENERIC (General Equation for the NonEquilibrium Reversible-Irreversible Coupling). We present a frame-work to construct structure-preserving integrators by splitting the system into reversible and irreversible dynamics. The reversible part, which is often degenerate and reduces to a Hamiltonian form on its symplectic leaves, is solved by using a symplectic method (e.g., Verlet) with degenerate variables being left unchanged, for which an associated modified Hamiltonian (and subsequently a modified energy) in the form of a series expansion can be obtained by using backward error analysis. The modified energy is then used to construct a modified friction matrix associated with the irreversible part in such a way that a modified degeneracy condition is satisfied. The modified irreversible dynamics can be further solved by an explicit midpoint method if not exactly solvable. Our findings are verified by various numerical experiments, demonstrating the superiority of structure-preserving integrators over alternative schemes in terms of not only the accuracy control of both energy conservation and entropy production but also the preservation of the conformal symplectic structure in the case of linearly damped systems.

Keywords: structure-preserving integrators, dissipative systems, GENERIC, conformal symplectic, discrete gradient methods.

1. INTRODUCTION

In the last few decades, considerable effort has been devoted to developing structure-preserving integrators for Hamiltonian systems. It has been demonstrated that the so-called symplectic integrators, which preserve the symplectic structure, have superior long time behavior compared to their nonsymplectic counterparts, and should be preferred in practice Hairer et al. (2006); Leimkuhler and Matthews (2015); Leimkuhler and Reich (2005). On the other hand, there has been growing interest in designing appropriate numerical methods for gradient flows Ambrosio et al. (2008); Hairer and Lubich (2014); Jordan et al. (1998); Otto (2001); Stuart and Humphries (1996) that respect their underlying properties. In contrast to the symplectic structure, the conformal symplectic structure Bhatt et al. (2016); Bhatt and Moore (2017); Dressler (1988); Hong et al. (2017); McLachlan and Perlmutter (2001); Moser (1994) for Hamiltonian systems that are perturbed by a linear damping (which can be thought of as a special case of the Rayleigh dissipation) has been less studied. It is also worth mentioning that variational integrators Kane et al. (2000) and specialized Runge–Kutta methods Jay (2003) have also been used to solve dissipative systems. It turns out that thermodynamically admissible evolution equations for nonequilibrium systems have a more general (including an additional variable known as entropy) and well-defined structure known as GENERIC (General Equation for the NonEquilibrium Reversible-Irreversible Coupling) Grmela and Öttinger (1997); Öttinger (2005, 2018); Öttinger and Grmela (1997), which possesses the following distinct features:

(i) conservation of the total energy;
(ii) separation of the reversible and irreversible dynamics;
(iii) the reversible dynamics preserves a Poisson structure;
(iv) entropy production is unaffected by the reversible dynamics;
(v) nonnegative entropy production rate.

More specifically, the GENERIC formulation of the time evolution for nonequilibrium systems is given by

$$\frac{\mathrm{d}x}{\mathrm{d}t} = L\frac{\partial E}{\partial x} + M\frac{\partial S}{\partial x}\,, \tag{1}$$

where x is the set of independent variables required to describe a given nonequilibrium system, E and S represent respectively the total energy and entropy as functions of

⋆ This is a resubmission of an extended abstract that was accepted for presentation at the MTNS 2020 in Cambridge.

the independent variables x, and L and M denote the antisymmetric Poisson matrix and the positive semidefinite (symmetric) friction matrix, respectively. Note that both L and M can also depend on the independent variables x so that the fundamental time evolution equation (1) could be highly nonlinear. We also point out that $\partial/\partial x$ in (1) simply implies the partial derivative although it typically denotes the functional derivative when x is a function/field. Moreover, (1) is supplemented by two degeneracy conditions:

$$L\frac{\partial S}{\partial x} = 0\,, \tag{2}$$

and

$$M\frac{\partial E}{\partial x} = 0\,. \tag{3}$$

Eqs. (2)–(3) indicate the conservation of the entropy by the reversible dynamics (i.e., the L contribution) and the conservation of the total energy in a closed system by the irreversible dynamics (i.e., the M contribution), respectively. Note that "reversible" and "irreversible" dynamics (in thermodynamics) are simply the names of the two fundamental contributions to the time evolution equation (1), and should not be confused with similar terms in other subjects. The rank of M has the interpretation of the number of dissipative processes taking place in the system. (See more discussions on the formulation of the GENERIC framework in Grmela and Öttinger (1997); Öttinger (2005, 2018); Öttinger and Grmela (1997).)

The usefulness and maturity of the GENERIC framework have been illustrated in a very large number of successful applications in a wide range of areas in Appendix E of Öttinger (2005) (see also a most recent review of Öttinger (2017) and references therein). In particular, despite its simple form, we believe that the irreversible dynamics in (1) is the most general form of meaningful irreversible equations in nonequilibrium thermodynamics—it is a belief based on both a very large variety of successful examples and statistical mechanics, so that it can be called knowledge (in particular, as this belief is widely accepted in the nonequilibrium thermodynamics community).

In order to further demonstrate the general properties of L and M, the Poisson bracket is given by

$$\{\mathcal{A},\mathcal{B}\} = \frac{\partial \mathcal{A}}{\partial x}\cdot L\frac{\partial \mathcal{B}}{\partial x}\,, \tag{4}$$

where $\mathcal{A}$ and $\mathcal{B}$ are sufficiently regular (and real-valued) functions of the independent variables x, and the dissipative bracket is given by

$$[\mathcal{A},\mathcal{B}] = \frac{\partial \mathcal{A}}{\partial x}\cdot M\frac{\partial \mathcal{B}}{\partial x}\,. \tag{5}$$

With the help of the two brackets and the chain rule, the time evolution equation of an arbitrary function $\mathcal{A}$ can then be written as

$$\frac{\mathrm{d}\mathcal{A}}{\mathrm{d}t} = \{\mathcal{A},E\} + [\mathcal{A},S]\,. \tag{6}$$

More specifically, the Poisson bracket (4) inherits the antisymmetry of L,

$$\{\mathcal{A},\mathcal{B}\} = -\{\mathcal{B},\mathcal{A}\}\,, \tag{7}$$

and satisfies the Leibniz rule,

$$\{\mathcal{A}\mathcal{B},\mathcal{C}\} = \mathcal{A}\{\mathcal{B},\mathcal{C}\} + \mathcal{B}\{\mathcal{A},\mathcal{C}\}\,, \tag{8}$$

where $\mathcal{C}$ is another arbitrary sufficiently regular (and real-valued) function of the independent variables x. In addition, the Poisson bracket is required to satisfy the Jacobi identity,

$$\{\mathcal{A},\{\mathcal{B},\mathcal{C}\}\} + \{\mathcal{B},\{\mathcal{C},\mathcal{A}\}\} + \{\mathcal{C},\{\mathcal{A},\mathcal{B}\}\} = 0\,. \tag{9}$$

The dissipative bracket (5) inherits the symmetry of M,

$$[\mathcal{A},\mathcal{B}] = [\mathcal{B},\mathcal{A}]\,, \tag{10}$$

and also satisfies the Leibniz rule,

$$[\mathcal{A}\mathcal{B},\mathcal{C}] = \mathcal{A}[\mathcal{B},\mathcal{C}] + \mathcal{B}[\mathcal{A},\mathcal{C}]\,. \tag{11}$$

The positive semidefinite nature of M leads to the nonnegativeness condition

$$[\mathcal{A},\mathcal{A}] \geq 0\,, \tag{12}$$

which implies the second law of nonequilibrium thermodynamics (i.e., the entropy production rate is always nonnegative),

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \frac{\partial S}{\partial x}\cdot M\frac{\partial S}{\partial x} = [S,S] \geq 0\,. \tag{13}$$

This article addresses the long-standing challenge of how to preserve the underlying structures when numerically discretizing GENERIC systems in practice. Although in recent years this topic has attracted increasing attention Kraus and Hirvijoki (2017); Krüger et al. (2016, 2011); Morrison (2017); Portillo et al. (2017), to the best of our knowledge, there are no such numerical integrators in the literature. Unlike common approaches that are based on exact energy conservation, we propose in this article a framework to construct structure-preserving integrators for dissipative systems, i.e., GENERIC integrators (also known as metriplectic integrators Grmela (1984); Kaufman (1984); Morrison (1984, 1986) in the mathematical literature), based on splitting the reversible and irreversible dynamics. The topic of structure-preserving integrators for GENERIC/metriplectic systems is the counterpart and generalization of the theory of symplectic integrators for Hamiltonian systems.

1.1 Full GENERIC integrators

We recall the definition of (full) GENERIC integrators given in Öttinger (2018). Analogous to the definition of symplectic integrators for Hamiltonian dynamics Moser (1968), a mapping, $x_0 \mapsto x_h$, is said to be a full GENERIC integrator if it corresponds to a continuous time evolution of a modified GENERIC system

$$\frac{\mathrm{d}x}{\mathrm{d}t} = L\frac{\partial \tilde{E}_h}{\partial x} + \tilde{M}_h\frac{\partial S}{\partial x}\,, \tag{14}$$

where $\tilde{E}_h$ and $\tilde{M}_h$ represent the modified energy and friction matrix associated with the integrator, respectively, satisfying a modified degeneracy condition:

$$\tilde{M}_h\frac{\partial \tilde{E}_h}{\partial x} = 0\,. \tag{15}$$

That is, given initial conditions $x(0) = x_0$, the analytical solution of (14), $x(t)$, should agree with what we obtain

from the integrator at time h, i.e., $x(h) = x_h$. A full GENERIC integrator $x \mapsto x_h$, which can be thought of as the formal solution of (14), possesses the following structure:

$$x_h = \exp\left\{ h \left(L\frac{\partial \tilde{E}_h}{\partial x} + \tilde{M}_h \frac{\partial S}{\partial x} \right) \cdot \frac{\partial}{\partial x} \right\} x \,. \tag{16}$$

Similar to symplectic integrators for Hamiltonian dynamics, the modified energy, $\tilde{E}_h$, is strictly conserved by a GENERIC integrator. The physical energy E is expected to remain close to the modified energy, $\tilde{E}_h$, even for long integration periods. Additionally, the modified friction matrix, $\tilde{M}_h$, should not introduce any additional dissipative processes not present in the original matrix M. We point out that full GENERIC integrators may only be available in special cases, for instance, a full GENERIC integrator in the case of a damped harmonic oscillator, where analytical solutions of the GENERIC system can be obtained, was proposed and discussed in Öttinger (2018). However, it should be noted that it is highly unlikely that analytical solutions would be available for general GENERIC systems. (Nevertheless, it might be eventually possible to recognise a full GENERIC integrator without exact solutions.) Therefore, in what follows we introduce a framework to construct "split" GENERIC integrators.

1.2 Split GENERIC integrators

Inspired by recent developments on splitting methods Abdulle et al. (2015); Leimkuhler et al. (2016); Leimkuhler and Matthews (2015, 2013a,b); Leimkuhler and Shang (2015, 2016a,b); Shang et al. (2017), we consider to split the reversible and irreversible parts of the GENERIC system in such a way that the reversible dynamics, which is often degenerate but possesses a Hamiltonian form on its symplectic leaves, can be integrated by using a symplectic method (e.g., Verlet) with degenerate variables being left unchanged, while the irreversible part (gradient flow) can be solved in such a way that as many structure elements as possible can be preserved (see more references on the challenging task of structure preservation on manifolds in Ambrosio et al. (2008); Hairer and Lubich (2014); Jordan et al. (1998); Matthes and Plazotta (2019); Matthes and Osberger (2014); Otto (2001); Stuart and Humphries (1996)).

An interesting question for the split GENERIC integrators is: under what conditions do a modified energy and an associated friction matrix, satisfying the modified degeneracy condition (15), exist? If they exist, how much do we know about their respective forms? GENERIC integrators share some common features of GENERIC systems discussed at the beginning of this article, which can also be thought of as the requirements for GENERIC integrators. Denoting the Jacobian matrix of the independent variables x as Ω, we have

(i) preservation of the Poisson structure for the reversible dynamics: $\Omega(x_0)L(x_0)\Omega^{\mathrm{T}}(x_0) = L(x_h)$;
(ii) nonnegative entropy production rate: $S(x_h) \geq S(x_0)$;
(iii) the modified degeneracy condition (15) is satisfied with the other (2) being unchanged;
(iv) preservation of the rank of the friction matrix: $\mathrm{rank}(\tilde{M}_h) = \mathrm{rank}(M)$.

As pointed out in Quispel and McLaren (2008), it has been proved in Zhong and Marsden (1988) that there cannot exist an integrator for "non-integrable" Hamiltonian dynamics that preserves both the symplectic (Poisson) structure and the energy (Hamiltonian). In fact, it has been discussed in Simo et al. (1992) that the preservation of either property has its advantages and disadvantages. While previous attempts to construct structure-preserving integrators for dissipative systems have been relying on the exact conservation of energy (i.e., the energy-conserving discrete gradient methods Cohen and Hairer (2011); McLachlan et al. (1999); Quispel and Turner (1996)), there is no obvious reason why integrators that preserve the Poisson structure for the reversible dynamics should be ignored.

Controller synthesis for an arbitrary length of mass chain

Kaoru Yamamoto *

* *Faculty of Information Science and Electrical Engineering, Kyushu University, Fukuoka 819-0395, Japan.* yamamoto@ees.kyushu-u.ac.jp.

Abstract: The disturbance suppression problem for a chain of masses is discussed. The particular focus is placed on synthesising mechanical networks between masses that effectively suppress the disturbance propagation along the chain of any length. This study is motivated by the problem of controlling multi-agent systems where agents may leave or join the network. That is, the size of the network may change over time. In this work, we give the explicit expressions of scalar transfer functions from disturbance to an intermass displacement as a function of the number of masses, N, and discuss the methodology of synthesising a controller such that the H^∞ norm is upper bounded by a prescribed value for any N.

Keywords: Mechanical networks, linear systems, decentralized systems, large-scale systems

1. INTRODUCTION

Decentralised control of multi-agent systems has been an active area of research with various applications such as consensus problems and flocking/formation/coverage control of mobile robots.

In such applications, one interesting problem is ensuring the ability to control a system behaviour even if the size of the system changes over time. This allows agents to join or leave the network in a flexible manner. In practice, however, such criteria are rarely satisfied since several key performance measures relating to global behaviours of multi-agent systems simply do not scale. Notable examples include the string instability (e.g., Seiler et al. (2004); Feng et al. (2019)) or network incoherence phenomena (e.g., Bamieh et al. (2012)). Nevertheless, it appears that average or local performance measures, for example those in Carli et al. (2009); Pates (2015); Bamieh et al. (2012); Yamamoto and Smith (2016); Pates and Yamamoto (2018), can be guaranteed independent of the size of the network.

Our focus here is to analyse how the agents react locally against disturbances in a multi-agent system modelled by a mass chain depicted in Fig. 1. Bidirectional control of a platoon of vehicles is one such example. In particular, we explicitly express the transfer function from the disturbance to a given intermass displacement as a function of the number of masses and propose a method to design a suitable controller that works well for any length of the chain.

This note is a resubmission of the work (Yamamoto (2021)) that has been accepted for presentation at the MTNS 2020 in Cambridge, but which was cancelled due to COVID-19.

General notation

The set of natural, real and complex numbers is denoted by $\mathbb{N}$, $\mathbb{R}$, $\mathbb{C}$, respectively. $\mathbb{R}^{m\times n}$ is the set of m-by-n real matrices. $\mathbb{C}_+$ is the closed right-half plane. H^∞ is the standard Hardy space on the right-half plane and $\|\cdot\|_\infty$ represents the H^∞-norm. The (i,j) entry of a matrix A is denoted by $[A]_{i,j}$. $\hat{f}$ denotes the Laplace transform of a signal f.

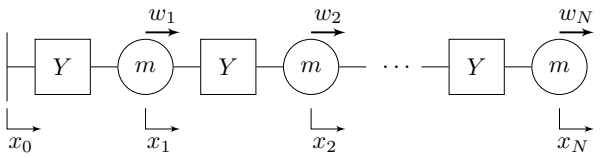

Fig. 1. Chain of N masses m connected by a mechanical admittance Y and connected to a movable point x_0. The disturbance on the ith mass is denoted as w_i.

2. CHAIN MODEL

We consider a chain of N identical point masses m connected by identical mechanical networks (Fig. 1). Each mechanical network provides an equal and opposite force on each mass and is assumed here to have negligible mass. It is also assumed that each mechanical network consists of a spring component in parallel with other components, i.e., the admittance takes the following form: $Y(s) = k/s + Y_c(s)$ where k is the spring coefficient. Here we assume that k is a given parameter and our task is to find a controller represented by an admittance $Y_c(s)$ that effectively supresses the disturbance in the chain.

The system is excited by a movable point $x_0(t)$ and external force acting on the ith mass, $w_i(t)$, $i \in \{1, 2, \ldots, N\}$. The displacement of the ith mass is then denoted by $x_i(t)$. Assuming that the system is initially at rest, the equations of motion in the Laplace transformed domain are given as

$$ms^2\hat{x} = sY(s)L_N\hat{x} + sY(s)\phi_1\hat{x}_0 + \hat{w},$$

and hence,

$$\hat{x} = (h(s)I - L_N)^{-1}\phi_1\hat{x}_0 + \frac{1}{sY(s)}(h(s)I - L_N)^{-1}\hat{w} \quad (1)$$

where I is the identity matrix,

$$h(s) \coloneqq ms/Y(s), \quad \hat{x} \coloneqq [\hat{x}_1, \dots, \hat{x}_N]^\top,$$
$$\hat{w} \coloneqq [\hat{w}_1, \dots, \hat{w}_N]^\top, \quad \phi_1 \coloneqq [1, 0, \dots, 0]^\top \in \mathbb{R}^N,$$
$$L_N \coloneqq \begin{bmatrix} -2 & 1 & 0 & \cdots & 0 \\ 1 & -2 & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & 1 \\ 0 & \cdots & 0 & 1 & -1 \end{bmatrix} \in \mathbb{R}^{N\times N}.$$

The intermass displacement $e_i \coloneqq x_{i-1} - x_i$ is given by

$$\hat{e} = G_{ex_0}(s)\hat{x}_0 + G_{ew}(s)\hat{w} \tag{2}$$

where $\hat{e} = [\hat{e}_1, \dots, \hat{e}_N]^\top$ and

$$\begin{aligned} G_{ex_0}(s) &= \left(I + M(h(s)I - L_N)^{-1}\right)\phi_1 \\ &=: [G_{e_1x_0}(s), \dots, G_{e_Nx_0}(s)]^\top, \\ G_{ew}(s) &= \frac{1}{sY(s)} M(h(s)I - L_N)^{-1}, \end{aligned}$$
$$M = \begin{bmatrix} -1 & 0 & \cdots & \cdots & 0 \\ 1 & -1 & \ddots & & \vdots \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & 1 & -1 \end{bmatrix} \in \mathbb{R}^{N\times N}.$$

To obtain an explicit inverse of the tridiagonal matrix $hI - L_N$, let us introduce the characteristic polynomials of $L_i \in \mathbb{R}^{i\times i}$ in the variable h:

$$d_i \coloneqq \det(hI - L_i),$$

and also the characteristic polynomials of $\overline{L}_i \in \mathbb{R}^{i\times i}$ in h:

$$\overline{d}_i \coloneqq \det(hI - \overline{L}_i)$$

where

$$\overline{L}_i \coloneqq \begin{bmatrix} -2 & 1 & 0 & \cdots & 0 \\ 1 & -2 & \ddots & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & 1 \\ 0 & \cdots & 0 & 1 & -2 \end{bmatrix}.$$

Then $d_1 = h + 1$ and $\overline{d}_1 = h + 2$. Using the Laplace expansion, we find that

$$\begin{aligned} d_i(h) &= (h+2)d_{i-1}(h) - d_{i-2}(h), \\ \overline{d}_i(h) &= (h+2)\overline{d}_{i-1}(h) - \overline{d}_{i-2}(h), \quad \text{for } i = 1, \dots, N \end{aligned} \tag{3}$$

with initial conditions

$$d_{-1} = 1, d_0 = 1, \overline{d}_{-1} = 0, \overline{d}_0 = 1.$$

The inverse of $hI - L_N$ is then given as

$$\left[(hI - L_N)^{-1}\right]_{i,j} = \overline{d}_{j-1}(h)d_{N-i}(h) \quad \text{for } i \geq j, \tag{4}$$

which can be easily derived using the theorem provided by Usmani (1994). Note that $hI - L_N$ is symmetric and hence $\left[(hI - L_N)^{-1}\right]_{i,j} = \left[(hI - L_N)^{-1}\right]_{j,i}$.

The transfer functions $G_{e_ix_0}(s)$ and $G_{ew}(s)$ in (2) are then written as (suppressing the dependence on $h(s)$ in d_i and $\overline{d}_i$)

$$G_{e_ix_0}(s) = \frac{d_{N-i+1} - d_{N-i}}{d_N}, \tag{5}$$

$$G_{e_iw_j}(s) = \begin{cases} \dfrac{1}{sY(s)}\dfrac{1}{d_N}\overline{d}_{j-1}(d_{N-i+1} - d_{N-i}) & \text{for } i > j, \\ \dfrac{1}{sY(s)}\dfrac{1}{d_N}d_{N-j}(\overline{d}_{i-2} - \overline{d}_{i-1}) & \text{for } i \leq j, \end{cases} \tag{6}$$

where $G_{e_iw_j}(s)$ is the (i,j)-entry of $G_{ew}(s)$.

We say that the mass chain of Fig. 1 is stable if all poles in the transfer functions $G_{ex_0}(s)$ and $G_{e_iw_j}(s)$ have negative real parts. The following proposition gives a sufficient condition for the stability:

Proposition 1. The mass chain of Fig. 1 is stable if $h(s) \in \mathbb{C} \setminus (-4, 0)$ and $sY(s) \neq 0$ for all $s \in \mathbb{C}_+$.

Proof. See (Yamamoto, 2021, Theorem 4). □

3. INTERMASS DISPLACEMENTS

We now define the following functions:

$$F_N^{(i,j)}(h) := \begin{cases} \dfrac{1}{d_N}\overline{d}_{j-1}(d_{N-i+1} - d_{N-i}) & \text{for } i > j, \\ \dfrac{1}{d_N}d_{N-j}(\overline{d}_{i-2} - \overline{d}_{i-1}) & \text{for } i \leq j. \end{cases} \tag{7}$$

Then, for $h(s) = ms/Y(s)$,

$$G_{e_1x_0}(s) = 1 + F_N^{(1,1)}(h(s)), \tag{8}$$

$$G_{e_ix_0}(s) = F_N^{(i,1)}(h(s)) \text{ for } i > 1, \tag{9}$$

$$G_{e_iw_j}(s) = \frac{1}{sY(s)}F_N^{(i,j)}(h(s)). \tag{10}$$

Treating h as an independent variable, the following theorem gives these closed-form expressions of $F_N^{(i,j)}(h)$:

Theorem 2. Let $\zeta \in \mathbb{C}$ be the root of

$$z^2 - (h+2)z + 1 = 0$$

satisfying $|\zeta| \leq 1$. For any $i, j \in \mathbb{N}$,

$$F_N^{(i,j)}(h) = \begin{cases} \dfrac{\zeta^{i-j}(1-\zeta^{2j})\left(1-\zeta^{2(N-i+1)}\right)}{(1+\zeta)\left(1+\zeta^{2N+1}\right)} & \text{for } i > j, \\ -\dfrac{\zeta^{j-i+1}(1+\zeta^{2i-1})\left(1+\zeta^{2(N-j)+1}\right)}{(1+\zeta)\left(1+\zeta^{2N+1}\right)} & \text{for } i \leq j. \end{cases} \tag{11}$$

suppressing the dependence on h in ζ.

Proof. See (Yamamoto, 2021, Theorem 4). □

3.1 Limits of the Sequences

It may be observed that the sequence $\left(F_N^{(i,j)}\right)$ in (11) is convergent for a fixed $\zeta \in \mathbb{C}$ with $|\zeta| < 1$ or $\zeta = \pm 1$, and divergent otherwise. The following theorem provides the condition for the convergence and its limit.

Theorem 3. The sequence $\left(F_N^{(i,j)}\right)$ converges pointwise to a limit $\mu^{(i,j)}$ for each $h \in \mathbb{C} \setminus (-4, 0)$ but fails to converge otherwise. In particular,

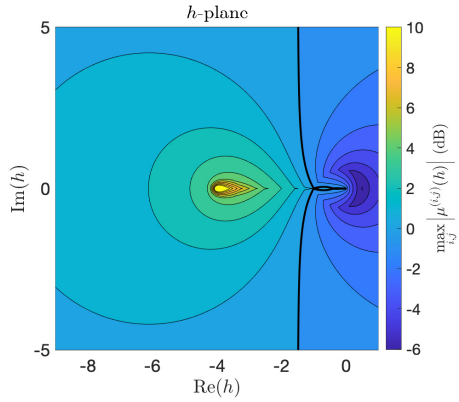

Fig. 2. Contour plot of $\max_{i,j} |\mu^{(i,j)}(h)|$ with $1 \le i, j \le 100$. The thick curve represents a contour of level 0 dB.

(1) For $h \in \mathbb{C} \setminus [-4, 0)$,

$$\mu^{(i,j)}(h) = \begin{cases} \dfrac{\zeta^{i-j}(1-\zeta^{2j})}{(1+\zeta)} & \text{for } i > j, \\ -\dfrac{\zeta^{j-i+1}(1+\zeta^{2i-1})}{(1+\zeta)} & \text{for } i \le j. \end{cases} \tag{12}$$

(2) For $h = -4$,

$$\mu^{(i,j)}(h) = \begin{cases} (-1)^{j-1} 2j & \text{for } i > j, \\ (-1)^{i-j-2}(2i-1) & \text{for } i \le j. \end{cases} \tag{13}$$

Proof. See (Yamamoto, 2021, Theorem 5). □

Hence, if $h(s) \in \mathbb{C} \setminus (-4, 0)$ for all $s \in \mathbb{C}_+$,

$$\sup_{\omega} \lim_{N\to\infty} |F_N^{(i,j)}(h(j\omega))| = \sup_{\omega} |\mu^{(i,j)}(h(j\omega))|. \tag{14}$$

Furthermore,

$$\sup_{N} \|F_N^{(i,j)}(h(s))\|_\infty \ge \sup_{\omega} |\mu^{(i,j)}(h(j\omega))|. \tag{15}$$

That is, $\sup_\omega |\mu^{(i,j)}(h(j\omega))|$ gives a lower bound of the supremum of H^∞-norm of $F_N^{(i,j)}(h(s))$ over N. A contour plot of the maximum magnitude of $\mu^{(i,j)}(h)$ over (i, j) with $0 \le i, j \le 100$ in the h-plane is shown in Fig. 2. The thick black curve represents $\max_{i,j} |\mu^{(i,j)}(h)| = 0$ (dB). The figure shows that the asymptotic value of $F_N^{(i,j)}(h(j\omega))$ as $N \to \infty$ is directly related to the proximity of $h(j\omega)$ to the point -4. From Theorem 3 we see that the magnitude of $|\mu^{(i,j)}(-4)|$ grows as we increase the indices and we must avoid this region.

3.2 Disturbance Amplification

In this subsection, we provide a graphical mean to design the interconnection admittance $Y(s)$.

Figure 3 shows a contour plot of $\max_{1\le N\le 200} |1 + F_N^{(1,1)}(h)|$ with the thick black curve representing a contour of level 0 dB. If the Nyquist diagram of $h(s)$ lies inside a contour of level γ, $\|G_{e_1x_0}(s)\|_\infty \le \gamma$ for any $N \in \mathbb{N}$. (Note that $G_{e_1x_0}(s) = 1 + F_N^{(1,1)}(h(s))$ from (8).) To demonstrate this, the Nyquist diagram of $h(s) = s^2/(2s+1)$ is also plotted in Fig. 3. Since it lies inside the curve of level 0 dB, $\|G_{e_1x_0}(s)\|_\infty \le 1$ for any $N \in \mathbb{N}$, as we can see in

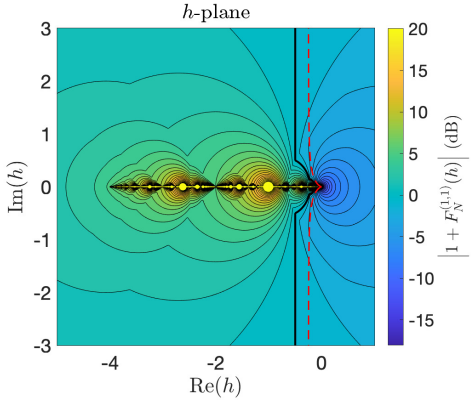

Fig. 3. Nyquist diagram of $h(s) = s^2/(2s+1)$ (red, dashed) and contour plot of $\max_{1\le N\le 200} |1+F_N^{(1,1)}|$. The thick black curve represents a contour of level 0 dB.

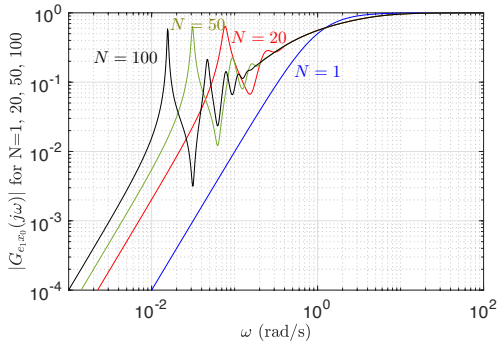

Fig. 4. The magnitude plot of $G_{e_1x_0}(j\omega)$ with $h(s) = s^2/(2s+1)$ for $N = 1, 20, 50, 100$.

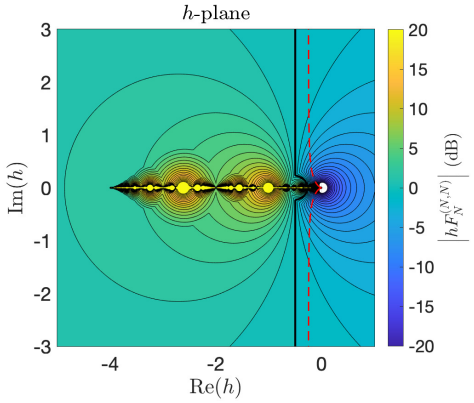

Fig. 5. Nyquist diagram of $h(s) = s^2/(2s+1)$ (red, dashed) and contour plot of $\max_{1\le N\le 200} |hF_N^{(1,N)}|$. The thick black curve represents a contour of level 0 dB.

Fig. 4 for $N = 1, 20, 50, 100$. $G_{e_ix_0}(s)$ can be evaluated similarly.

To evaluate $G_{e_iw_j}(s)$ in a similar way, we first rewrite (10) as

$$G_{e_iw_j}(s) = \frac{1}{sY(s)} F_N^{(i,j)}(h(s)) = \frac{1}{ms^2} h(s) F_N^{(i,j)}(h(s)) \tag{16}$$

and draw a contour plot of $\max_N |hF_N^{(i,j)}(h)|$. Figure. 5 shows this contour map for $(i, j) = (1, N)$ again with the

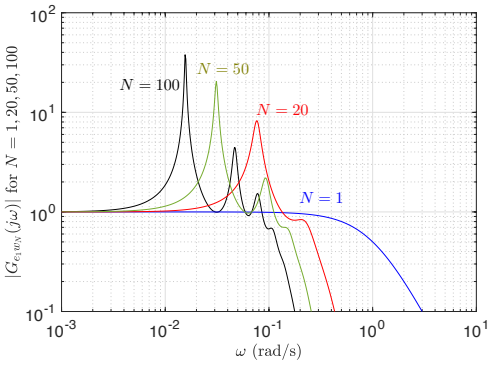

Fig. 6. The magnitude plot of $G_{e_1 w_N}(j\omega)$ with $h(s) = s^2/(2s+1)$ for $N = 1, 20, 50, 100$.

Nyquist diagram of $h(s) = s^2/(2s+1)$. Although Fig. 5 looks similar to Fig. 3, since $1/ms^2$ is multiplied as in (16), the same interconnection $h(s) = s^2/(2s+1)$ will result in large frequency response of $G_{e_1 w_N}(s)$ in the low frequency range. Indeed, this is observed in Fig. 6. To remedy this, we need to shape the locus of $h(j\omega)$ at $\omega \approx 0$ suitably. However, because of the existence of the parallel spring, the limiting behaviour of $h(j\omega)$ as $\omega \to 0$ cannot be drastically changed using passive interconnection, i.e., positive-real $Y(s)$. Whether the use of an active controller may lead to an improvement is yet to be explored.

4. CONCLUSION

Convenient representations of transfer functions from disturbance to a given intermass displacement in a homogeneous mass chain have been derived to evaluate how the system dynamics change as the number of masses N changes. The limiting behaviour of these transfer functions as N tends to infinity has been studied. Moreover, the possibility of designing a controller that achieves a prespecified disturbance attenuation level independent of N has been explored. Such a size-independent performance can be achieved using passive interconnection when only the movable point displacement is present as the disturbance. However, it is not the case when the disturbance on each mass is present. The use of active controllers is considered as a future work.

date: 14 June 2022

Abstract: Motivated by reachability questions in coherently controlled open quantum systems coupled to a thermal bath, as well as recent progress in the field of thermo-/vector-majorization we generalize classical majorization from unital quantum channels to channels with an arbitrary fixed point D of full rank. Such channels preserve some Gibbs-state and thus play an important role in the resource theory of quantum thermodynamics, in particular in thermo-majorization.

Based on this we investigate D-majorization on matrices in terms of its topological and order properties, such as existence of unique maximal and minimal elements, etc. Moreover we characterize D-majorization in the qubit case via the trace norm and elaborate on why this is a challenging task when going beyond two dimensions.

Keywords: Open quantum systems, quantum control theory, reachable sets, quantum thermodynamics, majorization

1. INTRODUCTION

Studying reachable sets of control systems is necessary to ensure well-posedness of a large class of (optimal) control tasks. In Dirr et al. (2019) toy models on the standard simplex of probability vectors were studied in order to answer reachability questions of controlled n-level systems coupled to a bath of finite temperature such that the coupling can be switched on and off. If the closed (unitary) part of the system can be fully controlled and the bath has temperature $T = 0$ then every quantum state [1] can be reached approximately from every initial state (that is, perhaps not exactly but at least with arbitrary precision). For $T = \infty$ an upper bound can be obtained by classical majorization techniques. For more details on this we refer to the first part of this talk: *Exploring the Limits of Open Quantum Dynamics I: Motivation, First Results from Toy Models to Applications*, as well as Section 3.3.

An obvious follow-up question is what can be said—if one can say anything at all—about the reachable set of such a system for $0 < T < \infty$? Even within the simplified diagonal toy model (cf. Part I) this is a rather difficult task and it seems that the notion necessary to handle such problems requires a more general form of majorization:

[1] A quantum state is a positive semi-definite matrix of unit trace.

2. ON THE ROAD TO D-MAJORIZATION

2.1 d-Majorization on Vectors

Majorization relative to a strictly positive vector $d \in \mathbb{R}^n_{++}$, as introduced by Veinott (1971) and in the quantum regime by Ruch et al. (1978) is defined as follows: a vector y is said to d-majorize x, denoted by $x \prec_d y$, if there exists a d-stochastic matrix $A \in \mathbb{R}^{n\times n}$ with $x = Ay$. Recall that $A \in \mathbb{R}^{n\times n}$ is d-stochastic if all its entries are non-negative and $Ad = d$, $e^\top A = e^\top$ with $e := (1, \dots, 1)^\top$. A variety of characterizations of $\prec_d$ and d-stochastic matrices can be found in the work of Joe (1990) or vom Ende and Dirr (2022). The most useful for numerical purposes is the following: $x \prec_d y$ if and only if $\sum_{j=1}^n x_j = \sum_{j=1}^n y_j$ and $\|d_i x - y_i d\|_1 \leq \|d_i y - y_i d\|_1$ for all $i = 1, \dots, n$, where $\|z\|_1 = \sum_{j=1}^n |z_j|$ is the usual vector-1-norm.

Classical majorization $\prec$, that is, $x \prec y$ for $x, y \in \mathbb{R}^n$, is originally defined via ordering x, y decreasingly and then comparing partial sums: $\sum_{j=1}^k x_j^{\cdot} \leq \sum_{j=1}^k y_j^{\cdot}$ for all $k = 1, \dots, n-1$ as well as $\sum_{j=1}^n x_j = \sum_{j=1}^n y_j$. For more on vector majorization we refer to Ch. 1 & 2 of Marshall et al. (2011). In particular it is well-known that setting $d = e$ in the definition of d-majorization recovers $\prec$ —which also shows that the definition via partial sums cannot extend beyond $e^\top$: as soon as two entries in $d \in \mathbb{R}^n_{++}$ differ one loses permutation invariance and reordering the vectors x, y makes a conceptual difference.

The above 1-norm characterization allows to rewrite the d-majorization polytope $M_d(y) := \{x \in \mathbb{R}^n \,|\, x \prec_d y\}$ for any

$y \in \mathbb{R}^n$ as the set of solutions to a nicely structured vector inequality $\mathcal{M}x \leq b$. Here $\mathcal{M} \in \mathbb{R}^{2^{n^2} \times n}$ is independent of y, d while the entries of $b = b(y,d) \in \mathbb{R}^{2^n}$ depend explicitly (and continuously) on y and d – for details cf. Thm. 10 in vom Ende and Dirr (2022). This description of d-majorization enables a proof of the existence of an extremal point $z \in M_d(y)$ such that $M_d(y) \subseteq M_e(z)$, i.e. there exists some $z \prec_d y$ which classically majorizes all $x \in M_d(y)$. Due to this result d-majorization is suited to analyse reachable sets in the toy model (cf. Part I of this talk)—yet as soon as one considers n-level quantum systems one needs a similar concept on (density) matrices.

2.2 Generalizing d-Majorization to Matrices

Classical majorization on the level of hermitian matrices uses their "eigenvalue vector" $\boldsymbol{\lambda}(\cdot)$ arranged in any order with multiplicities counted. For $A, B \in \mathbb{C}^{n\times n}$ hermitian, A is said to be majorized by B if $\boldsymbol{\lambda}(A) \prec \boldsymbol{\lambda}(B)$, cf. Ando (1989). The most naïve approach to define D-majorization on matrices (with [2] $D = \mathrm{diag}(d)$ for some $d \in \mathbb{R}^n_{++}$) would be to replace $\prec$ by $\prec_d$ and leave the rest as it is. However such a definition is unfeasible because it depends on the arrangement of the eigenvalues in $\boldsymbol{\lambda}$, due to the lack of permutation invariance of d (unless $d = e$).

The most natural way out of this dilemma is to remember that classical majorization on matrices can be equivalently characterised via linear maps which are completely positive and trace-preserving (CPTP) and which have the identity matrix $\mathrm{id} = \mathrm{diag}(1, \ldots, 1)$ as a fixed point. Therefore it seems utmost reasonable to generalize d-majorization on square matrices as follows:

Definition 1. Given $n \in \mathbb{N}$ and $A, B \in \mathbb{C}^{n\times n}$ as well as a positive definite matrix $D \in \mathbb{C}^{n\times n}$ we say that A is D-majorized by B (denoted by $A \prec_D B$) if there exists a CPTP map Φ such that $\Phi(B) = A$ and $\Phi(D) = D$.

Such a definition is also justified by the following: given real vectors x, y and a positive vector $d \in \mathbb{R}^n_{++}$ one can show that $\mathrm{diag}(x) \prec_{\mathrm{diag}(d)} \mathrm{diag}(y)$ if and only if $x \prec_d y$. In other words the diagonal case reduces to d-majorization on vectors as expected.

Be aware that one *could* define matrix D-majorization via positive (instead of completely positive) trace-preserving maps, and that this would make a conceptual difference – unless $D \neq \mathrm{id}$ (Ando, 1989, Thm. 7.1), more on this at the end of Section 3.1. However, we defined D-majorization via CPTP maps because this class has a richer theory behind it and because it is the more natural choice if one comes from quantum information and control.

3. PROPERTIES OF D-MAJORIZATION

Using CPTP maps in Definition 1 also allows for a physical interpretation of D-majorization: Given some n-level system (with Hamiltonian $H_0 \in \mathbb{C}^{n\times n}$) coupled to a bath of some temperature $T > 0$, the Gibbs state (that is, the thermodynamic equilibrium state) of the system is given by

$$\rho^{H_0,T}_{\mathrm{Gibbs}} := \frac{\exp(-H_0/T)}{\mathrm{tr}(\exp(-H_0/T))} > 0\,.$$

Because every positive definite $n \times n$ matrix of unit trace is the Gibbs state of *some* n-level system this links D-majorization to Gibbs-preserving CPTP maps. Moreover in the high-temperature limit the above definition reduces to $\lim_{T\to\infty} \rho^{H_0,T}_{\mathrm{Gibbs}} = \frac{1}{n}\,\mathrm{diag}(1, \ldots, 1)$, which connects classical majorization to baths of infinite temperature.

3.1 Characterizations of D-Majorization

An important observation is that for any $A, B \in \mathbb{C}^{n\times n}$ and $D > 0$ one has $A \prec_D B$ if and only if $UAU^* \prec_{UDU^*} UBU^*$ for all unitary matrices $U \in \mathbb{C}^{n\times n}$. Thus we can w.l.o.g. assume that D is diagonal in the standard basis.

Now if one deals with qubits, i.e. two-dimensional systems, then D-majorization can be characterized as follows.

Proposition 2. Let $d \in \mathbb{R}^2_{++}$, $D = \mathrm{diag}(d)$ and $A, B \in \mathbb{C}^{2\times 2}$ hermitian be given. The following are equivalent.

(i) $A \prec_D B$

(ii) *There exists a positive trace-preserving map Φ with $\Phi(D) = D$ and $\Phi(B) = A$.*

(iii) $\|A - tD\|_1 \leq \|B - tD\|_1$ *for all* $t \in \mathbb{R}$ *with* $\|\cdot\|_1 = \mathrm{tr}\sqrt{(\cdot)^*(\cdot)}$ *being the trace norm.*

(iv) $\mathrm{tr}(A) = \mathrm{tr}(B)$ *and* $\|A - b_i D\|_1 \leq \|B - b_i D\|_1$ *for* $i = 1, 2$ *as well as for the generalized fidelity*

$$\left\|\sqrt{A - b_1 D}\sqrt{b_2 D - A}\right\|_1 \geq \left\|\sqrt{B - b_1 D}\sqrt{b_2 D - B}\right\|_1$$

Here $\sigma(D^{-1/2} B D^{-1/2}) = \{b_1, b_2\}$ ($b_1 \leq b_2$) with $\sigma(\cdot)$ being the spectrum.

Of course property (iv) is the closest to the 1-norm characterization of $\prec_d$ from Sec. 2.1 and, moreover, the key to easily check (e.g., on a computer) if some hermitian matrix D-majorizes another. Unfortunately *none* of these characterizations generalize to dimensions larger than 2 because the counterexample to the Alberti-Uhlmann theorem in higher dimensions, given by Heinosaari et al. (2012), pertains to our problem: Consider the hermitian matrices

$$A = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & -i \\ 0 & i & 2 \end{pmatrix} \quad B = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & i \\ 0 & -i & 2 \end{pmatrix} \quad D = \begin{pmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{pmatrix}. \quad (1)$$

Then $\sigma(D) = \{2, 2+\sqrt{2}, 2-\sqrt{2}\}$ so $D > 0$. Obviously, $B^\top = A$ and $D^\top = D$ so because the transposition map is well-known to be linear, positivity- and trace-preserving one has $\|A - tD\|_1 = \|(B - tD)^\top\|_1 = \|B - tD\|_1$ for all $t \in \mathbb{R}$. But there exists no CPTP map, i.e. no $\Phi \in Q(n)$ such that $\Phi(B) = A$ and $\Phi(D) = D$ as shown in (Heinosaari et al., 2012, Proposition 6). For now finding simple-to-verify conditions for $\prec_D$ beyond two dimensions remains an open problem.

3.2 Order Properties of D-Majorization

As is readily verified $\prec_d$ is a preorder but it is not a partial order—the same holds for $\prec_D$ and the counterexample which shows that $\prec_d$ is not a partial order transfers to the matrix case. Moreover, now, one can characterize minimal and maximal elements in this preorder.

[2] Here and henceforth $\mathrm{diag}(x) \in \mathbb{C}^{n\times n}$ is the matrix which has $x \in \mathbb{C}^n$ on its diagonal and the remaining entries are 0.

Theorem 3. Let $d \in \mathbb{R}^n_{++}$ be given and let

$$\mathfrak{h}_d := \{X \in \mathbb{C}^{n\times n} \,|\, X \text{ hermitian and } \operatorname{tr}(X) = e^\top d\}$$
$$\mathfrak{h}_d^+ := \{X \in \mathbb{C}^{n\times n} \,|\, X \geq 0 \text{ and } \operatorname{tr}(X) = e^\top d\}$$

be the trace hyperplane induced by d within the hermitian and the positive semi-definite matrices, respectively. The following statements hold.

(i) $D = \operatorname{diag}(d)$ is the unique minimal element in $\mathfrak{h}_d$ with respect to $\prec_D$.

(ii) $(e^\top d)e_k e_k^\top$ is maximal in $\mathfrak{h}_d^+$ with respect to $\prec_D$ where k is chosen such that d_k is minimal in d. It is the unique maximal element in $\mathfrak{h}_d^+$ with respect to $\prec_D$ if and only if d_k is the unique minimal element of d.

From a physical point of view this is precisely what one expects: from the state with the largest energy one can generate every other state (in an equilibrium-preserving manner) and there is no other state with this property.

3.3 Reachable Sets & D-Majorization

Let us finally connect our notion of D-majorization to the reachability questions we touched upon in the introduction. Markovian quantum control systems are generally modelled via a controlled GKSL-equation [Gorini et al. (1976); Lindblad (1976)]:

$$\dot\rho(t) = -i\Big[H_0 + \sum\nolimits_{j=1}^m u_j(t)H_j, \rho(t)\Big] - \gamma(t)\Gamma(\rho(t)) \quad (2)$$

with initial state $\rho(0) = \rho_0 \in \mathbb{C}^{n\times n}$, control Hamiltonians $H_1, \dots, H_m$, and control amplitudes $u_1, \dots, u_m, \gamma$. Here $\Gamma(\rho) := \sum_{j\in I}(\frac{1}{2}(V_j^*V_j\rho + \rho V_j^*V_j) - V_j\rho V_j^*)$ describes the dissipative effect on the system by means of the matrices $(V_j)_{j\in I} \subset \mathbb{C}^{n\times n}$ which in principle can be arbitrary.

Now given any n-level system described by a hermitian matrix $H_S \in \mathbb{C}^{n\times n}$ with spectral decomposition $\sum_{j=1}^n E_j|g_j\rangle\langle g_j|$, $E_1 \leq \dots \leq E_n$ and a bath of some temperature $T > 0$ the coupling of the system to said bath can be modelled by (2) if the generators of the dissipation $(V_j)_{j\in I}$ are chosen to be the modified ladder operators

$$\begin{aligned}\sigma_+^d &=: \sum\nolimits_{j=1}^{n-1} \sqrt{\frac{j(n-j)e^{-E_j/T}}{e^{-E_j/T} + e^{-E_{j+1}/T}}}\, |g_j\rangle\langle g_{j+1}| \\ \sigma_-^d &=: \sum\nolimits_{j=1}^{n-1} \sqrt{\frac{j(n-j)e^{-E_{j+1}/T}}{e^{-E_j/T} + e^{-E_{j+1}/T}}}\, |g_{j+1}\rangle\langle g_j|\,.\end{aligned} \quad (3)$$

In order to analyze the reachable set of (2) with $H_0 = H_S$ and dissipation generators σ_+^d, σ_-^d we (as in Section 2.1) define the set of all matrices which are D-majorized by some state ρ or a collection of states $S \subseteq \mathbb{C}^{n\times n}$:

$$\begin{aligned}M_D : \mathcal{P}(\mathbb{C}^{n\times n}) &\to \mathcal{P}(\mathbb{C}^{n\times n}) \\ S &\mapsto \bigcup\nolimits_{\rho\in S}\{X \in \mathbb{C}^{n\times n} \,|\, X \prec_D \rho\}\end{aligned}$$

with $\mathcal{P}$ being the power set and $M_D(X) := M_D(\{X\})$ for all $X \in \mathbb{C}^{n\times n}$. This operator is used to upper bound the reachable set of the "toy model" Λ_d (cf. Part I)[3] and is expected to do so in the matrix case, as well. Important properties of M_D are:

(i) $M_D(X)$ is convex for all $X \in \mathbb{C}^{n\times n}$.

(ii) If $P \subset \mathbb{C}^{n\times n}$ is compact, then $M_D(P)$ is compact.

(iii) If P is a collection of quantum states then $M_D(P)$ is star-shaped with respect to the Gibbs state $\frac{D}{\operatorname{tr}(D)}$.

(iv) When restricting M_D to the compact subsets of $\mathbb{C}^{n\times n}$ then M_D is non-expansive (so in particular continuous) with respect to the Hausdorff metric.

The last property formulates that for a system in the state ρ which is coupled to a bath of temperature $T \geq 0$, "small" changes in ρ cannot change the set of D-majorized states "too much".

Coming back to footnote 3, the crucial step in the proof is to identify an extreme point of $M_d(x_0)$ which is maximal w.r.t. classical majorization. While an extreme point analysis of the set of matrices $M_D(\rho_0)$ is way more difficult—as the convex polytope techniques from the vector case break down—the idea of a maximal extreme point might be equally useful in analyzing general open quantum control problems in the future.

4. CONNECTION TO THERMO-MAJORIZATION

Over the last few years, sparked by Brandão et al. (2015); Horodecki and Oppenheim (2013) and others [Gour et al. (2015); Lostaglio et al. (2018); Sagawa et al. (2021)] thermo-majorization has been a widely discussed and studied topic in quantum physics and in particular quantum thermodynamics. In the abelian case thermo-majorization, on a mathematical level, is described by vector d-majorization which begs the question of how to define thermo-majorization for general quantum states.

Indeed Faist et al. (2015) have shown that it makes a conceptual difference whether one defines thermo-majorization on non-diagonal states via Gibbs-preserving maps (i.e. CPTP maps having the Gibbs state $D > 0$ as a fixed point, cf. Definition 1) or if one restricts to the smaller class of thermal operations. The latter, given some Hamiltonian of the system H_S and a fixed bath temperature $T \geq 0$, are defined as follows, cf. also Lostaglio (2019):

Definition 4. A linear map $\Phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ is a thermal operation w.r.t. H_S if there exist $m \in \mathbb{N}$, $H_R \in \mathbb{C}^{m\times m}$ hermitian, and $U \in \mathbb{C}^{mn\times mn}$ unitary such that

$$[U, H_S \otimes \mathrm{id}_R + \mathrm{id}_S \otimes H_R] = 0 \quad (4)$$

and

$$\Phi(\rho) = \operatorname{tr}_R(U(\rho \otimes \rho_{\text{Gibbs}}^{H_R,T})U^*)$$

for all $\rho \in \mathbb{C}^{n\times n}$ (or equivalently for all quantum states ρ). We denote the collection of all thermal operations by $\mathsf{TO}(H_S, T)$.

Thermal operations are the free operations of the resource theory of quantum thermodynamics as those encompass the dynamics which preserve the Gibbs-state and which satisfy (4) (conserve the global energy, that is, the energy of the larger system $H_{SR} = H_S \otimes \mathrm{id}_R + \mathrm{id}_S \otimes H_R$). One readily verifies that $\mathsf{TO}(H_S, T)$ forms a path-connected semigroup with identity and – although $\mathsf{TO}(H_S, T)$ in general is not closed – its closure even is convex and compact.

In the vector case the state transitions possible with thermal operations are the same as with general Gibbs-

[3] More precisely we proved that $\mathfrak{reach}_{\Lambda_d}(x_0) \subseteq (M_e \circ M_d)(x_0)$ for any initial state x_0 and $d \in \mathbb{R}^n_{++}$ corresponding to a spin system, i.e. $d = (\alpha^{j-1})_{j=1}^n$ for some $\alpha \in (0, 1)$.

preserving maps described by d-stochastic matrices. However in the operator case there is a discrepancy between the two coming from the fact that there exist Gibbs-preserving maps which generate coherent superpositions of energy levels, whereas no thermal operation is capable of doing such a thing. In fact for all $H_S \in \mathbb{C}^{n\times n}$, $T \geq 0$ one finds the inclusions

$$\mathsf{TO}(H_S, T) \subseteq \mathsf{EnTO}(H_S, T) \subsetneq Q_{e^{-H_S/T}}(n) \qquad (5)$$

where $Q_{e^{-H_S/T}}(n)$ is the collection of all CPTP maps which have $e^{-H_S/T}$ – and thus $\rho^{H_S,T}_{\text{Gibbs}}$ – as a fixed point, and

$$\mathsf{EnTO}(H_S, T) := \{\Phi \in Q_{e^{-H_S/T}}(n) \,:\, [\Phi, \mathrm{ad}_{H_S}] = 0\}$$

are the enhanced thermal operations (also called "covariant Gibbs-preserving maps"). This is an important observation as the covariance property $[\Phi, \mathrm{ad}_{H_S}] = 0$ forces that the diagonal and the off-diagonal action of any channel are strictly separated, assuming H_S has non-degenerate spectrum. Note that this insight is of importance to us because the solution to the uncontrolled master equation (2) (i.e. $H_1 = \ldots = H_m = 0$, $\gamma \equiv 1$) with dissipation generators σ^d_+, σ^d_- from (3) lives in EnTO at all times.

Be aware that in (5), if the thermal operations are replaced by their closure then the first set inclusion is an equality if $n = 2$ and becomes a strict inclusion for $n \geq 3$ as shown by Ding et al. (2021). Even worse this discrepancy between TO and EnTO remains when looking at the *action* of the respective sets on certain states; more precisely, there exist quantum states $\rho, \omega \in \mathbb{C}^{3\times 3}$ and an enhanced thermal operation Φ such that $\Phi(\rho) = \omega$ but no element in TO or its closure can map ρ to ω.

This observation is particularly important for the field of quantum control as there one usually wonders which state transitions can be realized under a given control scenario. Thus beyond qubits it makes a conceptional difference which of the sets in (5) one uses to model a given thermodynamic control problem. Moreover, quantum control problems usually come in the framework of quantum-dynamical semigroups so one in addition needs to identify those quantum maps from a certain set (usually carrying the structure of a semigroup) which can be written as the solution to a controlled master equation of Gorini-Kossakowski-Sudarshan-Lindblad type [Gorini et al. (1976); Lindblad (1976)], that is, to identify those channels which are time-dependent Markovian. In other words from a Lie-theoretical perspective one wants to determine the Lie wedge of the respective semigroup in order to characterize the desired quantum channels as solutions of suitable (bi)linear master equations.

The question of Markovian state transitions in thermodynamics has only been tackled recently by Lostaglio and Korzekwa (2021) for the set of enhanced thermal operations and the simpler case of diagonal states – recall that in this realm the problem reduces to vector-d majorization. They were able to fully characterize which state transitions are possible under Markovian thermal processes (i.e. maps from EnTO which are solutions of a time-dependent GKSL-equation) in the classical realm, and they even gave algorithms to check for a Markovian path from a given initial to a given final state. While incredibly important, their work of course is but a first step in this direction and the ultimate goal will be to extend their results and concepts to general thermodynamic quantum control systems.

Abstract: Which quantum states can be reached by controlling open Markovian n-level quantum systems? Here, we address reachable sets of coherently controllable quantum systems with switchable coupling to a thermal bath of temperature T. — The core problem reduces to a toy model of studying points in the standard simplex allowing for two types of controls: (i) permutations within the simplex, (ii) contractions by a dissipative semigroup [Dirr et al. (2019)]. By illustration, we put the problem into context and show how toy-model solutions pertain to the reachable set of the original controlled Markovian quantum system. Beyond the case $T = 0$ (amplitude damping) we present new results for $0 < T < \infty$ using methods of d-majorisation.

Keywords: Quantum Control Theory; Markovian Quantum Dynamics; Reachable Sets; Quantum Thermodynamics; Majorisation, d-Majorisation.

1. INTRODUCTION

Here we show how reachability problems of (finite dimensional) Markovian open quantum systems may reduce to hybrid control systems on the standard simplex of $\mathbb{R}^n$. Consider a bilinear control system [Jurdjevic (1997); Elliott (2009)]

$$\dot{\mathbf{x}}(t) = -(A + \sum\nolimits_j u_j(t) B_j)\mathbf{x}(t)\,, \quad \mathbf{x}(0) = \mathbf{x}_0\,, \qquad (1)$$

where as usual A denotes an uncontrolled drift, while the control terms consist of (piecewise constant) control amplitudes $u_j(t) \in \mathbb{R}$ and control operators B_j. The state $\mathbf{x}(t)$ may be thought of as (vectorized) density operator. The corresponding system Lie algebra, which provides the crucial tool for analysing controllability and accessibility questions, reads $\mathfrak{k} := \langle A, B_j \,|\, j = 0, 1, \ldots, m\rangle_{\mathsf{Lie}}$.

For 'closed' quantum systems, i.e. systems which do not interact with their environment, the matrices A and B_j involved are skew-hermitian and thus it is known [Jurdjevic and Sussmann (1972); Brockett (1972); Jurdjevic (1997)] that the reachable set of (1) is given by the orbit of the initial state under the action of the dynamical systems group $\mathbf{K} := \langle \exp \mathfrak{k} \rangle$, provided $\mathbf{K}$ is a closed and thus compact subgroup of the unitary group.

More generally, for 'open' systems undergoing Markovian dissipation, the reachable set takes the form of a (Lie) semigroup orbit, see, e.g., [Dirr et al. (2009)]. – Here we address a scenario with coherent controls $\{B_j\}_{j=1}^m$ and a *bang-bang switchable* dissipator B_0 as motivated by recent experimental progress [Chen et al. (2014); Wong et al. (2019)] and described in Bergholm et al. (2016).

Specification of the Toy Model — These assumptions and the 'thermal' condition (*vide infra*) that B_0 leaves the set of diagonal matrices invariant simplify the reachability analysis of (1) to the core problem of diagonal states represented by probability vectors of the standard simplex

$$\Delta^{n-1} := \left\{ x \in \mathbb{R}^n_+ \,|\, \textstyle\sum_{i=1}^n x_i = 1 \right\}, \qquad (2)$$

i.e. $\mathbf{x}(t) = \mathrm{diag}(x(t))$. In order to make the main features match the quantum dynamical context, let us fix the following stipulations for the toy model: Its controls shall amount to permutation matrices acting instantaneously on the entries of $x(t)$ and a continuous-time one-parameter semigroup $(e^{-tB_0})_{t\in\mathbb{R}^+}$ of stochastic maps with a unique fixed point d in Δ^{n-1}. As $(e^{-tB_0})_{t\in\mathbb{R}^+}$ results from the restriction of the bang-bang switchable dissipator B_0, with abuse of notation we will denote its infinitesimal generator again by B_0. The '*equilibrium state*' d is defined in (8) by system parameters and the absolute temperature $T \geq 0$ of an external bath.

These stipulations suggest the following hybrid/impulsive scenario to define the 'toy model' Λ on $\Delta^{n-1} \subset \mathbb{R}^n$ by

$$\begin{aligned} &\dot{x}(t) = -B_0 x(t)\,, \quad x(t_k) = \pi_k x_k\,, \quad t \in [t_k, t_{k+1})\,, \\ &x_0 \in \Delta^{n-1}\,, \quad x_{k+1} = e^{-(t_{k+1}-t_k)B_0} x(t_k)\,, \quad k \geq 0\,. \end{aligned} \qquad (3)$$

Furthermore, $0 =: t_0 \leq t_1 \leq t_2 \leq \ldots$ is an arbitrary switching sequence and π_k are arbitrary permutation ma-

Bayreuth, Germany, 12-16 September 2022

trices. Both the switching points and the permutation matrices are regarded as controls for (3). For simplicity, we assume that the switching points do not accumulate on finite intervals. For more details on hybrid/impulsive control systems see, e.g., [Lakshmikantham et al. (1989); Alur et al. (1996)]. The reachable sets of (3)

$$\mathfrak{reach}_\Lambda(x_0) := \{x(t) \,|\, x(\cdot) \text{ is a solution of (3), } t \geq 0\}$$

allow for the characterisation $\mathfrak{reach}_\Lambda(x_0) = \mathcal{S}_\Lambda x_0$, where $\mathcal{S}_\Lambda \subset \mathbf{L}(n,\mathbb{R})$ is the contraction semigroup generated by $(e^{-tB_0})_{t\in\mathbb{R}_+}$ and the set of all permutation matrices π.

2. STATE-OF-THE-ART

Henceforth, let $\mathbf{\Gamma}$ stand for a GKSL-operator acting on complex $n \times n$ matrices, see (5). Then A in (1) can be regarded as its matrix representation (e.g., in the Kronecker formalism (Horn and Johnson, 1991, Chap. 4)). If $\mathbf{\Gamma}$ leaves the set of diagonal matrices invariant—as in *enhanced thermal operations* [Lostaglio (2019)] we use as controllable resource—its reduction to the action on diagonal states represented as vectors is denoted B_0 since it originates from *switchable* noise. — In this picture, our recent results [Dirr et al. (2019)] can be sketched as follows.

Take the n-level toy model $\Lambda := \Lambda_0$ with controls by permutations and an infinitesimal generator B_0 which results from coupling to a bath of temperature $T = 0$ (i.e. $\mathbf{\Gamma} := \mathbf{\Gamma}_0$ given by single $V := \sigma_-$ see (10) with $\theta = \frac{\pi}{2}$).

Theorem 1. The closure of the reachable set of any initial vector $x_0 \in \Delta^{n-1}$ under the dynamics of Λ_0 exhausts the full standard simplex, i.e. $\overline{\mathfrak{reach}_{\Lambda_0}(x_0)} = \Delta^{n-1}$.

Moving from a single n-level system (qu*d*it) with $x_0 \in \Delta^{n-1}$ to a tensor product of m such n-level systems gives $x_0 \in \Delta^{n^m-1} \subset (\mathbb{R}^n)^{\otimes m}$. If the bath of temperature $T = 0$ is coupled to just one (say the last) of the m qu*d*its, $\mathbf{\Gamma}_0$ is generated by $V := I_{n^{m-1}} \otimes \sigma_-$ and one obtains the following generalization.

Theorem 2. The statement of Theorem 1 holds analogously for all m-qudit states $x_0 \in \Delta^{n^m-1}$.

In a first round to generalise the findings from the extreme cases $T = 0$ or $T = \infty$ to finite temperatures $0 < T < \infty$ we found the following: Let $\mathbf{\Gamma} := \mathbf{\Gamma}_d$ be the dissipator for temperature $T > 0$ with $\mathbf{\Gamma}_d$ comprising the generators σ_-^d and σ_+^d of (9) and (10) as detailed in Sec. 4 and let $d \in \Delta^{n-1}$ be its unique attractive fixed point given by (8). For equidistant eigenvalues in H_0 (see Sec. 5) one gets:

Theorem 3. Again allowing for permutations as controls interleaved with dissipation resulting from $B_0(\mathbf{\Gamma}_d)$ one obtains for the reachable set of the thermal state d under the dynamics of the respective toy model $\Lambda := \Lambda_d$ the inclusion $\mathfrak{reach}_{\Lambda_d}(d) \subseteq \{x \in \Delta^{n-1} \,|\, x \prec d\}$, where '$\prec$' refers to the standard concept and notation of majorisation [Marshall et al. (2011); Ando (1989)].

Our recent toy-model results in Dirr et al. (2019) thus extend (the diagonal part of) the qu*b*it picture previously analysed by Bergholm et al. (2016) to n-level systems, and even more generally to systems of m qu*d*its. Here we explore further generalisations to finite temperatures $0 < T < \infty$, e.g., by allowing for general initial states x_0 instead of the thermal state d in Theorem 3.

3. RELATION TO CONTROLLED QUANTUM MARKOVIAN DYNAMICS

Let $\mathcal{D}(n)$ denote all $n \times n$ density matrices (positive semi-definite with trace 1) and $\mathcal{L}(\mathbb{C}^{n\times n})$ be the space of all linear operators acting on complex $n \times n$-matrices. Then

$$\dot\rho(t) = -\mathbf{\Gamma}(\rho(t)), \quad \rho(0) = \rho_0 \in \mathcal{D}(n) \tag{4}$$

with $\mathbf{\Gamma} \in \mathcal{L}(\mathbb{C}^{n\times n})$ of the GKSL-form [Gorini et al. (1976); Lindblad (1976)] with $V_k \in \mathbb{C}^{n\times n}$ chosen arbitrary in

$$\mathbf{\Gamma}(\rho) := \sum\nolimits_k \left(\tfrac{1}{2}\big(V_k^\dagger V_k \rho + \rho V_k^\dagger V_k\big) - V_k \rho V_k^\dagger\right) \tag{5}$$

ensures the time evolution $\rho(t) = e^{-t\mathbf{\Gamma}}\rho_0$ solving (4) remains in $\mathcal{D}(n)$ for all $t \in \mathbb{R}_+$. So $(e^{-t\mathbf{\Gamma}})_{t\in\mathbb{R}_+}$ is a completely positive trace-preserving (i.e. CPTP) linear contraction semigroup leaving $\mathcal{D}(n)$ invariant.

The overarching goal is to characterise control systems Σ extending (4) by coherent controls (generated by hermitian H_j and (piece-wise constant) $u_j(t) \in \mathbb{R}$) and by making dissipation bang-bang switchable in the sense

$$\dot\rho(t) = -\mathrm{i}\Big[H_0 + \sum_{j=1}^m u_j(t) H_j, \rho(t)\Big] - \gamma(t)\mathbf{\Gamma}(\rho(t)) \tag{6}$$

with $\gamma(t) \in \{0, 1\}$. A general analytic description of reachable sets of (6) is challenging in particular in higher dimensional cases except for a few scenarios which allow explicit characterizations: (a) In the unital case $\mathbf{\Gamma}(I_n) = 0$, one has [Ando (1989); Yuan (2010)]

$$\mathfrak{reach}_\Sigma(\rho_0) \subseteq \{\rho \in \mathcal{D}(n) \,|\, \rho \prec \rho_0\}. \tag{7}$$

(b) If in addition $\mathbf{\Gamma}$ is generated by a single normal V, one gets (up to closure) equality in (7) provided the unitary part of (6) is *controllable* and the switching function $\gamma(t)$ gives extra control (cf. [Bergholm et al. (2016)] for finite and [vom Ende et al. (2019)] for infinite dimensions).

Under the controllability scenario given in (b) plus the invariance of diagonal states imposed by enhanced thermal operations [Lostaglio (2019)], the closure of the unitary orbit of $\mathrm{diag}\big(\mathfrak{reach}_\Lambda(x_0)\big)$ sits in the closure of $\mathfrak{reach}_\Sigma(U\,\mathrm{diag}(x_0)U^\dagger)$. Settings beyond thermal relaxation are pursued with similar techniques, e.g., by Rooney et al. (2018) at the expense of arriving at conditions that are hard to verify for higher-dimensional systems.

4. THERMAL STATES AND d-MAJORISATION

By unitary controllability choose H_0 diagonal (with increasing eigenvalues ϵ_k), so the equilibrium state resulting from coupling to a bath of temperature T is the *Gibbs vector*

$$d = \frac{(e^{-\epsilon_k/T})_{k=1}^n}{\sum_{k=1}^n e^{-\epsilon_k/T}} \in \Delta^{n-1} \tag{8}$$

with $\rho_{\mathsf{Gibbs}} = \mathrm{diag}(d) \in \mathcal{D}(n)$. As shown in Dirr et al. (2019), $\mathrm{diag}(d)$ can then be obtained as the unique fixed point of (4) when choosing the two Lindblad terms as

$$V_1 = \sigma_+^d := \sum\nolimits_{k=1}^{n-1} \sqrt{k(n-k)}\cos(\theta_k)\, E_{k,k+1} \tag{9}$$

$$V_2 = \sigma_-^d := \sum\nolimits_{k=1}^{n-1} \sqrt{k(n-k)}\sin(\theta_k)\, E_{k+1,k}, \tag{10}$$

where the $E_{i,j}$ denote standard Weyl matrices and

$$\theta_k := \arccos\sqrt{1 + d_{k+1}/d_k} \in (0, \tfrac{\pi}{2}). \tag{11}$$

Since diagonal states remain diagonal under enhanced thermal operations as with $\mathbf{\Gamma} := \mathbf{\Gamma}_d$ and V_1, V_2 above, the connection to the toy model Λ_d is obvious. — What one can do with thermal resources is determined via d-majorisation (a.k.a. thermomajorisation in Horodecki and Oppenheim (2013) or Brandão et al. (2015)) as generalisation of common majorisation [Marshall et al. (2011)] to majorisation with respect to a strictly positve vector d [Veinott (1971)] representing the 'Gibbs state':

Definition 1. For $x, y \in \mathbb{R}^n$ and $d \in \Delta^{n-1}$, the vector x is d-majorised by y, written $x \prec_d y$, if there is a column stochastic matrix $A \in \mathbb{R}^{n\times n}$ (all elements non-negative, columns summing up to one) with $Ad = d$ and $Ay = x$.

Note that d-majorisation reproduces conventional majorisation with A being doubly stochastic if d is the maximally mixed state $d = \frac{1}{n}e$ and e is the vector with all entries 1.

For numerics a convenient equivalent characterisation [vom Ende and Dirr (2022)] is: $x \prec_d y$ if and only if

$$(a)\ \ \Sigma_i x_i = \Sigma_i y_i \quad \text{and} \tag{12}$$

$$(b)\ \ \|d_i\, x - y_i\, d\|_1 \leq \|d_i\, y - y_i\, d\|_1 \ \forall\, i \in \{1, \ldots, n\}, \tag{13}$$

where $\|z\|_1 := \sum_{i=1}^n |z_i|$ is the vector 1-norm.

5. OVERVIEW OF NEW RESULTS

To motivate the study of the d-majorisation polytope (and its operator lift) in Part II, we illustrate new results for n-level systems by dynamics of three-level systems (qutrits) in the toy-model scenario with its population flips and its dynamics by coupling the system to a bath of various temperatures $0 \leq T \leq \infty$ entailing unique equilibrium states d given by (8). Henceforth we invoke

Assumption A: H_0 has equidistant energy eigenvalues.

Moreover define the set of vectors in the simplex Δ^{n-1} that are d-majorised by the initial state x_0 as

$$\Delta_d^{n-1}(x_0) := \{z \in \Delta^{n-1} \,|\, z \prec_d x_0\}\,, \tag{14}$$

while those conventionally majorised by x_0 shall be denoted as $\Delta_e^{n-1}(x_0)$. For the toy-model dynamics one gets:

(1) $e^{-tB_0}x_0 \in \Delta_d^{n-1}(x_0)$ for all $t \geq 0$;
(2) $\Delta_d^{n-1}(x_0)$ is a convex subset within the simplex Δ^{n-1},

which means the *dissipative time evolution* of any x_0 remains within the convex set of states d-majorised by x_0.

Beyond pure dissipative evolution the toy model also allows for permutations π, so one naturally obtains

$$\mathfrak{reach}_{\Lambda_d}(x_0) = \mathfrak{reach}_{\Lambda_d}(\pi(x_0)) \quad \forall \pi \in \mathcal{S}_n\,. \tag{15}$$

Clearly, the simplex region $\Delta_d^{n-1}(x_0)$ intertwines overall permutations π (in the symmetric group $\mathcal{S}_n$) in the sense

$$\pi\, \Delta_d^{n-1}(x_0) = \Delta_{\pi(d)}^{n-1}(\pi(x_0))\,. \tag{16}$$

For the maximally mixed state ($d \simeq e$) this boils down to permutation invariance under conventional majorisation

$$\pi\, \Delta_e^{n-1}(x_0) = \Delta_e^{n-1}(\pi(x_0)) = \Delta_e^{n-1}(x_0)\,. \tag{17}$$

Eq. (16) entails as a first new result:

Theorem 4. (generalising Thm. 3). Assuming **A** those initial states $\tilde{x}_0$ conventionally majorised by d (i.e. $\tilde{x}_0 \in \Delta_e^{n-1}(d)$) remain within $\Delta_e^{n-1}(d)$ under the dynamics of the toy model Λ_d. In other words $\mathfrak{reach}_{\Lambda_d}(\tilde{x}_0) \subseteq \Delta_e^{n-1}(d)$.

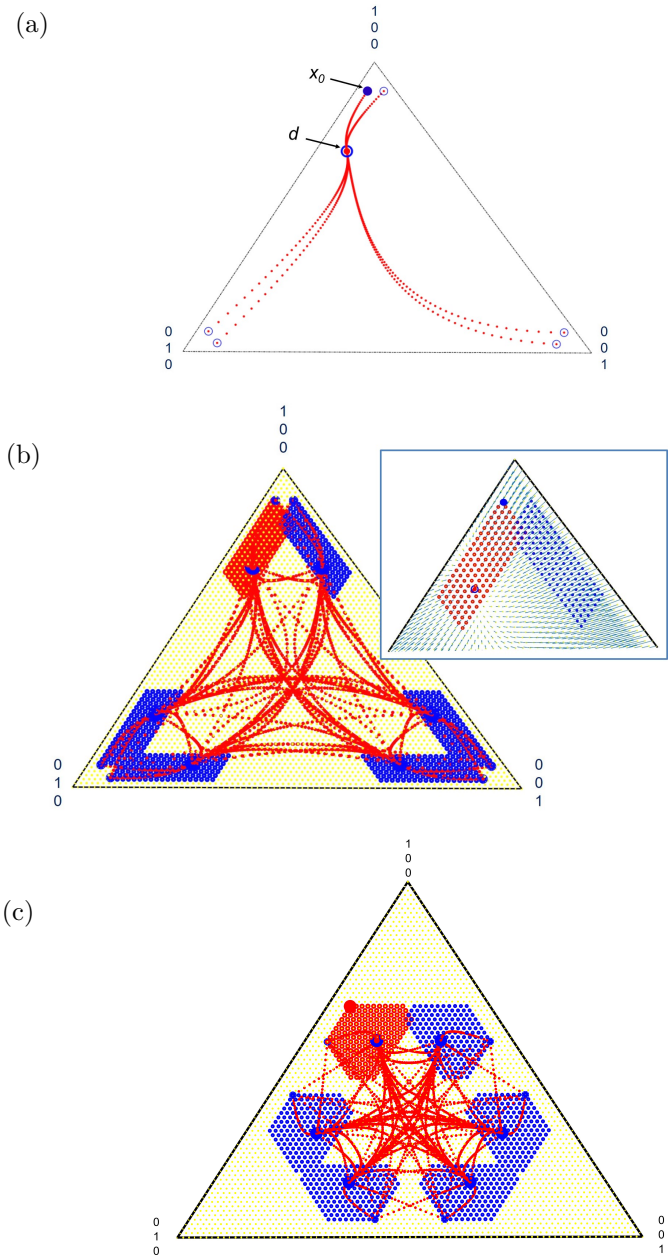

Fig. 1. **(a)** Evolutions of initial state $x_0 = (0.9, 0.07, 0.03)^\top$ and its permutations $\pi(x_0)$ under $\mathbf{\Gamma}_d$ with V_1, V_2 of (9) and $\theta = \frac{\pi}{6}$ of (11) drive into fixed point d;
(b) includes all permutations of trajectories starting with permutations of d, i.e. $x_0 = \pi(d)$; red region shows the states d-majorised by x_0, blue regions are their permutations; the convex hull over red and blue regions embraces entire reachable set $\mathfrak{reach}_{\Lambda_d}(x_0)$; inset gives the vector field to the dynamics Λ_d.
(c) For $\theta = \frac{\pi}{5}$ in (11) as in the generic case, the extreme point $z = (0.65, 0.30, 0.05)^\top$ in red differs from $x_0 = (0.55, 0.40, 0.05)^\top$ and $d = (0.55, 0.29, 0.16)^\top$.

In the next step, writing $x_0^\downarrow$ for ordering the entries of x_0 in descending magnitude (so that $x_0^\downarrow$ and d—with d being

the thermal state hence sorted by descending entries—are in the same Weyl chamber), one arrives at:

Theorem 5. Under assumption **A** the reachable set of the dynamics Λ_d is included in the set of all states conventionally majorised by $\Delta_d^{n-1}(x_0^{\downarrow})$ in the formal sense

$$\mathfrak{reach}_{\Lambda_d}(x_0) \subseteq \Delta_e^{n-1}\big(\Delta_d^{n-1}(x_0^{\downarrow})\big)\,. \tag{18}$$

The proof uses two facts: (i) There exists a (unique) extreme point z of the d-majorisation polytope $\Delta_d^{n-1}(x_0^{\downarrow})$ which conventionally majorises all points in $\Delta_d^{n-1}(x_0^{\downarrow})$, i.e. $\Delta_d^{n-1}(x_0^{\downarrow}) \subset \Delta_e^{n-1}(z)$. (ii) The vector field driving the dynamics of Λ_d points *inside* the conventional majorisation polytope $\Delta_e^{n-1}(z)$ at each of its $n!$ extreme points $\pi(z)$ with $\pi \in \mathcal{S}_n$ (cf. Fig. 1(c)). Once knowing how to construct z (see Part-II and [vom Ende and Dirr (2022)] for more detail), the results may be summarised and significantly simplified from d-majorisation to conventional majorisation via the extremal state z:

Theorem 6. Invoke assumption **A**. Then for the toy model Λ_d with Gibbs state d the reachable set is included in the following convex hull

$$\mathfrak{reach}_{\Lambda_d}(x_0) \subseteq \operatorname{conv}\big\{\pi(z)\,|\,\pi \in \mathcal{S}_n\big\} = \Delta_e^{n-1}(z)\,. \tag{19}$$

Fig. 1 illustrates these findings in three-level systems again assuming equidistant separation of energy eigenvalues for the underlying drift term H_0.

Conclusion and Outlook — For any initial state x_0, the time evolutions of probability vectors $x(t)$ following the underlying toy model Λ_d (thermal relaxation interdispersed with level-permutation) remain within the convex hull of extreme points resulting from the set of all states d-majorised by the initial state x_0. Yet, upon moving from the toy model to the full quantum dynamics of thermal relaxation interdispersed with unitary coherent evolution, the scenario gets more involved. In accompanying studies presented at this conference we pursue different approaches to handle the general case: (i) lifting d-majorisation to the operator level which leads to the concept of D-majorisation and (ii) projecting the full dynamics along the unitary orbits to the standard simplex by symmetric Lie algebra techniques giving an enhanced toy model for the reduced control system on Δ^{n-1}.

ACKNOWLEDGEMENTS

Fruitful discussion with David Reeb on unital systems at a very early phase of the project is gratefully acknowledged.

Keywords: Nonlinear model reduction, Balanced realization, variational system, controllability and observability Gramians, extended differential singular values

1. INTRODUCTION

Model reduction is the method of designing a lower-dimensional copy of the original high-dimensional model of the dynamical system which mimics the dominant behaviour of the actual system with considerable accuracy. Balanced truncation is one of the well known and effective *model reduction* techniques which was first proposed in Moore (1981). A thorough exposition of different model reduction techniques for linear systems can be found in Antoulas (2005). Recently an extension of generlized balanced truncation has been put forward in Borja et al. (2022) for continuous-time LTI systems which can provide tighter priori error bounds and brings on the flexibility of preserving structures such as a port-Hamiltonian structure, an electrical network structure, etc. For nonlinear systems balancing has been introduced for the first time in Scherpen (1993). Afterwards there have been several developments in different types of balancing, minimality considerations, association with nonliear Hankel operator in e.g. Verriest and Gray (2000), Fujimoto and Scherpen (2010), Gray and Verriest (2006), Lall et al. (2002). Recently a new approach of nonlinear model reduction has been introduced in Kawano and Scherpen (2017a) which is called *differential balanced truncation*. Differential balancing is basically performing balancing in the contraction framework where a nonlinear system and its variational dynamics have been considered together, which is being called a prolonged system. Generalized differential balancing is computationally tractable way of nonlinear balancing for systems with constant input vector-fields and linear output vectors. Generalized differential balanced truncation has been proposed in Kawano and Scherpen (2015) to find a reduced order model for this kind of nonlinear systems with a prior error bound and stability guarantees. In this work we have extended this idea to extended differential balancing which can provide a less conservative prior error bound in comparison with generalized differential balanced truncation. Apart from that it brings on possibility of preserving certain structures and properties of the nonlinear dynamical system.

On the other hand, structure-preserving model reduction methods for port-Hamiltonian systems have been studied via various approaches, e.g. via balanced truncation Lopezlena et al. (2003),Fujimoto (2008),Kawano and Scherpen (2018), moment matching Polyuga and van der Schaft (2010), Ionescu and Astolfi (2013b), Ionescu and Astolfi (2013a), Kalman decomposition Scherpen and van der Schaft (2008), and Projection-based approach such as Proper Orthogonal Decomposition Chaturantabut et al. (2016). In Lopezlena et al. (2003), balanced truncation is performed via supply and storage functions and the port-Hamiltonian structure is preserved under specific conditions. In Fujimoto (2008), it has been shown that the pH structure is preserved if the Hamiltonian is either identical to so-called weighted controllability function or weighted observability function. In this work, we extend the notion of traditional nonlinear balancing to generalized nonlinear balancing. We define generalized controllability and observability functions which are solutions of two nonlinear partial-differential inequalities and can provide bounds to the traditional controllability and observability functions respectively. Moreover, these generalized functions bring forth the flexibility to propose a balanced truncation approach while preserving the port-Hamiltonian structure in the reduced-order model as well.

2. GENERALIZED DIFFERENTIAL GRAMIANS

Consider the nonlinear system

$$\Sigma : \begin{cases} \dot{x} = f(x) + Bu, \\ y = Cx, \end{cases} \tag{1}$$

where $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$ and $y(t) \in \mathbb{R}^p$. The function $f : \mathbb{R}^n \to \mathbb{R}^n$ is of class C^1, $B \in \mathbb{R}^{n\times m}$ and $C \in \mathbb{R}^{p\times n}$. Let $\phi(t, x_0, u)$ denote the solution $x(t)$ of the system (1) at time $t \in \mathbb{R}_+$ starting from $x_0 \in \mathbb{R}^n$ with input $u(t) \in \mathbb{R}^m$.

Now, we consider the variational system associated with the nonlinear system as

$$d\Sigma : \begin{cases} \delta\dot{x} = \dfrac{\partial f(x)}{\partial x}\delta x + B\delta u, \\ \delta y = C\delta x, \end{cases} \tag{2}$$

where $\delta x(t) \in \mathbb{R}^n$, $\delta u(t) \in \mathbb{R}^m$ and $\delta y(t) \in \mathbb{R}^p$ denote the state, input and output of the variational system respectively. The system (1) together with (2) is called the prolonged system.

The generalized differential controllability and generalized differential observability Gramian are defined as the solutions $P \succ 0$, $Q \succ 0$ of the following differential Lyapunov inequalities

$$\frac{\partial f(x)}{\partial x}P + P\frac{\partial^\top f(x)}{\partial x} + BB^\top \preceq -\epsilon P, \tag{3}$$

$$Q\frac{\partial f(x)}{\partial x} + \frac{\partial^\top f(x)}{\partial x}Q + C^\top C \preceq -\epsilon Q, \tag{4}$$

for all $x \in \mathbb{R}^n$, $\epsilon > 0$. This is slightly different from the original definition of generalized differential Gramians Kawano and Scherpen (2017b),Kawano and Scherpen (2015) where $\epsilon = 0$ is assumed. However, $\epsilon > 0$ guarantees stability properties of the system (1) based on the generalized differential Gramians Kawano (2022). If the solutions exist then the function $\bar{L}_{\mathcal{P}}(\delta x_0) := \frac{1}{2}\delta x_0^\top P^{-1}\delta x_0$ is said to be the generalized differential controllabilty function and the function $\bar{L}_{\mathcal{O}}(\delta x_0) := \frac{1}{2}\delta x_0^\top Q\delta x_0$ is said to be the generalized differential observability function. The solutions of (3) and (4) are not unique and consequently the generalized differential functions are not unique. However, they provide bounds to differential energy functions as follows $\bar{L}_{\mathcal{C}}(\delta x_0) \leq L_{\mathcal{C}}(\delta x_0, x_0)$, $\bar{L}_{\mathcal{O}}(\delta x_0) \geq L_{\mathcal{O}}(\delta x_0, x_0)$, where $x_0 \in \mathbb{R}^n$, $\delta x_0 \in \mathbb{R}^n$, $L_{\mathcal{C}}(\delta x_0, x_0)$ and $L_{\mathcal{O}}(\delta x_0, x_0)$ are the differential controllability function and the differential observability function respectively as defined in Kawano and Scherpen (2015).

3. EXTENDED DIFFERENTIAL GRAMIANS

Extended Gramians have been defined for discrete-time LTI systems in Sandberg (2010) and for continuous-time systems in Scherpen and Fujimoto (2018),Borja et al. (2022). In this section, we use a similar notion to define extended differential Gramians for nonlinear systems. Before proceeding any further, we have the following standing assumption.

Assumption 1. The Jacobian $\partial f(x)/\partial x$ is globally bounded with respect to its argument i.e. $|\frac{\partial f_i}{\partial x_j}| < \infty$, $1 \leq i \leq n$, $1 \leq j \leq n$ for all $x \in \mathbb{R}^n$.

Consider solutions of (3) and (4) are positive definite. Now, we can define $\check{P} := P^{-1}$, where $\check{P}$ is positive definite. For the ease of readability we define

$$\begin{aligned} X_o(x) &:= -Q\frac{\partial f(x)}{\partial x} - \frac{\partial^\top f(x)}{\partial x}Q - C^\top C - \epsilon Q, \\ X_c(x) &:= -\check{P}\frac{\partial f(x)}{\partial x} - \frac{\partial^\top f(x)}{\partial x}\check{P} - \check{P}BB^\top\check{P} - \epsilon\check{P}. \end{aligned} \tag{5}$$

Now, let us consider the following two time-varying LMIs,

$$\begin{bmatrix} X_o(x) & Q - (\alpha I_n + \frac{\partial^\top f}{\partial x})S \\ Q - S^\top(\alpha I_n + \frac{\partial f}{\partial x}) & (S + S^\top) \end{bmatrix} \succeq 0 \tag{6}$$

and

$$\begin{bmatrix} -\check{P}\frac{\partial f}{\partial x} - \frac{\partial^\top f}{\partial x}\check{P} - \epsilon\check{P} & -\check{P} + (\beta I_n + \frac{\partial^\top f}{\partial x})T & -2\check{P}B \\ \check{P} - T^\top(\beta I_n + \frac{\partial f}{\partial x}) & T + T^\top & 2T^\top B \\ -2B^\top\check{P} & 2B^\top T & 4I_m \end{bmatrix} \succeq 0 \tag{7}$$

where $X_o(x)$ is as defined in (5) and $\alpha, \beta > 0$. We then call the solutions (Q, S, α) of (6) and $(\check{P}, T, \beta)$ of (7) as extended differential observability Gramian and inverse of the extended differential controllability Gramian for the variational system (2) respectively.

Theorem 1. Assume $X_o(x) \succ 0$ for all $x \in \mathbb{R}^n$, then the inequality (4) has a solution Q for all $x \in \mathbb{R}^n$ if and only if (6) has a solution (Q, S, α) with $Q \succ 0$, $S = S^\top \succ 0$ and α large enough for all $x \in \mathbb{R}^n$.

Theorem 2. Assume $X_c(x) \succ 0$ for all $x \in \mathbb{R}^n$, then the inequality (3) has a solution P for all $x \in \mathbb{R}^n$ if and only if (7) has a solution $(\check{P}, T, \beta)$ with $\check{P} \succ 0$, $T = T^\top \succ 0$ and β large enough for all $x \in \mathbb{R}^n$.

Now, the nonlinear system (1) is said to be extended differentially balanced if there exists an invertible matrix $W_e \in \mathbb{R}^{n\times n}$ which transforms the system (1) and (2) into a realization where

$$W_e^\top T^{-1} W_e = W_e^{-1} S W_e^{-\top} = \Lambda_{ST}, \tag{8}$$

such that

$$\Lambda_{ST} = \mathsf{diag}\{\sigma_1, \sigma_2, \cdots, \sigma_n\},$$

where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n > 0$.

Remark 1. It can be shown in a similar fashion as for linear systems that there always exists an invertible matrix $W_e \in \mathbb{R}^{n\times n}$ which satisfies (8). Moreover, it can be observed that $T^{-1}S = W_e^{-1}\Lambda_{ST}^2 W_e$ which implies that $\sigma_i (i = 1, 2, \cdots, n)$ are the singular values of $T^{-1}S$. We call them the **extended differential singular values** of the prolonged nonlinear system.

4. MODEL REDUCTION AND THE ERROR BOUND

One of the essential features of balanced truncation for linear systems is that it can provide an apriori error bound for the reduction. For linear systems this error bound can be computed through frequency domain analysis of the actual and reduced order models. On the other hand a prior bound could not be provided for balanced truncation of nonlinear systems. However, as generalized differential balancing and extended differential balancing exploit the variational dynamics of the nonlinear system (which is essentially the linearization along the trajectories of the nonlinear system), an apriori error bound can be rendered for the reduced order nonlinear model.

To proceed further let us consider the nonlinear system and the associated variational dynamics in balanced coordinates as

$$\bar{\Sigma} : \begin{cases} \dot{\bar{x}} = \bar{f}(\bar{x}) + \bar{B}u \\ y = \bar{C}\bar{x} \end{cases} \tag{9}$$

$$d\bar{\Sigma} : \begin{cases} \delta\dot{\bar{x}} = \dfrac{\partial \bar{f}(\bar{x})}{\partial \bar{x}}\delta\bar{x} + \bar{B}\delta u \\ \delta y = \bar{C}\delta\bar{x} \end{cases} \tag{10}$$

where,

$$\begin{aligned} &\bar{f}(\bar{x}) := W_e^{-1} f(W_e\bar{x}), \quad \frac{\partial \bar{f}(\bar{x})}{\partial \bar{x}} := W_e^{-1}\frac{\partial f(x)}{\partial x}W_e, \\ &\bar{B} := W_e^{-1}B, \quad \bar{C} := CW_e, \quad x = W_e\bar{x}. \end{aligned} \tag{11}$$

We can split $\bar{x}$ as

$$\bar{x} = \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{bmatrix},$$

where $\bar{x}_1 \in \mathbb{R}^r$ is the part of the state to be kept and $\bar{x}_2 \in \mathbb{R}^{n-r}$, is the part of the state to be truncated while performing the model reduction. Similarly, we can split

$$\bar{f}(\bar{x}) = \begin{bmatrix} \bar{f}_1(\bar{x}_1, \bar{x}_2) \\ \bar{f}_2(\bar{x}_1, \bar{x}_2) \end{bmatrix}, \quad \bar{B} = \begin{bmatrix} \bar{B}_1 \\ \bar{B}_2 \end{bmatrix}, \quad \bar{C} = \begin{bmatrix} \bar{C}_1 & \bar{C}_2 \end{bmatrix} \quad (12)$$

with $\bar{f}_1 : \mathbb{R}^n \to \mathbb{R}^r$, $\bar{f}_2 : \mathbb{R}^n \to \mathbb{R}^{n-r}$, $\bar{B}_1 \in \mathbb{R}^{r\times m}$, $\bar{B}_2 \in \mathbb{R}^{(n-r)\times m}$, $\bar{C}_1 \in \mathbb{R}^{p\times r}$ and $\bar{C}_2 \in \mathbb{R}^{p\times(n-r)}$.

Hence, the truncation of the state component $\bar{x}_2$ leads to the the reduced-order model as follows

$$\hat{\Sigma} : \begin{cases} \dot{\hat{x}} = \hat{f}(\hat{x}) + \hat{B}u \\ \hat{y} = \hat{C}\hat{x}, \end{cases} \quad (13)$$

where,

$$\hat{x} := \bar{x}_1, \quad \hat{f} := \bar{f}_1, \quad \hat{B} := \bar{B}_1, \quad \hat{C} := \bar{C}_1.$$

Assumption 2. The drift vector field of the nonlinear system is an odd function of the state vector, i.e. $f(x) = -f(-x)$.

This assumption is used to provide an apriori error bound for the reduced order model. Though the assumption seems to be quite conservative in nature, odd nonlinear functions for the drift occur in several physical systems e.g. mass-spring-damper systems with nonlinear springs, a nonlinear pendulum, mechanical systems with frictional, backlash nonlinearities, electronic circuits with nonlinear resistors, etc. In addition to that standard static nonlinearities such saturations can be modeled by a hyperbolic tangent function which is odd in nature as well.

Theorem 3. Suppose the system (1) is balanced with the extended differential observability Gramian (Q, S, α) and inverse of extended differential controllability Gramian $(\check{P}, T, \beta)$ as defined in (6) and (7) respectively. If the system is in the balanced coordinates, i.e.

$$S = T^{-1} = \Lambda_{ST} = \mathsf{diag}\{\sigma_1, \sigma_2, \cdots, \sigma_n\},$$

and the drift vector field is odd in nature, then the output of the actual model and output of reduced order model satisfy

$$||y - \hat{y}||_2 \leq 2 \sum_{j=r+1}^{n} \sigma_j ||u||_2$$

where $\sigma_r \gg \sigma_{r+1}$ and $\alpha = \beta$.

5. GENERALIZED ENERGY FUNCTIONS FOR NONLINEAR SYSTEMS

In this section we introduce the generalized observability and generalized controllability functions. These generalized energy functions provide bounds to the original energy functions as is evident from the following proposition.

Theorem 4. If $\tilde{L}_o(x) > 0$ is a smooth solution of

$$\frac{\partial \tilde{L}_o(x)}{\partial x}(x) f(x) + \frac{1}{2} h^\top(x) h(x) \leq 0, \quad \tilde{L}_o(0) = 0, \quad (14)$$

and if the system is locally stable in a neighbourhood of the origin, then $\tilde{L}_o(x_0)$ is called the generalized observability function which satisfies

$$L_o(x_0) \leq \tilde{L}_o(x_0). \quad (15)$$

Moreover, if $\tilde{L}_c(x) > 0$ is a smooth solution of

$$\frac{\partial \tilde{L}_c(x)}{\partial x} f(x) + \frac{1}{2} \frac{\partial \tilde{L}_c(x)}{\partial x} g(x) g^\top(x) \frac{\partial^\top \tilde{L}_c(x)}{\partial x} \leq 0, \tilde{L}_c(0) = 0, \quad (16)$$

and if there exists an anti-stabilizing input $u(x)$ such that $x(-\infty) = 0$ and $x(0) = x_0$, then then $\tilde{L}_c(x_0)$ is called the generalized controllability function which satisfies

$$L_c(x_0) \geq \tilde{L}_c(x_0). \quad (17)$$

6. GENERALIZED BALANCING FOR NONLINEAR PORT-HAMILTONIAN SYSTEMS

Consider an input-state-output nonlinear port-Hamiltonian system

$$\Sigma_{PH} : \begin{cases} \dot{x} = (J(x) - R(x)) \dfrac{\partial \mathcal{H}(x)}{\partial x} + g(x)u, \\ y = g^\top(x) \dfrac{\partial \mathcal{H}(x)}{\partial x}, \end{cases} \quad (18)$$

where $t \in \mathbb{R}$, the state $x(t) \in \mathbb{R}^n$, the input $u(t) \in \mathbb{R}^m$, and the output $y(t) \in \mathbb{R}^m$. $J(x) = -J^\top(x)$ and $R(x) = R^\top(x) \succeq 0$ represent the interconnection and dissipation matrix respectively. $\mathcal{H} : \mathbb{R}^n \to \mathbb{R}$, $\mathcal{H}(x) \succ 0$ is the Hamiltonian function which represents the total energy of the system. To simplify the notation, we define $F(x) := (J(x) - R(x))$. Without loss of generality let us consider that $\frac{\partial \mathcal{H}}{\partial x}(0) = 0$ and $\frac{\partial^2 \mathcal{H}}{\partial x^2}(0) \succ 0$. We also consider that the system is asymptotically stable on a neighbourhood of the origin.

Assumption 3. For a nonlinear port-Hamiltonian system (18), assume the following holds

- 0 is an asymptotically stable equilibrium of $F(x)\frac{\partial \mathcal{H}(x)}{\partial x}$ on some neighbourhood W of 0.
- The linearized system at the origin is asymptotically stable.
- (14) and (16) have smooth solutions on W.
- $\frac{\partial^2 \tilde{L}_c}{\partial x^2}(0) \succ 0$, $\frac{\partial^2 \tilde{L}_o}{\partial x^2}(0) \succ 0$ and $\frac{\partial^2 \mathcal{H}}{\partial x^2}(0) \succ 0$.

Assumption 4. There exists $\tilde{L}_c(x)$, $\tilde{L}_o(x) > 0$ such that the eigenvalues of $\frac{\partial^2 \tilde{L}_c}{\partial x^2}(0)^{-1} \frac{\partial^2 \tilde{L}_o}{\partial x^2}(0)$ as well as the eigenvalues of $\frac{\partial^2 \mathcal{H}}{\partial x^2}(0)^{-1} \frac{\partial^2 \tilde{L}_c}{\partial x^2}(0)^{-1} \frac{\partial^2 \tilde{L}_o}{\partial x^2}(0)$ are distinct.

Theorem 5. Suppose that Assumption 3 and 4 hold. Then there exists a transformation $\bar{\Phi} : \mathbb{R}^n \to \mathbb{R}^n$ on a neighbourhood U of the origin such that $x = \bar{\Phi}(\bar{z}), \bar{\Phi}(0) = 0$ which converts the system into a new realization where the following holds

$$\begin{aligned} \tilde{L}_c(\bar{\Phi}(\bar{z})) &= \frac{1}{2} \sum_{i=1}^{n} \frac{\bar{z}_i^2}{\bar{\sigma}_i(\bar{z}_i)}, \\ \tilde{L}_o(\bar{\Phi}(\bar{z})) &= \frac{1}{2} \sum_{i=1}^{n} \bar{z}_i^2 \bar{\sigma}_i(\bar{z}_i), \\ \mathcal{H}(\bar{\Phi}(\bar{z})) &= \frac{1}{2} \sum_{i=1}^{n} z_i^2 \frac{\bar{\eta}_i(\bar{z}_i)}{\bar{\sigma}_i(\bar{z}_i)}, \end{aligned} \quad (19)$$

where $\bar{\sigma}_1(\bar{z}_1) \geq \bar{\sigma}_2(\bar{z}_2) \geq \cdots \geq \bar{\sigma}_n(\bar{z}_n)$ and $\bar{\eta}_1(\bar{z}_1) \geq \bar{\eta}_2(\bar{z}_2) \geq \cdots \geq \bar{\eta}_n(\bar{z}_n)$ are smooth functions.

Now, we can split $\bar{z}$ into two parts as $\bar{z} = [\bar{z}_r^\top, \bar{z}_t^\top]^\top$, where $\bar{z}_r = [\bar{z}_1, \bar{z}_2, \cdots, \bar{z}_k]^\top \in \mathbb{R}^n$ and $\bar{z}_t = [\bar{z}_{k+1}, \bar{z}_{k+2}, \cdots, \bar{z}_n]^\top \in \mathbb{R}^{n-k}$. Similarly, we can split

$$J_{\bar{z}} = \begin{bmatrix} J_{\bar{z},rr}(\bar{z}_r,\bar{z}_t) & J_{\bar{z},rt}(\bar{z}_r,\bar{z}_t) \\ -J_{\bar{z},rt}^{\top}(\bar{z}_r,\bar{z}_t) & J_{\bar{z},tt}(\bar{z}_r,\bar{z}_t) \end{bmatrix},$$
$$R_{\bar{z}} = \begin{bmatrix} R_{\bar{z},rr}(\bar{z}_r,\bar{z}_t) & R_{\bar{z},rt}(\bar{z}_r,\bar{z}_t) \\ R_{\bar{z},rt}(\bar{z}_r,\bar{z}_t) & R_{\bar{z},tt}(\bar{z}_r,\bar{z}_t) \end{bmatrix},$$
$$g_{\bar{z}} = \begin{bmatrix} g_{\bar{z},r}(\bar{z}_r,\bar{z}_t) \\ g_{\bar{z},t}(\bar{z}_r,\bar{z}_t) \end{bmatrix},$$

where $J_{\bar{z},rr}(\bar{z}_r,\bar{z}_t)$ and $J_{\bar{z},tt}(\bar{z}_r,\bar{z}_t)$ are skew-symmetric, $R_{\bar{z},rr}(\bar{z}_r,\bar{z}_t)$ and $R_{\bar{z},tt}(\bar{z}_r,\bar{z}_t)$ are symmetric and positive semidefinite. In addition to that we can split the Hamiltonian of the system in two parts as follows

$$\mathcal{H}_{\bar{z}}(\bar{z}) = \mathcal{H}_{\bar{z}}(\bar{z}_r,0) + \mathcal{H}_{\bar{z}}(0,\bar{z}_t). \tag{20}$$

Theorem 6. Consider a continuous-time nonlinear input-state-output port-Hamiltonian system Σ_{PH} as in (18). Suppose that Assumption 3 and Assumption 4 are satisfied and we obtain a balanced realization of the system as in (19). Then a reduced-order model of (18) can be represented as follows

$$\begin{aligned} \dot{\bar{z}}_r &= (J_{\bar{z},rr}(\bar{z}_r,0) - R_{\bar{z},rr}(\bar{z}_r,0))\frac{\partial \mathcal{H}_{\bar{z}}(\bar{z}_r,0)}{\partial \bar{z}_r} + g_{\bar{z},r}(\bar{z}_r,0)u, \\ y_r &= g_{\bar{z},r}^{\top}(\bar{z}_r,0)\frac{\partial \mathcal{H}_{\bar{z}}(\bar{z}_r,0)}{\partial \bar{z}_r}, \end{aligned} \tag{21}$$

which is also a port-Hamiltonian system with the Hamiltonian $\mathcal{H}_{\bar{z}}(\bar{z}_r,0)$ representing the total energy of the reduced model. Moreover, $\tilde{L}_o(\bar{\Phi}(\bar{z}_r,0))$ and $\tilde{L}_c(\bar{\Phi}(\bar{z}_r,0))$ satisfy (14) and (16) respectively for the reduced order system.

We will include the corresponding proofs, further details and the application of the theoretical results via an illustrative example in the presentation.

Semialgebraic Convex Bodies

Chiara Meroni *

* *Max Planck Institute for Mathematics in the Sciences, Inselstraße 22, 04103 Leipzig, Germany (e-mail: chiara.meroni@mis.mpg.de)*

Abstract
Convex Algebraic Geometry lives at the intersection of Convex Geometry, Optimization, Algebraic Geometry and Real Algebra. Classically, convex geometry has been studied from an analytical point of view. Here, we approach it using tools from real and complex algebraic geometry, with a focus on semialgebraic convex bodies, beyond polytopes.

Keywords: Convex Algebraic Geometry, Algebraic boundary, Convex bodies, Zonoids, Semialgebraic geometry.

MSC classes: 52A99, 14P10, 52A21.

What is convex algebraic geometry? By this name we refer to the study of convex geometry from the point of view of algebraic geometry and real algebra. This approach has its origin in the theory of polytopes, connected to linear algebra and combinatorics. From there, it is natural to go beyond linear algebra and enter the world of *nonlinear algebra* (Michałek and Sturmfels (2021)).

In this setting we study the family of semialgebraic convex bodies. They are convex, compact, non-empty, semialgebraic (see Bochnak et al. (2013)) subsets of some Euclidean space. These objects were first studied in the context of semidefinite and polynomial optimization; in particular, we refer to Lasserre (2009) and Blekherman et al. (2013). Convex geometry is classically interested in analytical and functional aspects of convex bodies, and these behave well with respect to semialgebraicity. Indeed, given a convex body $K \subset \mathbb{R}^n$, the following are equivalent:

- K is semialgebraic;
- the support function of K is a semialgebraic function;
- the radial function of K is a semialgebraic funciton;
- the dual/polar body of K is semialgebraic.

Moving towards algebraic geometry and convex geometry, the object that better encodes this interaction is the *algebraic boundary*. Let $K \subset \mathbb{R}^n$ be a convex body. Its *algebraic boundary* is the smallest variety that contains the topological boundary of K. In other words, it is the closure of the topological boundary with respect to the Zariski topology. In this way, we associate a variety to a convex body. We can study such a variety using tools from algebraic geometry in order to get information about K. For instance, the algebraic boundary detects the semialgebraicity of a convex body: K is semialgebraic if and only if its algebraic boundary is an algebraic hypersurface. Polytopes are an example of semialgebraic convex bodies, and their algebraic boundary is the hyperplane arrangement defined by the facets. One hopes to extend notions and techniques from the theory of polytopes to semialgebraic convex bodies. Some examples are Plaumann et al. (2021), where the authors develop a broad definition of an f-vector, and Saunderson and Chandrasekaran (2020), that discusses a generalization of the neighborliness for non-polyhedral convex cones.

One can generalize polytopes in many ways, in order to obtain classes of semialgebraic convex bodies. The family of *spectrahedra* is one option (Ramana and Goldman (1995)). They arise as the intersection of the cone of positive semidefinite matrices with a linear subspace. Spectrahedra are relevant in optimization because they are the feasible regions of semidefinite programming. Their study is intimately related to the study of matrices and determinantal varieties. Another direction is that of the *convex hull of a variety* (Ranestad and Sturmfels (2011, 2012)). Understanding the boundary of a convex hull is a difficult task in general. However, algebraic geometry gives the answer in the case of convex hulls of varieties, as stated in (Ranestad and Sturmfels, 2011, Theorem 1.1). Such a formula describes the components of the algebraic boundary of K, where K is the convex hull of a smooth compact real algebraic variety in $\mathbb{R}^n$.

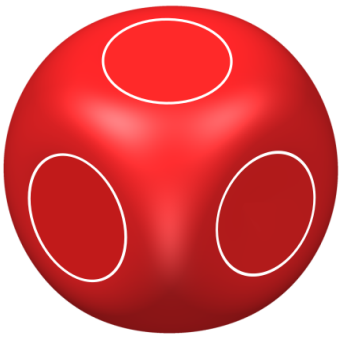

Figure 1. The Minkowski sum of three 2-dimensional discs.

Not all convex bodies are semialgebraic. For instance, *zonoids* have a non-empty intersection with the set of semialgebraic convex bodies, but are not contained in it. Hence, the immediate question is: which zonoids are semialgebraic? This lies in the context of the Zonoid Problem

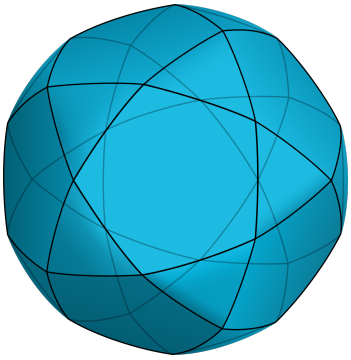

Figure 2. The intersection body of the icosahedron.

(Blaschke (1923); Bolker (1971)). This problem is very hard to tackle (see Weil (1977, 1982)): restricting to the subclass of semialgebraic convex bodies would potentially make it easier. In Gesmundo and Meroni (2022), we investigate a class of semialgebraic zonoids called *discotopes*. They are Minkowski sums of finitely many discs, see Figure 1. We study their algebraic boundary, in order to be able to characterize them. The beauty and the strength of this problem is that it can be approached from many points of view: algebraic geometry, as in our work, measure theory, random geometry.

Many areas of convex geometry investigate objects that are defined starting from a convex body. A goal is to understand how semialgebraic geometry behaves with respect to these constructions.

The notion of *fiber polytope* was introduced by Billera and Sturmfels (1992). It encodes a number of combinatorial features about the polytopes involved. Notably, the same definition works for more general convex bodies. In Mathis and Meroni (2021), we focused on this generalization in the following setting. Let K be a convex body in $\mathbb{R}^{n+m}$ and $\pi : \mathbb{R}^{n+m} \to V$ be the orthogonal projection onto a subspace $V \subset \mathbb{R}^{n+m}$ of dimension n. The fiber body of K with respect to π is the *average* of the fibers of K under this projection:

$$\Sigma_\pi K = \int_{\pi(K)} \left(K \cap \pi^{-1}(x)\right) dx \subset \mathbb{R}^m,$$

where this is a Minkowski integral. Among other properties, we prove that the fiber body of a zonoid, with respect to any projection, is again a zonoid. On the other hand, this construction does not behave well with semialgebraicity: we provide an example of a semialgebraic convex body, the dice in Figure 1, having a non-semialgebraic fiber body.

Another interesting construction that plays a central role in geometric tomography (see Gardner (2006)) is that of the *intersection body*. Let $K \subset \mathbb{R}^n$ be a full dimensional convex body. Its intersection body is the set $IK = \{x \in \mathbb{R}^n \,|\, \rho_K(x) \geq 1\}$, for the radial function

$$\rho_K(x) = \frac{1}{\|x\|} \operatorname{vol}\left(K \cap x^\perp\right),$$

where $x^\perp$ is the hyperplane orthogonal to x. In Berlow et al. (2022) we examined the case when K is a polytope; Figure 2 shows the intersection body of a icosahedron. Our main contribution states that the intersection body of a polytope is a semialgebraic set. It can be associated to a zonotope whose face structure reflects that of the intersection body. We provide an algorithm for computing intersection bodies of polytopes. Its implementation is available at `https://mathrepo.mis.mpg.de/intersection-bodies`, together with interactive three-dimensional models that highlight interesting features.

Abstract: The operation of gas pipeline networks leads to problems of optimal boundary control for systems governed by the isothermal Euler equations. In this contribution we consider a problem of optimal Dirichlet control with an objective function of integral type that is given as the sum of a tracking term for a desired stationary state and the corresponding control cost. We study the well-posedness and exact controllability properties of the system. We study regular solutions that generate a field of non-intersecting characteristic curves without rarefaction fan that transport the information about the state. We also consider the exact controllability properties of the system. We define a problem of optimal boundary control and show the existence of a solution. We present an integral turnpike result and a result about the turnpike phenomenon with interior decay for such an optimal control problem.

Keywords: gas pipeline flow, boundary control, optimal control, hyperbolic partial differential equation, turnpike phenomenon, isothermal Euler equations

1. INTRODUCTION

We consider an optimal control problem for the operation of gas pipelines. As a model for gas pipeline flow we consider the isothermal Euler equations (see e.g. Banda et al. (2006), Gugat and Herty (2022))

$$\begin{cases} \rho_t + q_x = 0, \\ q_t + \left(p + \dfrac{q^2}{\rho}\right)_x = -\dfrac{1}{2}\theta \dfrac{q\,|q|}{\rho}. \end{cases} \tag{1}$$

Here ρ denotes the gas density, p the pressure q the mass flow rate and θ is a friction parameter. At the end $x = 0$, the desired pressure $p_d > 0$ is prescribed, $p(t,\, 0) = p_d$. At the other end $x = L$ of the pipe, the flow rate is controlled, $q(t,\, L) = u(t)$. In the optimal control problem, state and control constraints in C^1 enforce the regularity of the generated states. In Gugat and Sokolowski (2022), a similar optimal control problem for gas networks is considered and the existence of an optimal control is shown. Equation (1) is a model for the flow through a horizontal pipeline. For a sloped pipeline, an additional source term that is proportional to the sine of the angle of inclination φ appears in the second equation on the right-hand side, namely $-g\,\rho\,\sin(\varphi)$, where g is the gravitational constant.

2. THE SYSTEM

Let a space interval $[0,\, L]$ be given; here $L > 0$ corresponds to the length of the pipe. Let a classical subsonic steady state $p_r(x)$, $q_r(x)$ ($x \in [0,\, L]$) with the constant control u_r and $p_r(0) = p_d$ be given. Assume that for all $x \in [0, L]$ we have $p_r(x) > 0$ and $(p_r,\, q_r) \in (H^2(0,\, L))^2$. For the case of ideal gas where $p = a^2\rho$ with the sound speed $a > 0$, the initial boundary value problem for our system is

$$(\mathbf{S}) \begin{cases} \rho(0,x) = \rho_0(x),\ q(0,x) = q_0(x),\ x \in (0,L), \\ p(t,\,0) = p_r(0),\ \ q(t,\,L) = u(t),\ t \in (0,T), \\ \begin{pmatrix} \rho \\ q \end{pmatrix}_t + \begin{pmatrix} 0 & 1 \\ a^2 - \dfrac{q^2}{\rho^2} & 2\,\dfrac{q}{\rho} \end{pmatrix} \begin{pmatrix} \rho \\ q \end{pmatrix}_x = \begin{pmatrix} 0 \\ -\dfrac{1}{2}\theta \dfrac{q\,|q|}{\rho} \end{pmatrix}. \end{cases}$$

Here $(\rho_0,\, q_0)$ denotes a given initial state.

The theory of semi-global classical solutions (see Li (2010)) asserts that for any given time horizon $T_0 > 0$ there exists a number $\varepsilon(T_0) > 0$ such that for all initial states $(\rho_0,\, q_0)$ that satisfy

$$\max\{\|\rho_0 - \rho_r\|_{C^1([0,\,L])},\, \|q_0 - q_r\|_{C^1([0,\,L])}\} \le \varepsilon(T_0) \tag{2}$$

and are C^1-compatible with p_d as a boundary value at $x = 0$ and all controls with

$$\|u - u_r\|_{C^1([0,\,T_0])} \le \varepsilon(T_0) \tag{3}$$

that are C^1-compatible with the initial state there exists a classical solution of (**S**) on $[0,\, T_0]$ that satisfies the *a priori* estimate

$$\max_{t\in[0,T_0]} \|(p(t,\cdot)-p_r, q(t,\cdot)-q_r)\|_{(C^1([0,L]))^2}$$
$$\leq C_1(T_0)\, \max\{\|\delta\rho\|_{C^1([0,\,L])},\, \|\delta q\|_{C^1([0,\,L])},\, \|\delta u\|_{C^1([0,\,T_0])}\}$$

where we use the notation $\delta\rho = \rho_0 - \rho_r$, $\delta q = q_0 - q_r$, $\delta u = u - u_r$.

Remark 1. Note that a similar result holds with C^1 replaced by H^2, see Bastin and Coron (2016).

To guarantee that a regular solution exists, in our optimal control problem we prescribe the control constraint

$$\|u - u_r\|_{C^1([0,\,T])} \leq \varepsilon_0 \tag{4}$$

with $\varepsilon_0 > 0$ and the C^1-compatibility conditions with the initial state. Moreover, for $T \geq T_0$ we impose the state constraint

$$\max_{t\in[0,T]} \|(p(t,\cdot)-p_r, q(t,\cdot)-q_r)\|_{(C^1([0,L]))^2} \leq C_0\, \varepsilon_0 \tag{5}$$

with $C_0 > 0$.

The constraints (4) and (5) allow to make the time horizon T arbitrarily large without losing the regularity of the solutions. This is possible since for given C^1-initial data (for example at the time T_0) that satisfies $\|(p(T_0,\cdot)-p_r, q(T_0,\cdot)-q_r)\|_{(C^1([0,L]))^2} \leq C_0\, \varepsilon_0$ a classical solution of (**S**) exists for a certain (possibly short) time interval starting at T_0, where a certain minimal length is guaranteed a priori as a function of the C^1-norm of the initial data and the boundary data.

Note that due to the definition of the C^1-norm, the constraints (4), (5) can be written as pointwise constraints for all $t \in [0,\, T]$, which is a form that is well-suited for turnpike analysis. In fact, (4), (5) are equivalent to

$$\begin{cases} |u(t) - u_r| \leq \varepsilon_0,\, t \in [0,\, T], \\ |u_t(t)| \leq \varepsilon_0,\, t \in [0,\, T], \\ |p(t,x) - p_r(x)| \leq C_0\, \varepsilon_0,\, t \in [0,\, T],\, x \in [0, L], \\ |p_x(t,x) - p_r'(x)| \leq C_0\, \varepsilon_0,\, t \in [0,\, T],\, x \in [0, L], \\ |q(t,x) - q_r(x)| \leq C_0\, \varepsilon_0,\, t \in [0,\, T],\, x \in [0, L], \\ |q_x(t,x) - q_r'(x)| \leq C_0\, \varepsilon_0,\, t \in [0,\, T],\, x \in [0, L]. \end{cases}$$

2.1 Exact controllability

System (**S**) is exactly controllable in a sufficiently large time interval:

Theorem 2. Assume that T_0 is sufficiently large and that

$$\max\{\|q_0 - q_r\|_{H_2([0,\,L])},\, \|\rho_0 - \rho_r\|_{H^2([0,\,L])}\} \leq \varepsilon_1 \tag{6}$$

with ε_1 chosen sufficiently small.

Then there exists a control $\hat{u} \in H^2(0, T_0)$ that generates a solution of (**S**) that satisfies the end condition $q(T_0,\, x) = q_r(x)$, $\rho(T_0,\, x) = \rho_r(x)$, $x \in (0, L)$. Moreover, there exists a constant $\hat{C} > 0$ such that $\|\hat{u} - u_r\|_{H^2(0,\,T_0)}$

$$\leq \hat{C} \max\{\|\rho_0 - \rho_r\|_{H^2(0,\,L)}, \|q_0 - q_r\|_{H^2(0,\,L)}\} \tag{7}$$

and

$$\max_{t\in[0,T_0]} \|(p(t,\cdot)-p_r, q(t,\cdot)-q_r)\|_{(H^2([0,L]))^2}$$
$$\leq \tilde{C} \max\{\|\rho_0 - \rho_r\|_{H^2(0,\,L)}, \|q_0 - q_r\|_{H^2(0,\,L)}\}.$$

Proof. The initial data $(q_0,\, p_0)$ and the terminal data $(q_r,\, p_r)$ determine the state on two domains bounded by characteristic curves from different families. Together with boundary data for $x = L$ on $[0,\, T_0]$, these data determine the boundary of a set that consists of a characteristic that starts a $(t, x) = (0, 0)$ until it reaches $x = L$, a piece of $[0,\, T_0] \times \{L\}$ and a characteristic that starts at $x = L$ for some $t < T$ and leads to $(t, x) = (T_0, 0)$. The corresponding boundary data can be obtained by a sufficiently smooth interpolation that does not increase the H^2-norm on the piece of $[0,\, T_0] \times \{L\}$. With these boundary data, the system state is completely determined on $[0,\, T_0] \times [0, L]$. The boundary trace at $x = 0$ yields the desired control. The corresponding a priori inequalities for the system where the stationary state is subtracted yield the inequality (7). The last inequality in the theorem also follows with the H^2 a priori estimate for the state.

Remark 3. In Gugat et al. (2017), a strict H^2-Lyapunov function is introduced for Neumann boundary feedback stabilization of the isothermal Euler equations. In Gugat et al. (2022), the constrained exact boundary controllability of a semilinear model for pipeline gas flow is studied with continuous states.

3. THE OPTIMAL CONTROL PROBLEM

The optimal control problem $\mathbf{P_{dyn}}(T)$ is to find a control function u that is C^1-compatible with $(q_0,\, \rho_0)$ such that the objective function

$$J_T(u) = \|u - u_r\|^2_{H^2(0,\,T)} \tag{8}$$
$$+\|p - p_r\|^2_{L^2([0,T]\times[0,L])} + \|q - q_r\|^2_{L^2([0,T]\times[0,L])}$$

is minimized and (4) and (5) hold, where $(p,\, q)$ denotes the solution of (**S**).

Note that this choice of the objective function mitigates pressure fluctuations and hence is useful to reduce hydrogen embrittlement of steel pipelines during transients. For a description of this effect see Hafsi et al. (2018).

A numerical method that is based upon a DAE approach for optimal control problems in the operation of gas netwrorks including storage reservoirs is presented in Hari et al. (2022).

3.1 Existence of solutions

In Theorem 4 we state that for all $T \geq T_0$ (with T_0 as in Theorem 2), the optimal control problem $\mathbf{P_{dyn}}(T)$ has a solution for suitably chosen problem parameters.

Theorem 4. Assume that $\varepsilon_0 > 0$ is chosen sufficiently small and $C_0 > 0$ is chosen sufficiently large, $(\rho_0,\, q_0) \in (H_2([0,\, L]))^2$ are C^1-compatible with p_d as a boundary value at $x = 0$ and

$$\max\{\|q_0 - q_r\|_{H_2([0,\,L])},\, \|\rho_0 - \rho_r\|_{H^2([0,\,L])}\} \leq \varepsilon_2 \tag{9}$$

with ε_2 chosen sufficiently small. Let $T \geq T_0$ be given.

Then a solution of the dynamic optimal control problem $\mathbf{P_{dyn}}(T)$ does exist.

Proof. Since (9) holds and $T \geq T_0$, Theorem 2 implies that there exists an exact control $u_{exact} \in H^2(0,\, T)$ that steers the system state from the initial state $(p_0,\, q_0)$ in finite time T_0 to $(p_r,\, q_r)$. After this finite time, we extend the control with the constant control value u_r. For u_{exact}, (4) is implied by (7) if ε_2 is chosen sufficiently small. By choosing ε_2 chosen sufficiently small, the a priori inequality implies (5). In this way we obtain a feasible control u_{exact}. Hence the set of admissible controls is non-empty.

We consider a minimizing sequence of feasible controls. Due to the H^2-term in the objective function J_T defined in (8), this sequence is bounded with respect to the H^2-norm hence it contains a subsequence that converges strongly in $C^1([0,\, T])$ to a limit point u^*. Due to the theory of semi-global solutions, the strong convergence implies that also the corresponding subsequence of generated states given by the classical solutions of (**S**) converges strongly to the solution that is generated by the limit point u^*. Moreover, (4) and (5) hold for this limit. Hence u^* is feasible and due to the sequential weak lower semicontinuity of J_T has a minimal value of the objective function. Thus u^* solves $\mathbf{P_{dyn}}(T)$.

3.2 An integral turnpike result

In this section we present our first turnpike result, which is an integral turnpike result. It states that for the optimal control and the generated state the integral in the objective function remains uniformly bounded with respect to T for arbitrarily large T. For a survey on the turnpike property, see the monograph Zaslavski (2019). The exponential turnpike property for optimal control problems in Hilbert spaces is studied in Trélat et al. (2018), see also Grüne et al. (2020), Faulwasser and Kellett (2021) and the references therein.

Theorem 5. Assume that the assumptions of Theorem 4 hold.

Then the solutions of the dynamic optimal control problem $\mathbf{P_{dyn}}(T)$ satisfy a turnpike inequality in the sense that there exists a constant $C_{int} > 0$ such that for all $T > 0$ we have

$$\|u - u_r\|^2_{H^2(0,\,T)} \tag{10}$$
$$+\|p - p_r\|^2_{L^2([0,T]\times[0,L])} + \|q - q_r\|^2_{L^2([0,T]\times[0,L])} \leq C_{int}.$$

Proof. The feasible control $u_{exact} \in H^2(0,\, T)$ from the proof of Theorem 4 is feasible for all $T \geq T_0$ and $J_T(u_{exact})$ is independent of T. Hence with the definition $C_{int} = J_{T_0}(u_{exact}) = J_T(u_{exact})$, the assertion follows.

3.3 The turnpike property with interior decay

In this section we show that the optimal state and the optimal control satisfy a turnpike property with interior decay as it is introduced in Gugat (2021),

Assume that the assumptions of Theorem 4 hold and that $T \geq 2\, T_0$.

Due to (10), we have

$$\|u - u_r\|^2_{H^2(0,\,T)} \leq C_{int}. \tag{11}$$

Moreover, due to the state constraints the state is a classical solution of (**S**). In particular, the Riemann invariants satisfy integral equations along the characteristic curves, which are well-defined for a classical solution.

Our aim is to show that also the full state is uniformly bounded in H^2 with respect to T.

For this purpose, we introduce the additional condition that $q_r(x) > 0$ for all $x \in [0, L]$. Moreover, now we assume that $C_0\varepsilon_0$ is sufficiently small so that the state constraint (5) implies that for the feasible states we have

$$q(t, x) > 0 \tag{12}$$

for all $t \in [0, T]$, $x \in [0, L]$. This is important, since the source term on the righ-hand side of (1) is in general only continuously differentiable as a function of q, since at $q = 0$ the second derivative with respect to q does not exist. Due to (12), we can also work with the second derivatives of the source term with respect to the state variables.

By our assumptions, the initial state is small in H^2 in the sense of (9).

By going to Riemann invariants $R = (R_+, R_-)$, system (1) can be written in the diagonal form

$$R_t + \Lambda(R)\, R_x = F(R)$$

with the diagonal matrix $\Lambda(R)$ that contains the eigenvalues of the system as functions of R and the function F that contains the source terms. Due to (12) we can assume that the second derivatives of F with respect to R exist for the feasible states. For a given state R, for R_x, with the notation $\hat{S} = R_x$ we obtain the semi-linear system

$$\hat{S}_t + \Lambda(R)\, \hat{S}_x = (\partial_R F(R))\hat{S} - \mathrm{diag}[(\partial_R \lambda_\pm(R))\hat{S}]\hat{S}$$

where $\partial_R F(R)$ denotes the functional matrix of F, $\lambda_\pm(R)$ denotes the eigenvalues of $\Lambda(R)$, $\partial_R \lambda_\pm(R)$ denotes the corresponding gradient and $\mathrm{diag}[(\partial_R \lambda_\pm(R))R_x]$ denotes the diagonal matrix with the corresponding entries.

For given R and R_x, for the second partial derivative R_{xx} with the notation $\bar{S} = R_{xx}$ we obtain the semi-linear system

$$\bar{S}_t + \Lambda(R)\, \bar{S}_x = (\partial_R F(R))\bar{S} + [(\partial^2_{RR} F(R))R_x]R_x$$
$$-2\,\mathrm{diag}[(\partial_R \lambda_\pm(R)) \cdot R_x]\bar{S} - \mathrm{diag}[(\partial_R \lambda_\pm(R))\bar{S}]R_x$$
$$-\mathrm{diag}\left[[(\partial^2_{RR} \lambda_\pm(R))R_x] \cdot R_x\right] R_x$$

where $[(\partial^2_{RR} F(R))R_x] = \partial_x\, \partial_R\, F(R)$ is the second derivative obtained from the chain rule and $\partial^2_{RR} \lambda_\pm(R)$ denotes the Hessian matrix of $\lambda_\pm(R)$.

Using appropriate Lyapunov functions, the semilinear systems allow to derive a priori bounds for the H^2 norm of the state in terms of the H^2 norms of the boundary data and the initial data.

Note that we know that the field of characteristics curves exists and is the same for all three systems, since we have a classical solution, For a certain fixed time $\tilde{T}$ the boundedness in H^2 of the state follows with the a priori bound described above. In order to show the uniform boundedness of the state with respect to T in H^2 we consider the problem where the roles of time and space are exchanged and u serves as 'initial' data. The a priori bound for the state that is determined by the values of

the boundary control yields the uniform boundedness of the state with respect to T.

Let us assume this in the sequel, then without loss of generality we have

$$\|p - p_r\|^2_{H^2([0,T]\times[0,L])} + \|q - q_r\|^2_{H^2([0,T]\times[0,L])} \leq C_{int}. \quad (13)$$

Then there exists $t_0 \in [0,\, T/2]$ such that

$$\|p(t_0,\cdot) - p_r\|^2_{H^2(0,L)} + \|q(t_0,\cdot) - q_r\|^2_{H^2(0,L)} \leq \frac{2\,C_{int}}{T}. \quad (14)$$

Theorem 2 implies that starting from $(\rho(t_0,\cdot),\, q(t_0,\cdot))$ the state can be controlled exactly to $(p_r,\, q_r)$ in the time T_0 with a control $u \in H^2([t_0,\, T])$ that satisfies

$$\max\{\|\hat{u} - u_r\|_{H^2(t_0,\,T)},\, \|(p - p_r, q - q_r)\|_{(H^2([t_0,\,T]\times[0,L]))^2}\}$$
$$\leq \tilde{C} \max\{\|\rho_0(t_0,\cdot) - \rho_r\|_{H^2(0,\,L)}, \|q_0(t_0,\cdot) - q_r\|_{H^2(0,\,L)}\}.$$

Now inequality (14) implies

$$\max\{\|\hat{u} - u_r\|_{H^2(t_0,\,T)},\, \|(p - p_r, q - q_r)\|_{(H^2([t_0,\,T]\times[0,L]))^2}\} \leq \frac{\sqrt{2\,C_{int}}\,\tilde{C}}{\sqrt{T}}.$$

Similar to the turnpike property with interior decay that is introduced in Gugat (2021), for $T \geq 2T_0$, this yields

$$\max\{\|\hat{u} - u_r\|_{H^2(\frac{T}{2},\,T)},\, \|(p - p_r, q - q_r)\|_{(H^2([\frac{T}{2},\,T]\times[0,L]))^2}\} \leq \frac{\sqrt{2\,C_{int}}\,\tilde{C}}{\sqrt{T}}.$$

This shows that on the second half of the time-interval, not only is the contribution of this part of the time interval uniformly bounded with respect to T but it even decays with the order $\mathcal{O}\left(\frac{1}{\sqrt{T}}\right)$.

Remark. We want to mention that (12) excludes the possibility of flow reversal. Flow reversal can be very important in the operation of pipeline networks in the case of large changes in the demand scenarios. This happens in some cases regularly within the seasons of a year, but sometimes also political reasons can cause dramatic changes in the demand scenarios.

4. CONCLUSION

In this paper, we present turnpike results for a system that is governed by the isothermal Euler equations. In general this system has discontinuous solutions. However, in the operation of gas pipelines, continuously differentiable solutions are desirable and shocks are harmful in the operation of the system. We have presented an optimal control problem, where regular states are enforced by state and control constraints. We have shown that this optimal control problem has desirable turnpike properties.

The Laplace transform and inconsistent initial values

Stephan Trenn

SCO @ BI(FSE), University of Groningen, Nijenborgh 9, 9747 AG Groningen, email: s.trenn@rug.nl

Abstract: Switches in electrical circuits may lead to Dirac impulses in the solution; a real world example utilizing this effect is the spark plug. Treating these Dirac impulses in a mathematically rigorous way is surprisingly challenging. This is in particular true for arguments made in the frequency domain in connection with the Laplace transform. A survey will be given on how inconsistent initials values have been treated in the past and how these approaches can be justified in view of the now available solution theory based on piecewise-smooth distributions.

Keywords: differential-algebraic equations, descriptor systems, Dirac delta, distributional solutions

1. INTRODUCTION

Modeling electrical circuits containing (ideal) switches naturally leads to a description via switched differential-algebraic equations (DAEs) of the form

$$E_{\sigma(t)}\dot{x}(t) = A_{\sigma(t)}x(t) + B_{\sigma(t)}u(t)$$

where x is the state (including algebraic variables), u is the input and σ is the switching signal (Trenn, 2012). The reason why it is in general not possible to find a more classical model in terms of ordinary differential equations (ODEs) is the fact, that the changing position of the switches changes the algebraic constraints; without including algebraic constraints in the model it would not be possible to incorporate *changing* algebraic constraints. Furthermore, the effect of *inconsistent* initial values can not be studied in a model already in the form of an ODE (because ODEs do not have inconsistent initial values). For a given switching signal σ the switched DAE can be viewed as a repeated initial value problem for the DAE

$$E\dot{x} = Ax + Bu \tag{1}$$

with initial condition $x(0) = x_0 \in \mathbb{R}^n$. As mentioned above, at a switching time the algebraic constraints may change, hence the initial value from the past may not be consistent anymore and the meaning of "$x(0) = x_0$" has to be made precise. In the context of electrical circuit this is a long standing question and can be traced back at least to Verghese et al. (1981). There have been different approaches to deal with inconsistent initial values, e.g. Sincovec et al. (1981); Cobb (1982); Opal and Vlach (1990); Rabier and Rheinboldt (1996); Reißig et al. (2002); Frasca et al. (2010), some of which will be discussed later. All have in common that jumps as well as Dirac impulses may occur in the solutions. The Dirac impulse is a distribution (a generalized function) hence one must enlarge the considered solution space to also include distributions.

This extended abstract is a revisitation of Trenn (2013) and will discuss the mathematical and conceptional difficulties arising from the notion of inconsistent initial values, in particular, when the Laplace transform is applied to the DAE (1) and arguments from the frequency domain are used. First some required notation from distribution theory is recalled, then a Laplace transform approach is presented on how to deal with inconsistent initial values and finally an alternative approach in the time domain is presented.

2. PRELIMINARIES ON DISTRIBUTION THEORY

The classical distribution theory by Schwartz (1957, 1959) is revised in the following. The space of *test functions* is $\mathcal{C}_0^\infty := \{ \varphi : \mathbb{R} \to \mathbb{R} \mid \varphi \in \mathcal{C}^\infty \text{ has compact support } \}$, which is equipped with a certain topology [1] . The space of distributions, denoted by $\mathbb{D}$, is then the dual of the space of test functions, i.e.

$$\mathbb{D} := \{ D : \mathcal{C}_0^\infty \to \mathbb{R} \mid D \text{ is linear and continuous } \}.$$

A large class of ordinary functions, namely locally integrable functions, can be embedded into $\mathbb{D}$ via the following injective [2] homomorphism $f \mapsto f_\mathbb{D}$ with $f_\mathbb{D}(\varphi) := \int_\mathbb{R} f\varphi$.

The main feature of distributions is the ability to take derivatives for any distribution $D \in \mathbb{D}$ via $D'(\varphi) := -D(\varphi')$, which is consistent with the classical derivative, i.e. if f is differentiable, then $(f_\mathbb{D})' = (f')_\mathbb{D}$. In particular, the Heaviside unit step $\mathbb{1}_{[0,\infty)}$ has a distributional derivative which can easily be calculated to be

$$(\mathbb{1}_{[0,\infty)_\mathbb{D}})'(\varphi) = \varphi(0) =: \delta(\varphi),$$

hence it results in the well known Dirac impulse δ (at $t = 0$). In general, the Dirac impulse δ_t at time $t \in \mathbb{R}$ is given by $\delta_t(\varphi) := \varphi(t)$. Furthermore, if g is a piecewise differentiable function with one jump at $t = t_J$, then

$$(g_\mathbb{D})' = (g')_\mathbb{D} + (g(t_J^+) - g(t_J^-))\delta_{t_J}, \tag{2}$$

where g' is the derivative of g on $\mathbb{R} \setminus \{0\}$.

[1] The topology is such that a sequence $(\varphi_k)_{k\in\mathbb{N}}$ of test functions converges to zero if, and only if, 1) the supports of all φ_k are contained within one common compact set $K \subseteq \mathbb{R}$ and 2) for all $i \in \mathbb{N}$, $\varphi_k^{(i)}$ converges uniformly to zero as $k \to \infty$

[2] Two locally integrable functions which only differ on a set of measure zero are identified with each other.

Now it is no problem to consider the DAE (1) (without the initial condition) in a distributional solution space; instead of x and u being vectors of functions they are now vectors of distributions, i.e. $x \in \mathbb{D}^n$ and $f \in \mathbb{D}^m$ where $n \times n$ and $n \times m$ are the size of the matrices E, A and B. The definition of the matrix vector product remains unchanged [3] so that (1) reads as m equations in $\mathbb{D}$.

Considering distributional solutions, however, does *not* help to treat inconsistent initial value; au contraire, distributions cannot be evaluated at a certain time because they are not functions of time, so writing $x(0) = x_0$ makes no sense. Even when assuming that a pointwise evaluation is well defined for certain distributions, the DAE (1) will still not exhibit (distributional) solution with arbitrary initial values. This is easily seen when considering, e.g., the DAE (1) with $(E, A, B) = (0, I, 0)$, which simply reads as $0 = x$.

So what does it then mean to speak of a solution of (1) with inconsistent initial value? The motivation for inconsistent initial values is the situation that the system descriptions gets active at the initial time $t = 0$ and before that the system was governed by different (maybe unknown) rules. This viewpoint was already expressed by Doetsch (1974) in the context of distributional solutions for ODEs:

> The concept of "initial value" in the physical science can be understood only when the past, that is the interval $t < 0$, has been included in our considerations. This occurs naturally for distributions which, without exception, are defined on the entire t-axis.

So mathematically, there is some given past trajectory x^0 for x up to the initial time and the DAE (1) only holds on the interval $[0, \infty)$. This means that a solution of the following *initial trajectory problem* (ITP) is sought:

$$\begin{aligned} x_{(-\infty,0)} &= x^0_{(-\infty,0)} \\ (E\dot{x})_{[0,\infty)} &= (Ax + Bu)_{[0,\infty)}, \end{aligned} \tag{3}$$

where $x^0 \in \mathbb{D}^n$ is an arbitrary past trajectory and D_I for some interval $I \subseteq \mathbb{R}$ and $D \in \mathbb{D}$ denotes a distributional restriction generalizing the restrictions of functions given by$f_I(t) = f(t)$ for $t \in I$ and $f(t) = 0$ otherwise.

A fundamental problem is the fact (Trenn, 2021) that such a distributional restriction does not exist!

This problem was resolved especially in older publication (Campbell, 1980, 1982; Verghese et al., 1981) by ignoring it and/or by arguing with the Laplace transform (see the next section). Cobb (1984) seems to be the first to be aware of this problem and he resolved it by introducing the space of piecewise-continuous distributions; Geerts (1993b,a) was the first to use the space of impulsive-smooth distributions (introduced by Hautus and Silverman (1983)) as a solution space for DAEs. Seemingly unaware of these two approaches, Tolsa and Salichs (1993) developed a distributional solution framework which can be seen as a mixture between the approaches of Cobb and Geerts. The more comprehensive space of piecewise-smooth distributions was later introduced (Trenn, 2009) to combine the advantages of the piecewise-continuous and impulsive-smooth distributional solution spaces. Further details are discussed in Section 4.

Cobb (1982) also presented another approach by justifying the impulsive response due to inconsistent initial values via his notion of *limiting solutions*. The idea is to replace the singular matrix E in (1) by a "disturbed" version E_ε which is invertible for all $\varepsilon > 0$ and $E_\varepsilon \to E$ as $\varepsilon \to 0$. If the solutions of the corresponding initial value ODE problem $\dot{x} = E_\varepsilon^{-1}Ax$, $x(0) = x_0$ converges to a distribution, then Cobb calls this the limiting solution. He is then able to show that the limiting solution is unique and equal to the one obtained via the Laplace-transform approach. Campbell (1982) extends this result also to the inhomogeneous case.

3. LAPLACE TRANSFORM APPROACHES

Especially in the signal theory community it is common to study systems like (1) in the so called *frequency domain* (in contrast to the *time domain*). The transformation between time and frequency domain is given by the *Laplace transform* defined via the Laplace integral:

$$\hat{g}(s) := \int_0^\infty e^{-st} g(t) \ \mathrm{d}t \tag{4}$$

for some function g and $s \in \mathbb{C}$. Note that in general the Laplace integral is not well defined for all $s \in \mathbb{C}$ and a suitable domain for $\hat{g}$ must be chosen (Doetsch, 1974). If a suitable domain exists, then $\hat{g} = \mathcal{L}\{g\}$ is called the *Laplace transform* of g and, in general, $\mathcal{L}\{\cdot\}$ denotes the Laplace transform operator. Again note that it is not specified at this point which class of functions have a Laplace transform and which class of functions are obtained as the image of $\mathcal{L}\{\cdot\}$. The main feature of the Laplace transform is the following property, where g is a differentiable function for which g and g' have Laplace transforms,

$$\mathcal{L}\{g'\}(s) = s\mathcal{L}\{g\}(s) - g(0), \tag{5}$$

which is a direct consequence of the definition of the Laplace integral invoking partial differentiation. If g is not continuous at $t = 0$ but $g(0^+)$ exists and g' denotes the derivative of g on $\mathbb{R} \setminus \{0\}$, then (5) still holds in a slightly altered form:

$$\mathcal{L}\{g'\}(s) = s\mathcal{L}\{g\}(s) - g(0^+). \tag{6}$$

In particular, the Laplace transform does not take into account at all how g behaved for $t < 0$ which is a trivial consequence of the definition of the Laplace integral. This observation will play an important role when studying inconsistent initial values.

Taking into account the linearity of the Laplace transform the DAE (1) is transformed into

$$sE\hat{x}(s) = A\hat{x}(s) + B\hat{u}(s) + Ex(0^+) \tag{7}$$

If the matrix pair (E, A) is regular [4] and $x(0^+) = 0$, the latter can be solved easily algebraically:

$$\hat{x}(s) = (sE - A)^{-1}B\hat{u}(s) =: G(s)\hat{u}(s), \tag{8}$$

where $G(s)$ is a matrix over the field of rational functions and is usually called transfer function.

[3] Some authors (Rabier and Rheinboldt, 2002; Kunkel and Mehrmann, 2006) use a different definition for the matrix vector product which is due to the different viewpoint of a distributional vector x as a map from $(\mathcal{C}_0^\infty)^n$ to $\mathbb{R}$ instead of a map from $\mathcal{C}_0^\infty$ to $\mathbb{R}^n$. The latter seems the more natural approach in view of applying it to (1), but it seems that both approaches are equivalent at least with respect to the solution theory of DAEs.

[4] (E, A) is called regular, if $\det(sE - A)$ is not identically zero.

A first systematic treatment of descriptor systems in the frequency domain was carried out by Rosenbrock (1970). He, however, only considered zero initial values and the input-output behavior. In particular, he was not concerned with a solution theory for general DAEs (1) with possible inconsistent values. Furthermore, he restricted attention to inputs which are exponentially bounded (guaranteeing existence of the Laplace transform), hence formally his framework could not deal with arbitrary (sufficiently smooth) inputs.

The definition of the Laplace transform can be extended to be well defined for certain distributions as well (Doetsch, 1974), therefore consider the following class of distributions:

$$\mathbb{D}_{\geq 0,k} := \left\{ D=(g_{\mathbb{D}})^{(k)} \;\middle|\; \begin{array}{l}\text{where } g:\mathbb{R}\to\mathbb{R} \text{ is continuous}\\ \text{and } g(t)=0 \text{ on } (-\infty,0)\end{array} \right\}.$$

For $D \in \mathbb{D}_{\geq 0,k}$ with $D = (g_{\mathbb{D}})^{(k)}$ the (distributional) Laplace transform is now given by

$$\mathcal{L}_{\mathbb{D}}\{D\}(s) := s^k \mathcal{L}\{g\}(s)$$

on a suitable domain in $\mathbb{C}$. Note that $\delta \in \mathbb{D}_{\geq 0,2}$ and it is easily seen that

$$\mathcal{L}_{\mathbb{D}}\{\delta\} = 1. \tag{9}$$

Furthermore, for every locally integrable function g for which $\mathcal{L}\{g\}$ is defined on a suitable domain it holds

$$\mathcal{L}_{\mathbb{D}}\{g_{\mathbb{D}}\} = s\mathcal{L}\left\{\int_0^{\cdot} g\right\} = s\frac{1}{s}\mathcal{L}\{g\} = \mathcal{L}\{g\}, \tag{10}$$

i.e. the distributional Laplace transform coincides with the classical Laplace transform defined by (4).

A direct consequence of the definition of $\mathcal{L}_{\mathbb{D}}$ is the following derivative rule for all $D \in \bigcup_k \mathbb{D}_{\geq 0,k}$:

$$\mathcal{L}_{\mathbb{D}}\{D'\}(s) = s\mathcal{L}_{\mathbb{D}}\{D\} \tag{11}$$

which seems to be in contrast to the derivative rule (6), because *no initial value occurs*. The latter can actually not be expected because general distributions do not have a well defined function evaluation at a certain time t. However, the derivative rule (11) is consistent with (6); to see this let g be a function being zero on $(-\infty, 0)$, differentiable on $(0,\infty)$ with well defined value $g(0^+)$. Denote with g' the (classical) derivative of g on $\mathbb{R}\setminus\{0\}$, then (invoking linearity of $\mathcal{L}_{\mathbb{D}}$)

$$\begin{aligned}\mathcal{L}_{\mathbb{D}}\{(g_{\mathbb{D}})'\} &\overset{(2)}{=} \mathcal{L}_{\mathbb{D}}\{(g')_{\mathbb{D}} + g(0^+)\delta\}\\ &= \mathcal{L}_{\mathbb{D}}\{(g')_{\mathbb{D}}\} + g(0^+)\mathcal{L}_{\mathbb{D}}\{\delta\} \overset{(9),(10)}{=} \mathcal{L}\{g'\} + g(0^+),\end{aligned}$$

which shows equivalence of (11) and (6). The key observation is that the distributional derivative takes into account the jump at $t = 0$ whereas the classical derivates ignores it, i.e. in the above context

$$(g_{\mathbb{D}})' \neq (g')_{\mathbb{D}}.$$

As it is common to identify g with $g_{\mathbb{D}}$ (even in Doetsch (1974)), the above distinction is difficult to grasp, in particular for inexperienced readers. As this problem plays an important role when dealing with inconsistent initial values, it is not surprising that researchers from the DAE community who are simply using the Laplace transform as a tool, struggle with the treatment of inconsistent initial values, c.f. Lundberg et al. (2007).

Revisiting the treatment of the DAE (1) in the frequency domain one has now to decide wether to use the usual Laplace transform resulting in (7) or the distributional Laplace transform resulting in

$$sE\hat{x}(s) = A\hat{x}(s) + B\hat{u}(s), \tag{12}$$

where the initial value $x(0^+)$ does not occur anymore. In particular, if $u = 0$ the only solution of (12) is $\hat{x}(s) = 0$, which implies $x = 0$. Altogether, the following dilemma occurs:

Dilemma. Consider the regular DAE (1) with zero input but non-zero initial value, then the following conflicting observations can be made:
• An adhoc analysis calls for *distributional solutions* in response to inconsistent initial values. For consistent initial value there exist classical (nonzero) solutions.
• Using the *distributional* Laplace transform to analyze the (distributional) solutions of (1) reveals that the *only* solution is the trivial one. In particular, no initial values (neither inconsistent nor consistent ones) are taken into account at all.

This problem was already observed by Doetsch (1974) and is based on the definition of the distributional Laplace transform which is only defined for distributions vanishing on $(-\infty, 0)$. The following "solution" to this Dilemma was suggested (Doetsch, 1974, p. 129): Define for $D \in \bigcup_k \mathbb{D}_{\geq 0,k}$ the "past-aware" derivative operator $\frac{\mathrm{d}_-}{\mathrm{d}t}$:

$$\tfrac{\mathrm{d}_-}{\mathrm{d}t} D := D' - d_0^- \delta \tag{13}$$

where $d_0^- \in \mathbb{R}$ is interpreted as a "virtual" initial value for $D(0^-)$. Note however, that by definition $D(0^-) = 0$ for every $D \in \bigcup_k \mathbb{D}_{\geq 0,k}$, hence at this stage it is not clear why this definition makes sense. This problem was also pointed out by Cobb (1982).

Using now the past-aware derivative in the distributional formulation of (1) one obtains:

$$Ex' = Ax + Bu + Ex_0^-\delta \tag{14}$$

where $x_0^- \in \mathbb{R}^n$ is the virtual (possible inconsistent) initial value for $x(0^-)$ and solutions are sought in the space $\left(\bigcup_k \mathbb{D}_{\geq 0,k}\right)^n$, i.e. x is assumed to be zero on $(-\infty, 0)$. Applying the distributional Laplace transform to (14) yields

$$sE\hat{x}(s) = A\hat{x}(s) + B\hat{u}(s) + Ex_0^- \tag{15}$$

In contrast to (7), x_0^- is not the initial value for $x(0^+)$ but is the virtual initial value for $x(0^-)$. If the matrix pair (E, A) is regular, the solution of (15) can now be obtained via $\hat{x}(s) = (sE-A)^{-1}(B\hat{u}(s)+Ex_0^-)$ and using the inverse Laplace transform; there are however the following major drawbacks:
(i) Within the frequency domain it is not possible to motivate the incorporation of the (inconsistent) initial values as in (14); in fact, Doetsch (1974) who seems to have introduced this notion needs to argue with the help of the distributional derivative and (13) within the time domain!
(ii) The Laplace transform ignores everything what was in the past, i.e. on the interval $(-\infty, 0)$; this is true for the classical Laplace transform (by definition of the Laplace integral) as well as for the distributional Laplace transform (by only considering distributions which vanish for $t < 0$). Hence the natural viewpoint of an initial trajectory problem (3) as also informally advocated by Doetsch is not possible to treat with the Laplace transform approach.
(iii) Making statements about existence and uniqueness

of solution with the help of the frequency domain heavily depends on an isomorphism between the time-domain and the frequency domain; there are, however, only a few special isomorphisms between certain special subspaces of the frequency and time domain, no general isomorphismus is available.

4. PIECEWISE-SMOOTH DISTRIBUTIONS

In order to rigorously analyse switched DAEs it was suggested in Trenn (2009) to use as an underlying solution space the space of piecewise-smooth distributions

$$\mathbb{D}_{\mathrm{pw}\mathcal{C}^\infty} := \left\{ D = f_{\mathbb{D}} + \sum_{t\in T} D_t \;\middle|\; \begin{array}{l} f \in \mathcal{C}^\infty_{\mathrm{pw}}, T \subseteq \mathbb{R} \text{ locally} \\ \text{finite, } \forall t \in T: \\ D_t \in \operatorname{span}\{\delta_t, \delta_t', \delta_t'', \ldots\} \end{array} \right\},$$

where $\mathcal{C}^\infty_{\mathrm{pw}}$ is the space of piecewise-smooth functions (with locally finitely many discontinuities). This space is closed under differentiation and therefore removes one shortcoming of Cobb's space of piecewise-continuous distributions and generalized the space of impulsive-smooth distributions, which only considers Dirac impulses at $t = 0$ [5].

A key result for the ITP (3) is then the following equivalence:

Theorem 1. (cf. Thm. 5.3 in Trenn (2013)). Consider the ITP (3) within the piecewise-smooth distributional solution framework with fixed initial trajectory $x^0 \in \mathbb{D}^n_{\mathrm{pw}\mathcal{C}^\infty}$ and inhomogeneity $u \in \mathbb{D}^m_{\mathrm{pw}\mathcal{C}^\infty}$. Then $x \in \mathbb{D}^n_{\mathrm{pw}\mathcal{C}^\infty}$ solves the ITP (3) if, and only if, $z := x - x^0_{(-\infty,0)} = x_{[0,\infty)}$ solves

$$\begin{aligned} z_{(-\infty,0)} &= 0 \\ (E\dot{z})_{[0,\infty)} &= (Az + Bu)_{[0,\infty)} + Ex^0(0-)\delta. \end{aligned} \tag{16}$$

Corollary 2. Consider a (possible inconsistent) initial value $x_0 \in \mathbb{R}^n$ for the regular DAE (1). Then for any trajectory $x^0 \in \mathbb{D}^n_{\mathrm{pw}\mathcal{C}^\infty}$ with $x^0(0^-) = x_0$ and any input u, the solution x of the ITP (3) restricted to $[0,\infty)$ equals the solution obtained via the Laplace transform approach (15) (under the assumption $(x,u)_{[0,\infty)} \in \left(\bigcup_k \mathbb{D}_{\geq 0,k}\right)^{n\times m}$).

5. CONCLUSION

Inconsistent initial values cannot be treated in a meaningful way when studying DAEs in the frequency domain. However, arguments in the time-domain based on piecewise-smooth distribution justify why adding the term Ex_0 to the right-hand side of the distributionally Laplace transformed DAE indeed results in a meaningful solution to the inconsistent initial value problem

[5] Rabier and Rheinboldt (1996) seem to be aware of this restriction and they introduce the space $\mathcal{C}_{\mathrm{imp}}(\mathbb{R}\setminus\mathcal{S})$, where $\mathcal{S} = \{\, t_i \in \mathbb{R} \mid i \in \mathbb{Z} \,\}$ is a strictly ordered set with $t_i \to \pm\infty$ as $i \to \pm\infty$ and $D \in \mathcal{C}_{\mathrm{imp}}(\mathbb{R}\setminus\mathcal{S})$ is such that $D_{(t_i,t_{i+1})}$ is induced by the corresponding restriction of a smooth function. A similar idea is proposed in Geerts and Schumacher (1996), however in both cases the resulting distributional space is not studied in detail.

Abstract: Controllability maximization problem under sparsity constraints is a node selection problem that selects inputs that are effective for control in order to minimize the energy to control for desired state. In this paper we discuss the equivalence between the sparsity constrained controllability metrics maximization problems and their convex relaxation. The proof is based on the matrix-valued Pontryagin maximum principle applied to the controllability Lyapunov differential equation.

Keywords: Sparse optimal control, node selection problem, controllability maximization

1. INTRODUCTION

Sparse optimal problems have attracted a lot of attention in the field of optimal control. Such an approach is useful to find a small number of essential information that is closely related to the control performance of interest, and it is applied widely, for example, Ikeda et al. (2021). This paper investigates the application of sparse optimization to controllability maximization problem, one of the control node selection problems. The problem is known as the optimization problem minimizing the energy to control for the desired state; see also Olshevsky (2014) and Pasqualetti et al. (2014) for other related metrics.

These problems are generally formulated as maximization of some metric of the controllability Gramian with L^0/l^0 constraints, but it is known that the problems include combinatorial structures. To circumvent this, relaxed problems, where the L^0/l^0 norms are replaced by the L^1/l^1 norms, are considered for its computational tractability. Then, the problem is how to prove the equivalence between the main problem and its relaxation. The paper Ikeda and Kashima (2018) proved the equivalence when the trace of controllability Gramian is adopted as the metric, but its usefulness as a metric is questionable since the designed Gramian may include the zero eigenvalue, so the trace metric does not automatically ensure the controllability. The paper Ikeda and Kashima (2022) considered the minimum eigenvalue and the determinant of the controllability Gramian which is useful as metrics, but it avoided the proof of equivalence because of the difficulty and treated approximation problems that are easy to prove the equivalence. In view of this, this paper newly proposes a method to prove the equivalence for general metrics of controllability. Specifically, we adopted the controllability Lyapunov differential equation. The controllability Lyapunov differential equation is a matrix-valued differential equation whose solution is the controllability Gramian. By considering the optimal control problem for this Lyapunov differential equation, we can strictly treat useful metrics that are related to the controllability Gramian.

The remainder of this paper is organized as follows. Section 2 provides mathematical preliminaries. Section 3 formulates our node scheduling problem using controllability Lyapunov differential equation, and gives a sufficient condition for the main problem to boil down to the relaxation problem. Section 4 offers concluding remarks.

Notation

For any $A, B \in \mathbb{R}^{n\times m}$, we denote the Frobenius norm of A by $\|A\| \triangleq \left(\sum_{i=1}^{n}\sum_{j=1}^{m} A_{i,j}^2\right)^{1/2}$, and the inner product of A and B by $(A, B) \triangleq \left(\sum_{i=1}^{n}\sum_{j=1}^{m} A_{i,j}B_{i,j}\right)$. Let C be a closed subset of $\mathbb{R}^{n\times m}$ and $A \in C$. A matrix $\Delta \in \mathbb{R}^{n\times m}$ is a *proximal normal* to the set C at the point A if and only if there exists a constant $\sigma \geq 0$ such that $(\Delta, B - A) \leq \sigma\|B - A\|^2$ for all $B \in C$. The *proximal normal cone* to C at A is defined as the set of all such Δ, which is denoted by $N_C^P(A)$. We denote the *limiting normal cone* to C at A by $N_C^L(A)$, i.e., $N_C^L(A) \triangleq \{\Delta = \lim_{i\to\infty}\Delta_i : \Delta_i \in N_C^P(A_i), A_i \to A, A_i \in C\}$. For other notations, see (Ikeda and Kashima, 2022, Section II).

2. PRELIMINARY

Let us consider the following continuous-time linear system

$$\begin{aligned} \dot{x}(t) &= Ax(t) + BV(t)u(t), \quad t \in [0, T], \\ V(t) &= \mathrm{diag}(v(t)), \quad v(t) \in \{0, 1\}^p, \end{aligned} \tag{1}$$

where $x(t) \in \mathbb{R}^n$ is the state vector consisting of n nodes, where $x_i(t)$ is the state of the i-th node at time t; $u(\cdot) \in \mathbb{R}^m$ is the exogenous control input that influences the network dynamics. Then the controllability Gramian for the system is defined by

⋆ This work was supported in part by JSPS KAKENHI under Grant Number JP18H01461 and JP21H04875.

$$G_c = \int_0^T e^{A(T-\tau)} BV(\tau)V(\tau)^\top B^\top e^{A^\top (T-\tau)} d\tau. \tag{2}$$

We next show why the controllability Gramian is used as the metric of the ease of control. We here recall the minimum-energy control problem:

$$\begin{aligned} \min_u \quad & \int_0^T \|u(t)\|^2 dt \\ \text{s.t.} \quad & \dot{x}(t) = Ax(t) + BV(t)u(t), \\ & x(0) = 0, \quad x(T) = x_f. \end{aligned} \tag{3}$$

The minimum control energy is then given by $x_f^\top G_c^{-1} x_f$ (Verriest and Kailath (1983)). Based on this, recent works have been considered to make G_c as large as possible. In this paper we design $BV(t)$ in order to maximize some metric of the controllability Gramian. As the constraints, we introduce L^0 and l^0 constraints on $v(t)$ to take account of the upper bound of the total time length of node activation and the number of activated nodes at each time. We consider the following optimal problem that maximizes some metric of G_c under sparsity constraints:

$$\begin{aligned} \max_v \quad & J(v) = K(G_c) \\ \text{s.t.} \quad & v(t) \in \{0,1\}^p \quad {}^\forall t \in [0,T], \\ & \|v_j\|_{L^0} \le \alpha_j \quad {}^\forall j \in \{1,2,\dots,p\}, \\ & \|v(t)\|_{l^0} \le \beta \quad {}^\forall t \in [0,T], \end{aligned} \tag{4}$$

where $K(G_c)$ is a metric of the controllability Gramian, and $\alpha_j > 0$ and $\beta > 0$ is constant.

Since the maximization problem in (4) is a combinatorial optimization problem, we consider the following relaxation problem:

$$\begin{aligned} \max_v \quad & J(v) = K(G_c) \\ \text{s.t.} \quad & v(t) \in [0,1]^p \quad {}^\forall t \in [0,T], \\ & \|v_j\|_{L^1} \le \alpha_j \quad {}^\forall j \in \{1,2,\dots,p\}, \\ & \|v(t)\|_{l^1} \le \beta \quad {}^\forall t \in [0,T]. \end{aligned} \tag{5}$$

This problem is easier to treat than the main problem (especially if K is concave, problem (5) is a convex optimization problem). We, however, have to consider the equivalence between the main problem and the corresponding relaxation problem. Ikeda and Kashima (2022) formulated alternative approximation problem instead of proving the equivalence. Then this paper proves the equivalence between the main problem and the relaxed one by using the controllability Lyapunov differential equation.

3. PROPOSED METHOD

In this section, we formulate a controllability Lyapunov differential equation which holds the controllability Gramian as a solution, and then formulate an optimization problem for a system in which the state space representation is given by the derived differential equation. We provide an equivalence theorem between the main problem and the corresponding relaxation problem.

3.1 Problem formulation and relaxation

Controllability Lyapunov differential equation is given as follows:

$$\begin{aligned} & \dot{G}_c(t) = AG_c(t) + G_c(t)A^\top + BV(t)V(t)^\top B^\top, \\ & G_c(0) = O_{n\times n}. \end{aligned} \tag{6}$$

Then the controllability Gramian G_c defined by (2) corresponds to the solution $G_c(T)$ of (6) at $t = T$. Here we consider the following optimal control problem.

Problem 1 (Main problem)**.**

$$\begin{aligned} \max_v \quad & J(v) = K(G_c(T)) \\ \text{s.t.} \quad & \dot{G}_c(t) = AG_c(t) + G_c(t)A^\top + BV(t)B^\top, \\ & G_c(0) = O_{n\times n}, \\ & v(t) \in \{0,1\}^p \quad {}^\forall t \in [0,T], \\ & \|v_j\|_{L^0} \le \alpha_j \quad {}^\forall j \in \{1,2,\dots,p\}, \\ & \|v(t)\|_{l^0} \le \beta \quad {}^\forall t \in [0,T]. \end{aligned} \tag{7}$$

Note that $V(\cdot)V(\cdot)^\top = V(\cdot)$ since $v(\cdot) \in \{0,1\}^p$, so we rewrite the controllability Lyapunov differential equation. Problem 1 is a combinatorial optimization problem, so we consider the following relaxed problem, where the L^0/l^0 norms are replaced by the L^1/l^1 norms, respectively.

Problem 2 (Relaxed problem)**.**

$$\begin{aligned} \max_v \quad & J(v) = K(G_c(T)) \\ \text{s.t.} \quad & \dot{G}_c(t) = AG_c(t) + G_c(t)A^\top + BV(t)B^\top, \\ & G_c(0) = O_{n\times n}, \\ & v(t) \in [0,1]^p \quad {}^\forall t \in [0,T], \\ & \|v_j\|_{L^1} \le \alpha_j \quad {}^\forall j \in \{1,2,\dots,p\}, \\ & \|v(t)\|_{l^1} \le \beta \quad {}^\forall t \in [0,T]. \end{aligned} \tag{8}$$

In what follows, we suppose that K is continuously differentiable.

3.2 discreteness and equivalence

We define the set of feasible solutions of Problem 1 and Problem 2 by $\mathcal{V}_0$ and $\mathcal{V}_1$, i.e.,

$$\begin{aligned} \mathcal{V}_0 \triangleq \{v : & v(t) \in \{0,1\}^p \quad {}^\forall t, \quad \|v_j\|_{L^0} \le \alpha_j \quad {}^\forall j, \\ & \|v(t)\|_{l^0} \le \beta \quad {}^\forall t\}, \\ \mathcal{V}_1 \triangleq \{v : & v(t) \in [0,1]^p \quad {}^\forall t, \quad \|v_j\|_{L^1} \le \alpha_j \quad {}^\forall j, \\ & \|v(t)\|_{l^1} \le \beta \quad {}^\forall t\}. \end{aligned}$$

Note that $\mathcal{V}_0 \subset \mathcal{V}_1$, since $\|v_j\|_{L^1} = \|v_j\|_{L^0}$ for all j and $\|v(t)\|_{l^1} = \|v(t)\|_{l^0}$ on $[0,T]$ for any measurable function v with $v(t) \in \{0,1\}^p$ on $[0,T]$. The inclusion is proper in general, since the L^1/l^1 constraints do not automatically guarantee the L^0/l^0 constraints and some functions in $\mathcal{V}_1$ are not obviously binary. Then, we first show the discreteness of solutions of Problem 2, which guarantees that the optimal solutions of Problem 2 belongs to the set $\mathcal{V}_0$. For this purpose, we prepare lemmas.

Lemma 1 (Matrix Pontryagin principle)**.** *Let us consider the following optimization problem*

$$\begin{aligned} \min_U \quad & J = L_f(X(T)) \\ \text{s.t.} \quad & \dot{X}(t) = F(X(t), U(t)), \\ & X(0) = X_0, \quad X(T) \in E, \quad U(t) \in \Omega, \end{aligned} \tag{9}$$

where L_f is continuously differentiable, F is continuous, $D_X F(X(t), U(t))$ is continuous with respect to t, X, U, $X(t) \in \mathbb{R}^{n\times m}$, $U(t) \in \mathbb{R}^{p\times q}$, $X_0 \in \mathbb{R}^{n\times m}$, $T > 0$, $E \subset \mathbb{R}^{n\times m}$, and $\Omega \subset \mathbb{R}^{p\times q}$. Note that $(L_f, F, X_0, T, E, \Omega)$ is given. We define Hamiltonian function $H : \mathbb{R}^{n\times m} \times \mathbb{R}^{n\times m} \times \mathbb{R}^{p\times q} \to \mathbb{R}$ associated to problem (9) by

$$H(X(t), P(t), U(t)) = \mathrm{Tr}\left(P(t)^\top F(X(t), U(t))\right). \tag{10}$$

Let the process $(X^*(t), V^*(t))$ be a local minimizer for the problem (9). Then there exists a matrix $P : [0,T] \to \mathbb{R}^{n\times m}$, and a scalar η equal to 0 or 1 satisfying the following conditions:

- *the nontriviality condition:*
$$(\eta, P(t)) \neq 0 \quad {}^\forall t \in [0,T], \tag{11}$$
- *the transversality condition:*
$$-P(T) \in \eta \nabla L_f(X^*(T)) + N_E^L(X^*(T)), \tag{12}$$
- *the adjoint equation for almost every $t \in [0,T]$:*
$$-\dot{P}(t) = D_X H(X^*(t), P(t), U^*(t)), \tag{13}$$
- *the maximum condition for almost every $t \in [0,T]$:*
$$H(X^*(t), P(t), U^*(t)) = \sup_{U\in\Omega} H(X^*(t), P(t), U). \tag{14}$$

Proof. We define a mapping $\psi_{nm} : \mathbb{R}^{n\times m} \to \mathbb{R}^{nm}$ by
$$\psi_{nm}(X) = \left[X_1^\top, \ldots, X_m^\top\right]^\top, \tag{15}$$
where $X_i \in \mathbb{R}^n$ denotes the ith column of a matrix $X \in \mathbb{R}^{n\times m}$. From Athans (1967), ψ_{nm} is a regular linear mapping (hence ψ_{nm}^{-1} exists), and preserves the inner product. Then problem (9) is equivalent to
$$\begin{aligned} \min_u \quad & J = l_f(x(T)) \\ \text{s.t.} \quad & \dot{x}(t) = f(x(t), u(t)), \\ & x(0) = x_0 \quad x(T) \in e, \quad u(t) \in \omega, \end{aligned} \tag{16}$$
where $x = \psi_{nm}(X), u = \psi_{pq}(U)$, and l_f, f, x_0, e, ω corresponds to L_f, F, X_0, E, Ω respectively. We define the Hamiltonian function $h : \mathbb{R}^{nm} \times \mathbb{R}^{nm} \times \mathbb{R}^{pq} \to \mathbb{R}$ associated to problem (16) by $h(x(t), p(t), u(t)) = p(t)^\top f(x(t), u(t))$ and denote the local minimizer for problem (16) by $(x^*(t), u^*(t))$. Then there exists an arc $p : [0,T] \to \mathbb{R}^{nm}$ and a scalar η equal to 0 or 1 satisfying the following conditions (Pontryagin's Maximum Principle (Clarke (2013))):

- the nontriviality condition:
$$(\eta, p(t)) \neq 0 \quad {}^\forall t \in [0,T], \tag{17}$$
- the transversality condition:
$$-p(T) \in \eta \nabla l_f(x^*(T)) + N_e^L(x^*(T)), \tag{18}$$
- the adjoint equation for almost every $t \in [0,T]$
$$-\dot{p}(t) = D_x h(x^*(t), p(t), u^*(t)), \tag{19}$$
- the maximum condition for almost every $t \in [0,T]$
$$h(x^*(t), p(t), u^*(t)) = \sup_{u\in\omega} h(x^*(t), p(t), u). \tag{20}$$

Since ψ_{nm}^{-1} exists, we obtain the Hamiltonian function associated to $h(x^*(t), p(t), u^*(t))$ as follows:
$$H(X^*(t), P(t), U^*(t)) = \mathrm{Tr}\left(P^\top(t) F(X^*(t), U^*(t))\right), \tag{21}$$
which satisfies (11), (12), (13), and (14), where $X^* = \psi_{nm}^{-1}(x^*)$, $U^* = \psi_{pq}^{-1}(u^*)$, $P = \psi_{nm}^{-1}(p)$. This completes the proof. □

Lemma 2. *Define a set*
$$E \triangleq \{A \in \mathbb{R}^{n\times n} : A_{i,j} \leq \alpha_{i,j}, \quad (i,j) \in \mathcal{I}\}, \tag{22}$$
and fix any $\gamma \in E$, where $\mathcal{I} \subset \mathbb{N}^{n\times n}$ is a set of positions of elements of A for which inequality constraints are given. Then any $\delta \in N_E^L(\gamma)$ satisfies
$$\delta_{i,j}(\gamma_{i,j} - \alpha_{i,j}) = 0 \quad {}^\forall (i,j) \in \mathcal{I}, \tag{23}$$
$$\delta_{i,j} \geq 0 \quad {}^\forall (i,j) \in \mathcal{I}, \tag{24}$$
$$\delta_{i,j} = 0 \quad {}^\forall (i,j) \notin \mathcal{I}. \tag{25}$$

Proof. Fix any $\hat{A} \in E$ and $\hat{a} = \psi_{nn}(\hat{A})$, where ψ_{nn} is from (15). Then we obtain a set e satisfying $\hat{a} \in e$ as follows:
$$e \triangleq \{a \in \mathbb{R}^{n^2} : a_j \leq \alpha'_j, \quad j \in \mathcal{I}'\}, \tag{26}$$
where $\alpha' = \psi_{nn}(\alpha)$ and $\mathcal{I}' \subset \mathbb{N}^{n^2}$ is a set corresponding to $\mathcal{I}$. Take any $\gamma' \in e$, then we have
$$\delta'_i(\gamma'_i - \alpha'_i) = 0 \quad {}^\forall i \in \mathcal{I}', \tag{27}$$
$$\delta'_i \geq 0 \quad {}^\forall i \in \mathcal{I}', \tag{28}$$
$$\delta'_i = 0 \quad {}^\forall i \notin \mathcal{I}' \tag{29}$$
for all $\delta' \in N_E^L(\gamma')$ (Ikeda and Kashima (2022)). Finally, we obtain (23), (24), (25) where $\delta = \psi_{nn}^{-1}(\delta')$ and $\gamma = \psi_{nn}^{-1}(\gamma')$. □

Theorem 1. *Let $G_c^*(t)$ and $V^*(t)$ be a local optimal solution of Problem 2. Assume that*
$$q_j(t) \triangleq b_j^\top e^{A^\top(T-t)} \frac{\partial K(G_c^*(T))}{\partial G_c^*(T)} e^{A(T-t)} b_j$$
and $q_i(t) - q_j(t)$ is not constant on $[0,T]$ for all $i, j \in \{1,2,\ldots,p\}$. Then any solution to Problem 2 takes only the values in the binary set {0,1} almost everywhere.

Proof. We first reformulate Problem 2 into a form to which Lemma 1 is applicable. The value $\|v_j\|_{L^1}$ is equal to the final state $y_j(T)$ of the system $\dot{y_j}(t) = v_j(t)$ with $y_j(0) = 0$. Define $Y(t) \triangleq \mathrm{diag}(y(t))$ and matrices $X(t), \bar{V}(t), \bar{A}, \bar{B}$ by
$$X(t) \triangleq \begin{bmatrix} G_c(t) & O_{n\times p} \\ O_{p\times n} & Y(t) \end{bmatrix}, \ \bar{V}(t) \triangleq \begin{bmatrix} V(t) & O_{p\times p} \\ O_{p\times p} & V(t) \end{bmatrix},$$
$$\bar{A} \triangleq \begin{bmatrix} A & O_{n\times p} \\ O_{p\times n} & O_{p\times p} \end{bmatrix}, \ \bar{B} \triangleq \begin{bmatrix} B & O_{n\times p} \\ O_{p\times p} & I_p \end{bmatrix}.$$
Then, Problem 2 is equivalently expressed as follows:
$$\begin{aligned} \min_v \quad & J(V) = -L_f(X(T)) \\ \text{s.t.} \quad & \dot{X}(t) = \bar{A}X(t) + X(t)\bar{A}^\top + \bar{B}\bar{V}(t)\bar{B}^\top, \\ & X(0) = O_{(n+p)\times(n+p)}, \quad X(T) \in E, \\ & v(t) \in \Omega \quad {}^\forall t \in [0,T], \end{aligned} \tag{30}$$
where $L_f(X(T)) = K(G_c(T))$, $E = \{X(T) : y_j(T) \leq \alpha_j \quad {}^\forall j \in \{1,2,\ldots,p\}\}, \Omega = \{v(t) : v(t) \in [0,1]^p, \|v(t)\|_{l^1} \leq \beta\}$. This is an optimal control problem to which Lemma 1 is applicable. We define the Hamiltonian function H associated to problem (30) by
$$H(X, P, V) = \mathrm{Tr}\left(P^\top(\bar{A}X(t) + X(t)\bar{A}^\top + \bar{B}\bar{V}(t)\bar{B}^\top)\right).$$
We define two matrices as follows:
$$X^*(t) \triangleq \begin{bmatrix} G_c^*(t) & O_{n\times p} \\ O_{p\times n} & Y^*(t) \end{bmatrix}, \quad \bar{V}^*(t) \triangleq \begin{bmatrix} V^*(t) & O_{p\times p} \\ O_{p\times p} & V^*(t) \end{bmatrix}. \tag{31}$$
Then $(X^*(t), \bar{V}^*(t))$ is the local minimizer of problem (30) because of the equivalence between Problem 2 and problem (30), and there exists a scalar η equal to 0 or 1 and a matrix $P : [0,T] \to \mathbb{R}^{n\times n}$ satisfying the conditions (11), (12), (13), (14). It follows from (13) that
$$-\dot{P}(t) = \bar{A}^\top P(t) + P(t)\bar{A},$$
which leads to
$$\begin{aligned} P(t) &= e^{\bar{A}^\top(T-t)} P(T) e^{\bar{A}(T-t)} \\ &= \begin{bmatrix} e^{A^\top(T-t)} P^{(11)}(T) e^{A(T-t)} & e^{A^\top(T-t)} P^{(12)}(T) \\ P^{(21)}(T) e^{A(T-t)} & P^{(22)}(T) \end{bmatrix}, \end{aligned} \tag{32}$$
where
$$P(t) = \begin{bmatrix} P^{(11)}(t) & P^{(12)}(t) \\ P^{(21)}(t) & P^{(22)}(t) \end{bmatrix} \tag{33}$$

with $P^{(11)}(t) \in \mathbb{R}^{n\times n}$ and $P^{(22)}(t) \in \mathbb{R}^{p\times p}$. Note that

$$\begin{bmatrix} -P^{(11)}(T) + \eta \dfrac{\partial K(G_c^*(T))}{\partial G_c^*(T)} & -P^{(12)}(T) \\ -P^{(21)}(T) & -P^{(22)}(T) \end{bmatrix} \in N_E^L(X^*(T))$$

by (12), then we have

$$P^{(22)}_{j,j}(T)(y_j(T) - \alpha_j) = 0 \quad j = \{1, 2, \dots, p\}, \tag{34}$$

$$P^{(22)}_{j,j}(T) \le 0 \quad j = \{1, 2, \dots, p\}, \tag{35}$$

$$P^{(22)}_{i,j}(T) = 0 \quad {}^\forall(i, j) \in \{(i, j) : i \neq j\}, \tag{36}$$

$$-P^{(11)}(T) + \eta \frac{\partial K(G_c^*(T))}{\partial G_c^*(T)} = O_{n\times n}, \tag{37}$$

$$P^{(12)}(T) = O_{n\times p}, \quad P^{(21)}(T) = O_{p\times n}, \tag{38}$$

from Lemma 2. Substituting these into (32), we get

$$P(t) = \begin{bmatrix} e^{A^\top(T-t)} \eta \dfrac{\partial K(G_c^*(T))}{\partial G_c^*(T)} e^{A(T-t)} & O_{n\times p} \\ O_{p\times n} & P^{(22)}(T) \end{bmatrix}. \tag{39}$$

Then, we have

$$\begin{aligned} \mathrm{Tr}\left(P^\top(t)\bar{B}\bar{V}(t)\bar{B}^\top\right) &= \mathrm{Tr}\left(\bar{B}^\top P^\top(t)\bar{B}\bar{V}(t)\right) \\ &= \mathrm{Tr}\left(\begin{bmatrix} B^\top P^{(11)\top}(t) B & O_{p\times p} \\ O_{p\times p} & P^{(22)}(t) \end{bmatrix} \bar{V}(t)\right) \\ &= \sum_{j=1}^{p} \left(\eta q_j(t) + P^{(22)}_{j,j}(T)\right) v_j(t). \end{aligned}$$

It follows from (14) that

$$v^*(t) = \arg\max_{v\in\Omega} \sum_{j=1}^{p} \left(\eta q_j(t) + P^{(22)}_{j,j}(T)\right) v_j. \tag{40}$$

We here claim that $\eta = 1$. Indeed, if $\eta = 0$, $P^{(22)}(T) \neq O_{p\times p}$ follows from (11), i.e., there exists some j that satisfies

$$P^{(22)}_{j,j}(T) < 0, \quad y_j^*(T) = \alpha_j. \tag{41}$$

Hence, from (40) and (41), we have $v_j^*(t) = 0$ for all $t \in [0, T]$, i.e., $y_j^*(T) = \|v_j^*\|_{L^1} = 0$. This contradicts to (41). Thus, $\eta = 1$. From the assumption, it is easy to verify that

1) we have $q_j(t) + P^{(22)}_{j,j}(T) \neq 0$ almost everywhere for all $j = \{1, 2, \dots, p\}$,
2) there exists $j_k : [0, T] \to \{1, 2, \dots, p\}$, $k = 1, 2, \dots, p$, such that
$q_{j_1(t)}(t) + P^{(22)}_{j_1(t),j_1(t)}(T) > \cdots > q_{j_p(t)}(t) + P^{(22)}_{j_p(t),j_p(t)}(T)$
almost everywhere.

Hence, we find

$$v_j^*(t) = \begin{cases} 1 & \text{if} \quad j \in \Xi_1(t) \cap \Xi_2(t), \\ 0 & \text{otherwise} \end{cases} \tag{42}$$

for almost every $t \in [0, T]$, where

$$\Xi_1(t) \triangleq \{j_1(t), j_2(t), \dots, j_\beta(t)\},$$

$$\Xi_2(t) \triangleq \{k \in \{1, 2, \dots, p\} : q_{j_k(t)}(t) + P^{(22)}_{j_k(t),j_k(t)}(T) > 0\}.$$

This completes the proof. □

The following theorem is the main result, which shows the equivalence between Problem 1 and Problem 2.

Theorem 2 (equivalence)**.** *Assume that $q_j(t)$ and $q_i(t) - q_j(t)$ is not constant on $[0, T]$ for all $i, j \in \{1, 2, \dots, p\}$. Denote the set of all solutions of Problem 1 and Problem 2 by $\mathcal{V}_0^*$ and $\mathcal{V}_1^*$, respectively. If the set $\mathcal{V}_1^*$ is not empty, then we have $\mathcal{V}_0^* = \mathcal{V}_1^*$.*

Proof. Denote any solution of Problem 2 by $\hat{v} \in \mathcal{V}_1^*$. It follows from Theorem 1 that $\hat{v}(t) \in \{0, 1\}^p$ almost everywhere. Note that the null set $\cup_{j=1}^p \{t \in [0, T] : \hat{v}_j(t) \notin \{0, 1\}\}$ does not affect the cost, and hence we can adjust the variables so that $\hat{v}(t) \in \{0, 1\}^p$ on $[0, T]$, without loss of the optimality. We have

$$\|\hat{v}(t)\|_{l^1} = \|\hat{v}(t)\|_{l^0}, \quad \|\hat{v}_j\|_{L^1} = \|\hat{v}_j\|_{L^0}$$

for all j. Since $\hat{v} \in \mathcal{V}_1$, we have $\|\hat{v}(t)\|_{l^0} \le \beta$ and $\|\hat{v}_j\|_{L^0} \le \alpha_j$ for all t and j. Thus, $\hat{v} \in \mathcal{V}_0$. Then,

$$J(\hat{v}) \le \max_{v\in\mathcal{V}_0} J(v) \le \max_{v\in\mathcal{V}_1} J(v) = J(\hat{v}), \tag{43}$$

where the first relation follows from $\hat{v} \in \mathcal{V}_0$, the second relation follows from $\mathcal{V}_0 \subset \mathcal{V}_1$, and the last relation follows from $\hat{v} \in \mathcal{V}_1^*$. Hence, we have

$$J(\hat{v}) = \max_{v\in\mathcal{V}_0} J(v), \tag{44}$$

which implies $\hat{v} \in \mathcal{V}_0^*$. Hence, $\mathcal{V}_1^* \subset \mathcal{V}_0^*$ and $\mathcal{V}_0^*$ is not empty.

Next, take any $\tilde{v} \in \mathcal{V}_0^*$. Note that $\tilde{v} \in \mathcal{V}_1$, since $\mathcal{V}_0^* \subset \mathcal{V}_0 \subset \mathcal{V}_1$. In addition, it follows from (44) that $J(\tilde{v}) = J(\hat{v})$. Therefore, $\tilde{v} \in \mathcal{V}_1^*$, which implies $\mathcal{V}_0^* \subset \mathcal{V}_1^*$. This gives $\mathcal{V}_0^* = \mathcal{V}_1^*$. □

4. CONCLUSION

In this paper, we discussed the equivalence between the sparsity constrained controllability metrics maximization problems and their convex relaxation. The proof is based on the matrix-valued Pontryagin maximum principle applied to the controllability Lyapunov differential equation. The existence of optimal solutions and computational cost are currently under investigation.

Abstract: Concepts of controllability and observability have been defined for a class of decentralized systems known as coordinated linear systems. The classical duality result does not extend to these systems. In the present paper, we generalize these notions of controllability and observability to poset-causal systems. We introduce the dual system associated with a poset-causal system and extend the classical duality result using this notion of a dual system.

Keywords: Decentralized systems, poset-causal systems, controllability and observability, duality.

1. INTRODUCTION

In this paper we consider poset-causal systems introduced by Shah and Parrilo in Shah et al. (2008) and further developed in the papers Shah et al. (2009, 2011, 2013) and the PhD thesis Shah (2011).

Poset causal systems are decentralized systems that consist of interconnected subsystems, labeled $1, 2, \ldots, p$, which are modeled by a partial order $\succeq$ on the set $P = \{1, 2, \ldots, p\}$. Hence, the pair $\mathcal{P} = (P, \succeq)$ is a partially ordered set (poset). In this setting subsystem j can 'influence' subsystem i in case $i \succeq j$. We assume that each subsystem is locally given by an input-state-output model with an input space $\mathcal{U}_i = \mathbb{R}^{m_i}$, a state space $\mathcal{X}_i = \mathbb{R}^{n_i}$ and an output space $\mathcal{Y}_i = \mathbb{R}^{r_i}$, with $m_i, n_i, r_i \in \mathbb{Z}_+$. The output y_i and state x_i are determined by the states and inputs of subsystems that can 'influence' subsystem i via interconnected state space system equations

$$\dot{x}_i(t) = \sum_{j \in \uparrow i} A_{ij} x_j + \sum_{k \in \uparrow i} B_{ik} u_k, \quad x_i(0) = x_{i,0},$$
$$y_i(t) = \sum_{j \in \uparrow i} C_{ij} x_j + \sum_{k \in \uparrow i} D_{ik} u_k, \quad t \geq 0,$$

where $\uparrow i = \{j \mid j \succeq i\}$. Here $x_{i,0} \in \mathbb{R}^{n_i}$ is the initial state of subsystem i and $A_{ij} \in \mathbb{R}^{n_i \times n_j}$, $B_{ij} \in \mathbb{R}^{n_i \times m_j}$, $C_{ij} \in \mathbb{R}^{r_i \times n_j}$ and $D_{ij} \in \mathbb{R}^{r_i \times m_j}$ are given matrices whenever $j \succeq i$. In case $j \not\succeq i$, set A_{ij}, B_{ij}, C_{ij} and D_{ij} equal to zero matrices of appropriate sizes and define

$$A = [A_{ij}],\ B = [B_{ij}],\ C = [C_{ij}],\ D = [D_{ij}], \qquad (1)$$

where $i, j = 1, 2, \ldots, p$. Then the combined input, state and output signals

$$u(t) = (u_1(t), \ldots, u_p(t))^\intercal \in \mathcal{U} = \oplus_{i=1}^p \mathcal{U}_i,$$
$$x(t) = (x_1(t), \ldots, x_p(t))^\intercal \in \mathcal{X} = \oplus_{i=1}^p \mathcal{X}_i,$$
$$y(t) = (y_1(t), \ldots, y_p(t))^\intercal \in \mathcal{Y} = \oplus_{i=1}^p \mathcal{Y}_i,$$

with $\oplus$ indicating orthogonal sums, satisfy

$$\dot{x}(t) = Ax(t) + Bu(t), \quad x(0) = x_0 \in \mathcal{X},$$
$$y(t) = Cx(t) + Du(t), \quad t \geq 0,$$

for $x_0 = (x_{1,0}, \ldots, x_{p,0})^\intercal \in \mathcal{X}$. In the block partitioning (1), the entries A_{ij}, B_{ij}, C_{ij} and D_{ij} are zero matrices whenever $i \not\succeq j$. Since $\succeq$ is a partial order, this zero-pattern is invariant under block matrix multiplication, provided the block sizes are compatible for multiplication. Poset causal systems have system matrices whose block zero patterns are determined by a partial order. The proofs of the results as well as a more detailed expositions will be presented in ter Horst et al. (2021).

Concepts of controllability and observability have been defined for a subclass of poset-causal systems known as coordinated linear systems in Kemper et al. (2012). In the present paper we extend these concepts of controllability and observability to poset-causal systems. The partially ordered structures that underly coordinated linear systems have a stronger notion of transitivity, defined in Bart et al. (2018) as in-ultra transitive, which do not allow for a suitable notion of duality. In the last part of the current paper we introduce a notion of duality for poset-causal systems, and present duality results for the notions of controllability and observability defined here.

2. POSET CAUSAL SYSTEMS

In this section we give a more formal definition of poset-causal systems and introduce the dual of a poset-causal system. For this we require some preliminary definitions and results on order structures and matrices with associated block zero-patterns.

2.1 Order structures

A *partially ordered set*, or *poset*, is a pair $\mathcal{P} = (P, \succeq)$ with P a set and $\succeq$ a partial order on P. That is, $\succeq$ is a

⋆ This work is based on research supported in part by the National Research Foundation of South Africa (Grant Numbers 118513 and 127364).

binary relation on P which is reflexive, transitive and antisymmetric. For $i, j \in P$ we write $i \succ j$ if $i \succeq j$ and $i \neq j$. Also, $i \preceq j$ and $i \prec j$ mean $j \succeq i$ and $j \succ i$, respectively. In the sequel we will only consider finite posets, usually of the form $P = \{1, 2, \ldots, p\}$ for some positive integer p. Given a subset $R \subseteq P$ of a poset $\mathcal{P} = (P, \succeq)$ we define its downstream set $\downarrow R$ and its upstream set $\uparrow R$ as

$$\begin{aligned} \downarrow R &= \{i \in P \colon \exists\, j \in R \text{ such that } j \succeq i\} \quad \text{and} \\ \uparrow R &= \{i \in P \colon \exists\, j \in R \text{ such that } i \succeq j\}. \end{aligned} \tag{2}$$

In the case that R is a singleton, say $R = \{i\}$, we simply write $\downarrow i$ and $\uparrow i$.

Definition 1. Given a poset $\mathcal{P} = (P, \succeq)$, we define the *dual poset* as $\mathcal{P}_d = (P, \succeq_d)$ where

$$j \succeq_d k \iff k \succeq j$$

for each $j, k \in P$.

Given the dual poset $\mathcal{P}_d = (P, \succeq_d)$ of some poset $\mathcal{P} = (P, \succeq)$, we also define the upstream- and downstream sets in terms of the dual poset:

$$\uparrow_d i = \{j \in P : j \succeq_d i\} \text{ and } \downarrow_d i = \{j \in P : j \preceq_d i\}.$$

Clearly we have $\uparrow_d i = \downarrow i$ and $\downarrow_d i = \uparrow i$.

Example 2. Consider posets $\mathcal{P}_1$ and $\mathcal{P}_2$ with Hasse diagrams given by:

Then $\mathcal{G}^{\downarrow}_{\mathcal{P}_1}$ is the underlying digraph of a coordinated linear system with one coordinator and two followers. It represents a in-ultra transitive order. $\mathcal{G}^{\downarrow}_{\mathcal{P}_2}$ is the dual of $\mathcal{G}^{\downarrow}_{\mathcal{P}_1}$ and is not in-ultra transitive and hence is not the underlying poset of a coordinated linear system.

2.2 Block matrices with prescribed zero-patterns

In this paper we are interested in classes of block matrices with prescribed zero-patterns, which are not necessarily square, but are closed under (block) matrix multiplication, provided the sizes of the blocks are compatible. This requires us to introduce some notation.

Given some $n \in \mathbb{Z}_+$, we will say $\underline{n} = (n_1, n_2, \ldots, n_p) \in \mathbb{Z}^p_+$ is a partition of n if $|\underline{n}| := n_1 + n_2 + \ldots + n_p = n$. Let $\underline{n} = (n_1, n_2, \ldots, n_p) \in \mathbb{Z}^p_+$ and $\underline{m} = (m_1, m_2, \ldots, m_q) \in \mathbb{Z}^q_+$ be two given partitions. We will write $A = [G_{ij}] \in \mathbb{R}^{\underline{n} \times \underline{m}}$, in which case it is to be understood that $G_{ij} \in \mathbb{R}^{n_i \times m_j}$. In case $\underline{r} \in \mathbb{Z}^p_+$ is another partition, then matrices $G \in \mathbb{R}^{\underline{r} \times \underline{n}}$ and $H \in \mathbb{R}^{\underline{n} \times \underline{m}}$ are said to be compatible for block matrix multiplication GH. When only the lengths p of $\underline{n}$ and q of $\underline{m}$ are specified, we will sometimes speak of $p \times q$ block matrices.

By analogy of the incidence algebras studied in Davis (1970), we define block matrices with zero-pattern prescribed by a partial order in the following manner.

Definition 3. Given a poset $\mathcal{P} = (P, \succeq)$, with $P = \{1, \ldots, p\}$ and partitions $\underline{n}, \underline{m} \in \mathbb{Z}^p_+$, we define the *block incidence vector space* $\mathcal{I}^{\underline{n} \times \underline{m}}_{\mathcal{P}} \subseteq \mathbb{R}^{\underline{n} \times \underline{m}}$ as the subspace

$$\mathcal{I}^{\underline{n} \times \underline{m}}_{\mathcal{P}} = \{G = [G_{ij}] \in \mathbb{R}^{\underline{n} \times \underline{m}} \colon G_{ij} = 0 \text{ if } j \not\succeq i\}.$$

By arguments similar to those in Davis (1970) it follows that the block zero structure is preserved under block matrix multiplication when the matrices are compatible for block matrix multiplication.

Proposition 4. Let $\mathcal{P} = (P, \succeq)$ be a poset with p elements and let $\underline{n}, \underline{m}, \underline{r} \in \mathbb{Z}^p_+$. If $G \in \mathcal{I}^{\underline{r} \times \underline{n}}_{\mathcal{P}}$ and $H \in \mathcal{I}^{\underline{n} \times \underline{m}}_{\mathcal{P}}$, then the product GH is well-defined and $GH \in \mathcal{I}^{\underline{r} \times \underline{m}}_{\mathcal{P}}$. If $G \in \mathcal{I}^{\underline{n} \times \underline{n}}_{\mathcal{P}}$ and $\det(G) \neq 0$, then $G^{-1} \in \mathcal{I}^{\underline{n} \times \underline{n}}_{\mathcal{P}}$.

Throughout the paper we work with block compressions associated with subsets of P. Note that we have defined partitionings in such a way that zero entries are allowed. It will be convenient in this paper to define compressions by simply setting some of the entries in the partitionings equal to zero.

Definition 5. Let $P = \{1, \ldots, p\}$ and let $R, S \subset P$. Let $G \in \mathbb{R}^{\underline{n} \times \underline{m}}$ for partitions $\underline{n}, \underline{m} \in \mathbb{Z}^p_+$. Then $G(R, S)$ denotes the block matrix in $\mathbb{R}^{\underline{n}_R \times \underline{m}_S}$ where

$$\underline{n}_R = (n_{1,R}, \ldots, n_{p,R}) \in \mathbb{Z}^p_+, \text{ with } n_{j,R} = \begin{cases} 0 & \text{if } j \notin R \\ n_j & \text{if } j \in R \end{cases}$$

$$\underline{m}_S = (m_{1,S}, \ldots, m_{q,S}) \in \mathbb{Z}^q_+, \text{ with } m_{j,S} = \begin{cases} 0 & \text{if } j \notin S \\ m_j & \text{if } j \in S \end{cases}$$

and where $G(R, S) = [\widetilde{G}_{ij}]_{i,j=1,\ldots,p}$ is defined by

$$\widetilde{G}_{ij} = G_{ij} \text{ if } i \in R \text{ and } j \in S$$

and $\widetilde{G}_{ij}$ vacuous if $i \notin R$ or $j \notin S$.

If R is a singleton, say $R = \{i\}$, we write $A(i, S)$ and likewise we write $A(R, j)$ if $S = \{j\}$. For one-sided compressions, we follow Matlab notation, and write $A(:, S)$ in case $R = P$, or $A(R, :)$ in case $S = P$.

Theorem 6. Given a poset $\mathcal{P} = (P, \succeq)$ with p elements, partitionings $\underline{n}, \underline{m}, \underline{r} \in \mathbb{Z}^p_+$ and subsets $Q, S \subset P$, for any block matrices $G \in \mathbb{R}^{\underline{r} \times \underline{n}}$ and $H \in \mathcal{I}^{\underline{n} \times \underline{m}}_{\mathcal{P}}$ we have

$$(GH)(Q, S) = G(Q, R)H(R, S),$$

for any subset $R \subseteq P$ with $\downarrow S \subseteq R$, in particular $(GH)(Q, S) = G(Q, \downarrow S)H(\downarrow S, S)$.

Finally, we define the block identity matrix $I_{\underline{n}} \in \mathbb{R}^{\underline{n} \times \underline{n}}$ with respect to a partitioning $\underline{n} \in \mathbb{Z}^p_+$ as the block diagonal matrix in $\mathbb{R}^{\underline{n} \times \underline{n}}$ with identity matrices as diagonal blocks. Then $I_{\underline{n}}(:, S)$ can be viewed as the embedding of $\mathbb{R}^{\underline{n}_S}$ into $\mathbb{R}^{\underline{n}}$ and $I_{\underline{n}}(S, :)$ as the projection from $\mathbb{R}^{\underline{n}}$ onto $\mathbb{R}^{\underline{n}_S}$.

2.3 Poset causal systems

Definition 7. Let $\mathcal{P} = (P, \succeq)$ be a poset with $P = \{1, \ldots, p\}$. A poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ (with underlying poset $\mathcal{P}$) is a linear time invariant system with structured system matrices

$$A \in \mathcal{I}^{\underline{n} \times \underline{n}}_{\mathcal{P}}, \quad B \in \mathcal{I}^{\underline{n} \times \underline{m}}_{\mathcal{P}}, \quad C \in \mathcal{I}^{\underline{r} \times \underline{n}}_{\mathcal{P}}, \quad D \in \mathcal{I}^{\underline{r} \times \underline{m}}_{\mathcal{P}}, \tag{3}$$

for $\underline{n}, \underline{m}, \underline{r} \in \mathbb{Z}^p_+$ and some initial state $x_0 \in \mathcal{X} = \mathbb{R}^{\underline{n}}$.

For a poset-causal systems $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$, with A, B, C, D as in (3), since $A(i, j) = 0$ if $j \not\succeq i$, for the transpose A^{T} we have $A^{\mathsf{T}}(j, i) = 0$ if $j \not\succeq i$, that is, if $i \not\preceq_d j$. Consequently, we have

$$A^{\mathsf{T}} \in \mathcal{I}^{\underline{n} \times \underline{n}}_{\mathcal{P}_d}, \quad B^{\mathsf{T}} \in \mathcal{I}^{\underline{m} \times \underline{n}}_{\mathcal{P}_d}, \quad C^{\mathsf{T}} \in \mathcal{I}^{\underline{n} \times \underline{r}}_{\mathcal{P}_d}, \quad D^{\mathsf{T}} \in \mathcal{I}^{\underline{m} \times \underline{r}}_{\mathcal{P}_d}.$$

This observation justifies the following definition of the dual system.

Definition 8. For a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$, we define its *dual poset-causal system* as

$$\Sigma_{\mathcal{P}_d} \sim (A^\intercal, C^\intercal, B^\intercal, D^\intercal).$$

Example 9. Consider the poset $\mathcal{P}_1$ in example 2. And consider a poset-causal system $\Sigma_{\mathcal{P}_1} \sim (A, B, C, 0)$ with $A \in \mathcal{I}_{\mathcal{P}_1}^{\underline{n}\times\underline{n}}$, $B \in \mathcal{I}_{\mathcal{P}_1}^{\underline{n}\times\underline{m}}$ and $C \in \mathcal{I}_{\mathcal{P}_1}^{\underline{r}\times\underline{n}}$ with $\underline{n} = (1,1,2)$, $\underline{m} = (1,1,1)$ and $\underline{r} = (1,1,1)$, given by

$$A = \left[\begin{array}{c|c|cc} 1 & 0 & 0 & 0 \\ \hline 1 & 1 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 0 \end{array}\right],\ B = \left[\begin{array}{c|c|c} 1 & 0 & 0 \\ \hline 0 & 1 & 0 \\ \hline 1 & 0 & 0 \\ \hline 0 & 0 & 1 \end{array}\right],\ C = \left[\begin{array}{c|c|cc} 1 & 0 & 0 & 0 \\ \hline 1 & 1 & 0 & 0 \\ \hline 1 & 0 & 0 & 1 \end{array}\right]$$

Then $\mathcal{X}_1 = \text{span}\{e_1\}$, $\mathcal{X}_2 = \text{span}\{e_2\}$ and $\mathcal{X}_3 = \text{span}\{e_3, e_4\}$. So that $\mathcal{X} = \text{span}\{e_1, e_2, e_3, e_4\} = \mathbb{R}^4$. The dual poset of $\mathcal{P}_1$ is $\mathcal{P}_d = \mathcal{P}_2$ given in example 2. And $\Sigma_{\mathcal{P}_d} \sim (A_d, B_d, C_d, 0)$ is given by:

$$A_d = A^\intercal = \left[\begin{array}{c|c|cc} 1 & 1 & 0 & 0 \\ \hline 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ \hline 0 & 0 & 0 & 0 \end{array}\right],\ B_d = C^\intercal = \left[\begin{array}{c|c|c} 1 & 1 & 1 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 1 \end{array}\right],$$

$$C_d = B^\intercal = \left[\begin{array}{c|c|cc} 1 & 0 & 1 & 0 \\ \hline 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 1 \end{array}\right]$$

Now $\Sigma_{\mathcal{P}_1}$ is a coordinated linear system and its dual system $\Sigma_{\mathcal{P}_d}$ is a poset-causal system which is not a coordinated linear system.

3. UPSTREAM CONTROLLABILITY AND DOWNSTREAM OBSERVABILITY

In this section we extend certain notions of controllability and observability introduced in Kemper et al. (2012) for coordinated linear systems to the setting of poset-causal systems. Consider a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ with n-dimensional state space $\mathcal{X}$. The reachable subspace $\mathcal{R}$ and unobservable subspace $\mathcal{N}$ of $\mathcal{X}$ are defined as

$$\mathcal{R} = \text{Im}\,\mathcal{C}(A, B) \quad \text{and} \quad \mathcal{N} = \text{Ker}\,\mathcal{O}(C, A), \tag{4}$$

where

$$\mathcal{C}(A, B) = \begin{bmatrix} B & AB & \cdots & A^{n-1}B \end{bmatrix},\ \mathcal{O}(C, A) = \mathcal{C}(A^\intercal, C^\intercal)^\intercal.$$

For $i \in P$ we define the *i-downstream reachable set* $\mathcal{R}_i$ as

$$\mathcal{R}_i := \text{Im}\ \mathcal{C}(A(\downarrow i, \downarrow i), B(\downarrow i, i)) \subseteq \mathcal{X}(\downarrow i), \tag{5}$$

with $\mathcal{X}(\downarrow i)$ defined as

$$\mathcal{X}(\downarrow i) := \bigoplus_{j \in \downarrow i} \mathcal{X}_j.$$

Hence a vector $\xi \in \mathcal{X}(\downarrow i)$ is in $\mathcal{R}_i$ if it is reachable in the system

$$\dot{x}^{\downarrow i}(t) = A(\downarrow i, \downarrow i)x^{\downarrow i} + B(\downarrow i, i)u_i,$$

which includes states which can be reached by applying only the i^{th} input u_i. In such a case we say that ξ is *i-downstream reachable.*

The following theorem extends Lemma 3.2 in Kemper et al. (2012) to poset-causal systems.

Theorem 10. Given a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, 0, 0)$ with $A \in \mathcal{I}_{\mathcal{P}}^{\underline{n}\times\underline{n}}$ and $B \in \mathcal{I}_{\mathcal{P}}^{\underline{n}\times\underline{m}}$, the reachable space $\mathcal{R} \subseteq \mathcal{X}$ is given in terms of $i-$downstream reachable sets $\mathcal{R}_i$ as

$$\mathcal{R} = \sum_{i=1}^{p} I_{\underline{n}}(:, \downarrow i)\mathcal{R}_i.$$

Note that $\mathcal{R}_j \subseteq \mathcal{X}(\downarrow j)$ and that $\mathcal{X}_i \subset \mathcal{X}(\downarrow j)$ for each $i \in \downarrow j$. For each $j \in P$ and $i \in \downarrow j$ we define the following subspaces of $\mathcal{X}_i$:

$$\overline{\mathcal{R}}_i^j := \mathcal{X}_i \cap \mathcal{R}_j \quad \text{and} \quad \widetilde{\mathcal{R}}_i^j := P_{\mathcal{X}_i}\mathcal{R}_j.$$

Here $P_{\mathcal{X}_i}$ is the orthogonal projection onto $\mathcal{X}_i$. One can view $\overline{\mathcal{R}}_i^j$ as the set of local states $x_i \in \mathcal{X}_i$ that can be reached from a local input u_j in such a way that the other states downstream from j remain unaffected. The subspace $\widetilde{\mathcal{R}}_i^j$, on the other hand, is the set of local states $x_i \in \mathcal{X}_i$ that can be reached from a local input u_j while the other states downstream from subsystem j may also be affected. By definition of the subspaces, we directly get that:

$$\bigoplus_{i \in \downarrow j} \overline{\mathcal{R}}_i^j \subseteq \mathcal{R}_j \subseteq \bigoplus_{i \in \downarrow j} \widetilde{\mathcal{R}}_i^j. \tag{6}$$

Next we define subspaces $\overline{\mathcal{R}}$ and $\widetilde{\mathcal{R}}$ which respect the structure imposed by the poset $\mathcal{P}$:

$$\begin{aligned} \overline{\mathcal{R}} &:= \bigoplus_{j \in P} \overline{\mathcal{R}}_j \quad \text{and} \quad \widetilde{\mathcal{R}} := \bigoplus_{j \in P} \widetilde{\mathcal{R}}_j, \quad \text{where} \\ \overline{\mathcal{R}}_j &:= \sum_{i \in \uparrow j} \overline{\mathcal{R}}_j^i \quad \text{and} \quad \widetilde{\mathcal{R}}_j := \sum_{i \in \uparrow j} \widetilde{\mathcal{R}}_j^i. \end{aligned} \tag{7}$$

Definition 11. We call a poset-causal system $\Sigma_{\mathcal{P}}$ *upstream controllable* if $\overline{\mathcal{R}}_j = \mathcal{X}_j$ for each $j \in P$ and we say $\Sigma_{\mathcal{P}}$ is *weakly upstream controllable* if $\widetilde{R}_j = \mathcal{X}_j$ for each $j \in P$.

The following result explains the connection with classical controllability.

Theorem 12. For a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ we have the following inclusions

$$\overline{\mathcal{R}} \subseteq \mathcal{R} \subseteq \widetilde{R}.$$

In particular, if $\Sigma_{\mathcal{P}}$ is upstream controllable, then it is controllable. If $\Sigma_{\mathcal{P}}$ is controllable, then it is weakly upstream controllable.

Example 13. Consider the poset-causal system $\Sigma_{\mathcal{P}_1} \sim (A, B, C, 0)$ given in example 9. We can calculate its reachable set $\mathcal{R}$ using (4) and its downstream reachable sets $\mathcal{R}_i$ for $i = 1, 2, 3$ using (5):

$$\begin{aligned} \mathcal{R} &= \text{span}\{e_1 + e_3, e_2, e_4\}, \quad \mathcal{R}_1 = \text{span}\{e_1 + e_3, e_2\} \\ \mathcal{R}_2 &= \text{span}\{e_2\} \quad \text{and} \quad \mathcal{R}_3 = \text{span}\{e_4\} \end{aligned}$$

We can now compute the spaces $\overline{\mathcal{R}}$ and $\widetilde{R}$ using (7):

$$\overline{\mathcal{R}} = \text{span}\{e_2, e_4\} \quad \text{and} \quad \widetilde{R} = \text{span}\{e_1, e_2, e_3, e_4\}.$$

From this we see that $\Sigma_{\mathcal{P}_1}$ is not upstream controllable nor is it controllable, but it is indeed weakly upstream controllable.

Next we define several parallel notions of observability for poset-causal systems.

For $i, j \in P$, define the subspaces

$$\mathcal{X}(\uparrow i) := \bigoplus_{j \in \uparrow i} \mathcal{X}_j \qquad \text{and} \qquad \mathcal{X}(P \backslash \uparrow i) := \bigoplus_{j \notin \uparrow i} \mathcal{X}_j.$$

Then clearly $\mathcal{X}(\uparrow i) \dotplus \mathcal{X}(P \backslash \uparrow i) = \mathcal{X}(P) = \mathcal{X}$. For $i \in P$, we define the i-upstream unobservable set $\mathcal{N}_i$ as

$$\mathcal{N}_i = \ker \mathcal{O}(C(i, \uparrow i), A(\uparrow i, \uparrow i)) \subseteq \mathcal{X}(\uparrow i).$$

Hence, a vector $\xi \in \mathcal{X}(\uparrow i)$ is in $\mathcal{N}_i$ if it is unobservable in the system

$$\begin{aligned} \dot{x}^{\uparrow i}(t) &= A(\uparrow i, \uparrow i)x^{\uparrow i}(t), \qquad x^{\uparrow i}(0) = \xi \\ y^{\uparrow i}(t) &= C(i, \uparrow i)x^{\uparrow i}(t). \end{aligned}$$

In such a case we say that ξ is i-upstream *unobservable*.

The following theorem generalizes Lemma 4.2 in Kemper et al. (2012) to poset-causal systems.

Theorem 14. Given a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, 0, C, 0)$ with $A \in \mathcal{I}_{\mathcal{P}}^{n\times n}$ and $C \in \mathcal{I}_{\mathcal{P}}^{r\times n}$, the unobservable space $\mathcal{N}$ is given in terms of i-upstream unobservable spaces as:

$$\mathcal{N} = \bigcap_{i=1}^{p} \left(\mathcal{N}_i \oplus \mathcal{X}(P\backslash\uparrow i)\right).$$

Recall that $\mathcal{N}_i \subseteq \mathcal{X}_{\uparrow i}$ and that $\mathcal{X}_j \subseteq \mathcal{X}_{\uparrow i}$ if $j \in \uparrow i$. For each $j \in \uparrow i$, we define

$$\overline{\mathcal{N}}_i^j := \mathcal{N}_i \cap \mathcal{X}_j \quad \text{and} \quad \widetilde{\mathcal{N}}_i^j := P_{\mathcal{X}_j}\mathcal{N}_i.$$

From these definitions, we immediately get the following inclusions:

$$\bigoplus_{j\in\uparrow i} \overline{\mathcal{N}}_i^j \subseteq \mathcal{N}_i \subseteq \bigoplus_{j\in\uparrow i} \widetilde{\mathcal{N}}_i^j, \tag{8}$$

In analogy with (7) we define the following structured subspaces of $\mathcal{X}$:

$$\begin{aligned} \overline{\mathcal{N}} &:= \bigoplus_{j\in P} \overline{\mathcal{N}}^j \quad \text{and} \quad \widetilde{\mathcal{N}} := \bigoplus_{j\in P} \widetilde{\mathcal{N}}^j, \quad \text{where} \\ \overline{\mathcal{N}}^j &:= \bigcap_{i\in\downarrow j} \overline{\mathcal{N}}_i^j \quad \text{and} \quad \widetilde{\mathcal{N}}^j := \bigcap_{i\in\downarrow j} \widetilde{\mathcal{N}}_i^j. \end{aligned} \tag{9}$$

Based on these spaces, we introduce the following notions of observability.

Definition 15. We call a poset-causal system $\Sigma_{\mathcal{P}}$ *downstream observable* if $\widetilde{\mathcal{N}} = \{0\}$ and *weakly downstream observable* if $\overline{\mathcal{N}} = \{0\}$.

In analogy with Theorem 12, we obtain the next theorem.

Theorem 16. For a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ we have the following inclusions

$$\overline{\mathcal{N}} \subseteq \mathcal{N} \subseteq \widetilde{\mathcal{N}}.$$

In particular, if $\Sigma_{\mathcal{P}}$ is downstream observable, then it is observable. If $\Sigma_{\mathcal{P}}$ is observable, then it is weakly downstream observable.

4. DUALITY

For classical centralized systems, duality between controllability and observability is given by the following well known result (see for example proposition 2.21 in Dullerud et al. (2013)).

Theorem 17. The pair (A, B) is controllable if and only if the pair $(B^\intercal, A^\intercal)$ is observable.

We now investigate a connection between controllability of a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ and observability of its dual system $\Sigma_{\mathcal{P}_d} \sim (A_d, B_d, C_d, D_d)$. We note that since $\uparrow_d i = \downarrow i$ for each $i \in P$, we have by definition that

$$C_d(i, \uparrow_d i) = B^\intercal(i, \downarrow i) = (B(\downarrow i, i))^\intercal.$$

From this, we can show that

$$\mathcal{X}_{\uparrow i} \ominus (\mathcal{R}_i)^d = \mathcal{N}_i \quad \text{and} \quad \mathcal{X}_{\downarrow i} \ominus (\mathcal{N}_i)^d = \mathcal{R}_i$$

for each $i \in P$, where $(\mathcal{R}_i)^d = \operatorname{Im} \mathcal{C}(A^d, B^d)$ and $(\mathcal{N}^i)^d = \ker \mathcal{O}(C^d, A^d)$. It is then possible to prove the next result.

Theorem 18. For a poset-causal system $\Sigma_{\mathcal{P}} \sim (A, B, C, D)$ and its dual $\Sigma_{\mathcal{P}_d} \sim (A^d, B^d, C^d, D^d)$, we have

$$(\overline{\mathcal{R}})^d = \widetilde{\mathcal{N}}^\perp, \quad (\widetilde{\mathcal{R}})^d = \overline{\mathcal{N}}^\perp, \quad (\overline{\mathcal{N}})^d = \widetilde{\mathcal{R}}^\perp, \quad (\widetilde{\mathcal{N}})^d = \overline{\mathcal{R}}^\perp.$$

In particular, $\Sigma_{\mathcal{P}}$ is upstream controllable (weakly upstream controllable) if and only if $\Sigma_{\mathcal{P}_d}$ is downstream observable (weakly downstream observable).

Example 19. For the dual system $\Sigma_{\mathcal{P}_d}$ given in example 9, we can now easily determine the subspaces $(\overline{\mathcal{N}})^d$, $\mathcal{N}^d$ and $(\widetilde{\mathcal{N}})^d$ using the duality result Theorem 18 and the subspace determined in example 13:

$$(\overline{\mathcal{N}})^d = \widetilde{\mathcal{R}}^\perp = \{0\},\ \mathcal{N}^d = \mathcal{R}^\perp = \operatorname{span}\{e_1 - e_3\} \quad \text{and}$$
$$(\widetilde{\mathcal{N}})^d = \overline{\mathcal{R}}^\perp = \operatorname{span}\{e_1, e_3\}$$

Hence in accordance with Theorem 18, we see that $\Sigma_{\mathcal{P}_d}$ is weakly downstream observable, but not observable or downstream observable.

The differences between port-Hamiltonian, passive and positive real descriptor systems

Karim Cherifi * **Hannes Gernandt** * **Dorothea Hinsen** *

Abstract: For linear time-invariant descriptor systems it is well known that port-Hamiltonian systems are passive and that passive systems are positive real. In our contribution we study under which assumptions also the converse implications hold. We also study the relationship between passivity, KYP inequalities and a finite required supply.

Keywords: Linear systems, Descriptor systems, Passivity, Dissipativity, Port-Hamiltonian systems, KYP inequality, Positive real.

1. INTRODUCTION

Port-Hamiltonian (pH) systems have been increasingly used in recent years as a unified structured framework for energy based modeling of systems (van der Schaft and Jeltsema (2014); Jacob and Zwart (2012); Ortega et al. (2001); van der Schaft (2004); Beattie et al. (2019); Mehrmann and Unger (2022)). This type of formulation has gained increased interest from engineers and mathematicians due to its modeling flexibility and robustness properties.

Specifically, pH systems are of particular interest in coupled networks of systems and multiphysics simulation and control. This network coupling oftentimes imposes additional algebraic constraints on the system which naturally lead to *linear time-invariant descriptor systems* in state-space form presented as

$$\begin{aligned} \tfrac{d}{dt}Ex(t) &= Ax(t) + Bu(t), \quad x(0) = x_0, \\ y(t) &= Cx(t) + Du(t), \end{aligned} \tag{1}$$

where $u : \mathbb{R} \to \mathbb{K}^m$, $x : \mathbb{R} \to \mathbb{K}^n$, $y : \mathbb{R} \to \mathbb{K}^m$ are the *input*, *state*, and *output* of the system and $E, A \in \mathbb{K}^{n\times n}, B \in \mathbb{K}^{n\times m}$, $C \in \mathbb{K}^{m\times n}$, $D \in \mathbb{K}^{m\times m}$, and $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$. The system (1) will be briefly denoted by $\Sigma = (E, A, B, C, D)$ and throughout it is assumed that the pair (E, A) is *regular* which means that $\lambda E - A$ is invertible for some $\lambda \in \mathbb{C}$.

It is well-known that pH descriptor systems are passive and that passive systems are positive real. Our aim is to provide sufficient conditions for the converse implications to hold.

2. NOTATIONS AND KNOWN RESULTS

For a pH descriptor systems the coefficients in (1) are assumed to have a special structure, see e.g. Beattie et al. (2018); van der Schaft (2013); van der Schaft and Maschke (2018); Morandin and Mehrmann (2019)

(pH) The system Σ is *port-Hamiltonian* if there exists $J, R, Q \in \mathbb{K}^{n\times n}$, $G, P \in \mathbb{K}^{n\times m}$, and $S, N \in \mathbb{K}^{m\times m}$ such that

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} (J-R)Q & G-P \\ (G+P)^H Q & S+N \end{bmatrix}, \quad E^H Q \geq 0, \\ \begin{bmatrix} R & P \\ P^H & S \end{bmatrix} \geq 0, \quad J = -J^H, N = -N^H. \tag{2}$$

Here the quadratic function $\mathcal{H}(x) := \frac{1}{2}x^H E^H Q x$ is called the *Hamiltonian* and can be interpreted as the energy of the system. Furthermore, for a matrix $M \in \mathbb{K}^{n\times m}$, M^H denotes its conjugate transpose.

In this contribution, we will compare for descriptor systems the existence of a pH formulation with two other typically used system theoretic properties, namely, *passivity* (Pa) and *positive realness* (PR) which are introduced below.

It is well known that even non-linear and time-varying pH descriptor systems satisfy a certain power balance equation, see Morandin and Mehrmann (2019). This in particular implies the following *passivity* property of pH descriptor systems.

(Pa) The system Σ is *passive* if there exists $Q \in \mathbb{K}^{n\times n}$ such that $Q^H E = E^H Q \geq 0$ and $\mathcal{S}(x) = \frac{1}{2}x^H Q^H E x$ satisfies for all $T > 0$ and all consistent initial values x_0 and smooth functions x, u, y

$$\mathcal{S}(x(T)) - \mathcal{S}(x(0)) \leq \int_0^T y(\tau)^H u(\tau) d\tau. \tag{3}$$

The functions $\mathcal{S}$ satisfying the above conditions will be called *storage functions*.

The property (Pa) is hard to verify in practice since one would have to consider all possible solution trajectories. A better suited algebraic criterion for (Pa) is a linear matrix inequality which can be obtained by differentiation of (3). It was developed for ordinary systems, i.e. $E = I_n$ and independently by Kalman, Yakubovich and Popov and for descriptor systems e.g. in Zhang et al. (2002); Freund and Jarre (2004).

(KYP) The system Σ has a solution Q to the *generalized KYP inequality* if

$$\begin{bmatrix} -A^HQ - Q^HA & C^H - Q^HB \\ C - B^HQ & D + D^H \end{bmatrix} \geq 0, \quad E^HQ \geq 0. \quad (4)$$

In many applications only input-output data is given and hence an important question is whether we can decide if a system is pH from this data and even more, we want to obtain a pH representation (2) of the system. The typical approach is to use apply a Laplace transform to (1) which leads to the *transfer function*

$$\mathcal{T}(s) := C(sE - A)^{-1}B + D \quad (5)$$

that describes the input-output behavior in the frequency domain. It is well known for ordinary system that the passivity implies that its transfer function is *positive real*, see Anderson (1967); Anderson and Vongpanitlerd (1973).

(PR) The system Σ and the transfer function $\mathcal{T}$ are called *positive real* if $\mathcal{T}$ has no poles in $\mathbb{C}^+ := \{s \in \mathbb{C} | \text{Re } s > 0\}$ and $\mathcal{T}(s) + \mathcal{T}(s)^H \geq 0$ for all $s \in \mathbb{C}^+$;

Hence, if we want to obtain a pH formulation of a system, the system must be passive implying that its transfer function is positive real. If the data does not allow us to conclude (PR), e.g. due to measurement errors, one determines the nearest positive real transfer function Gillis and Sharma (2018). Therefore, the remaining task is to find a pH state space representation (2) of this positive real transfer function, i.e. one has to reconstruct the coefficients.

In the case of ODE systems which are controllable and observable, i.e. *minimal*, it is well known that (pH), (Pa), (PR) are equivalent. Hence our focus lies on the non-minimal case. For non-minimal ODE systems, a detailed study has been conducted in (Brogliato et al., 2007, Chapter 3) but without including pH systems. Another recent survey was given in Hughes and Branford (2021) see p. 59 therein for a discussion on unobservable and uncontrollable systems. The main goal is to study which implications between the aforementioned properties hold for descriptor systems, and to carve out for which implications the controllability and observability assumptions are crucial.

3. MAIN CONTRIBUTION

For descriptor systems the relations between (pH),(Pa), (KYP) and (PR) were already studied in numerous works Zhang et al. (2002); Freund and Jarre (2004); Masubuchi (2006); Camlibel and Frasca (2009); Reis and Stykel (2010); Reis et al. (2015); Reis and Voigt (2015). However to the best of our knowledge not all four properties have been investigated at the same time and oftentimes the minimality of the descriptor system is assumed.

As a first step, those of the aforementioned results which do not require minimality to obtain

$$\text{(pH)} \implies \text{(KYP)} \implies \text{(Pa)} \implies \text{(PR)}.$$

The following examples show that without further assumptions the converse implications are not true.

(i) The system $\dot{x} = -x + u, \quad y = 0$ has a solution to the KYP inequalities (4), but it is not pH.
(ii) The descriptor system $x = 0$, $y = x$ is passive but there is no solution to the KYP.
(iii) The system
$$\dot{x} = x, \quad y = x + u$$
is positive real but it is not passive.

Hence the remaining questions which we will answer in the talk are

(Q1) When do solutions to the KYP inequality lead to a pH formulation?
(Q2) When does passivity leads to solutions of the KYP inequality?
(Q3) Can every positive real transfer function be realized as a pH system?

The counter example (i) indicates that answer to question (Q1) is related to observability properties of the system. It was shown already for ODE systems in (van der Schaft, 2009, p. 55) that only those solutions Q to the KYP which satisfy

$$\ker Q \subseteq \ker A \cap \ker C \quad (6)$$

lead to a pH formulation. Conversely, the Q used in (pH) automatically satisfies (6).

We show that the same condition is true for descriptor systems. If the system is behaviorally observable then $\ker A \cap \ker C = \{0\}$ and hence the existence of a pH formulation is equivalent to the existence of invertible solutions to the KYP inequality.

The question (Q2) was already studied in Reis et al. (2015); Camlibel and Frasca (2009) where it was shown that passivity only guarantees the KYP inequality to hold on certain subspaces and as a consequence, we can only derive a pH formulation on a subspace. As a contribution, we derive for descriptor systems with index one a modified KYP inequality which can be solved for passive descriptor systems. If the system is in addition behaviorally observable then we derive a pH formulation of the system.

Regarding (Q3) we can explicitly construct a minimal realization as a pH system based on the well-known representation of positive real functions

$$\mathcal{T}(s) = M_1 s + \mathcal{T}_p(s)$$

for some $M_1 \geq 0$ and a proper positive real rational function $\mathcal{T}_p(s)$.

Abstract: In this study, we develop a quantitative strategy for controlling cash-flow fluctuations of power utilities in electricity trading market using adequate financial instruments. In particular, we focus on hedging of thermal power generations and provide mixed positions of derivatives and forwards in a flexible manner, where we apply nonparametric regression techniques to find optimal payoff structure of derivatives and/or optimal units of forward contracts with fine granularity. An empirical backtest is conducted to illustrate our proposed hedging strategy.

Keywords: Forward contracts, derivatives, thermal power generators, hedging, nonparametric regressions.

1. INTRODUCTION

In the liberalized electricity market as illustrated in Figure 1, electricity retailing companies purchase spot electricity through the central power exchange and deliver it to their consumers, in which their volume for procurement needs to match future demand with uncertainty. On the other side of the market, power generation companies place sales orders and produce electricity based on the executed volume. In addition, due to the rapid increase of renewable power generation, the generators' supply volume depends on renewable energy sources (such as solar power) affected by weather conditions. In this situation, both electricity price and volume fluctuate in time, resulting in the risk of loss caused by high volatility of future cashflow. The objective of this study is to construct a quantitative strategy for reducing the cash-flow volatility in the electricity trading market based on financial instruments known as derivatives/forwards.

Derivatives/forwards are financial contracts whose payoffs depend on the values of underlying indexes at a future period and can be used as insurance purpose in electricity markets. For example, a power utility company (a power generator or a retailer) may be suffered from the loss caused by extremely high (or low) electricity price in the electricity market, but such risk can be avoided by purchasing an electricity derivative that compensates unexpected price difference. Also, weather or electricity derivatives can be used for the loss of volume changes resulting from unexpected weather condition (Bhattacharya et al. (2020), Oum et al. (2006), Matsumoto and Yamada (2021a), Coulon et al. (2013)).

In this study, we assume that such derivatives are offered by an insurance company and are constructed in flexible manner. In other words, we apply nonparametric regression techniques to find optimal payoff structure of derivatives and/or optimal units of forward contracts with fine granularity. Note that this work follows the results provided in our recent work of Yamada and Matsumoto (2021), but differs in the following aspects: Mixed positions of derivatives and forwards are constructed based on the balance between standard and specific products and the trading strategy is provided; Most recent data periods are covered to reflect the effect of COVID-19 pandemic and extreme price movement happened in January 2021 in Japan; Thermal power generations are particularly focused, where the thermal power generators' volume may approximately be given by demand minus renewable energy power generations, being largely influenced by solar radiations and other weather conditions.

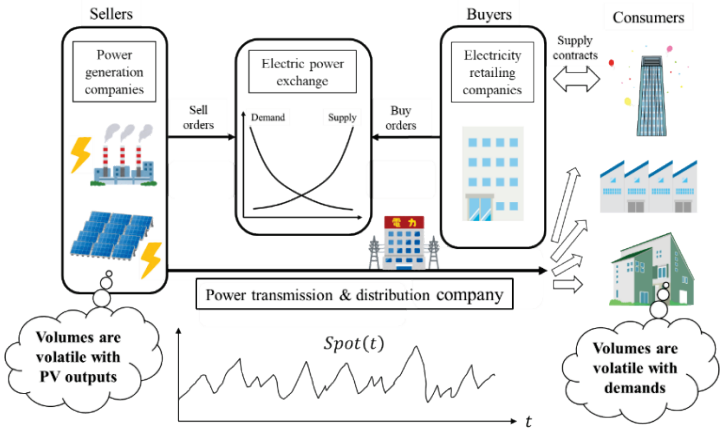

Figure 1. Electricity trading market.

2. PROBLEM SETTING

We introduce the notation and data used in our analysis as follows, where the data was observed in the Tokyo area, Japan from April 1st, 2016, (when the Japanese electricity market was fully liberalized) to December 31st, 2021:

$S_{t,m}$ [Yen/kWh]: JEPX spot price on day t delivering 1 kWh of electricity between hours m and $m+1$ (http://www.jepx.org/market/index.html).

$V_{t,m}$ [kWh]: Power generation of thermal generators between hours m and $m+1$ on day t. (https://www.tepco.co.jp/forecast/html/area_data-j.html)

$T_{t,m}$ [° C] : Temperature index in constructed using the electricity consumption-based weighted average of nine observation points in Tokyo area at hour m on day t. (https://www.data.jma.go.jp/gmd/risk/obsdl/)

$R_{t,m}$ [MJ/m^2]: Solar radiation index constructed using an installed capacity of local photovoltaics (PV) weighted average of seven observation points in Tokyo area between hours m and $m+1$ on day t. (https://www.data.jma.go.jp/gmd/risk/obsdl/)

Assume that there is a supply aggregator that compiles all the generation stacks from thermal generators and that the supply generator is willing to mitigate the fluctuations of total cash-flows for power generation at each period defined by $V_{t,m}S_{t,m}$. One measure of cash-flow variation is its variance, $\mathrm{Var}[V_{t,m}S_{t,m}]$, and in this study, we consider the problem of minimizing the cash-flow variance using forwards and derivatives. Such a strategy may be referred to as minimum variance hedging and has been investigated in energy markets (see e.g., Halkos and Tsirivis (2019) and references therein).

At the heart of hedging is to replicate the target cash-flow using another cash-flow defined by payoff of a portfolio of forward/derivative contracts. In this work, we construct a mixed position of forward and derivative contracts on weather and electricity indexes for thermal generators (or the supply aggregator). To the end, we apply the following generalized additive model (GAM; Hastie and Tibshirani (1990), Wood (2017)) for each $m \in \{0, \dots, 23\}$:

$$V_{t,m}S_{t,m} = \delta_m(t)S_{t,m} + \gamma_m(t)T_{t,m} + h_m(R_{t,m}) + Calendar_m(t) + \epsilon_{t,m} \quad (1)$$

where δ_m and γ_m are yearly cyclical spline functions that modelled with by-variables, $S_{t,m}$ and $T_{t,m}$ (see Wood (2017)), h_m is a smoothing spline function and $\epsilon_{t,m}$ is a residual satisfying zero mean condition, $\overline{\epsilon_{t,m}} = 0$. Note that radiation derivatives (term $h_m(R_{t,m})$) are applied daytime only for $m \in \{8, \dots, 15\}$ and assume that $h_m \equiv 0$ for $m \notin \{8, \dots, 15\}$.

In (1), $Calendar_m(t)$ contains day of week, long-term, and seasonal trends as

$$Calendar_m(t) = \beta_1 Mon_t + \cdots + \beta_6 Sat_t + \beta_7 Holidays_t + Seasonal(t) + Longterm(t) + c \quad (2)$$

where $Mon_t, \dots, Sat_t$, and $Holidays_t$ denote day-of-week and holiday dummy variables that take $Mon_t = 1$ if the day of t is Monday or $Mon_t = 0$ otherwise, and so on. $Seasonal(t)$ denotes a yearly cyclical smoothing spline function and reflects the seasonal trend in $V_{t,m}S_{t,m}$, whereas $Longterm(t)$ is a smoothing spline function (e.g., a cubic spline function) of the day variable t. In GAM (1), all the spline functions and coefficients are estimated to minimize the so-called penalized residual sum of squares (PRSS) which corresponding to minimizing the sample variance of $\epsilon_{t,m}$ with smoothing conditions (Matsumoto and Yamada (2021a), Yamada and Matsumoto (2021)), in which the estimated coefficients and spline functions differ by hour m, but we omit specifying this dependence for brevity.

Note that $V_{t,m}S_{t,m}$ defines the cash-inflow for power generators whereas $\delta_m(t)S_{t,m} + \gamma_m(t)T_{t,m} + h_m(R_{t,m}) + Calendar_m(t)$ in (1) the cash-outflow when constructing the hedge position. In this case, the hedge portfolio may be constructed by taking short positions of electricity and temperature forwards for $\delta_m(t)$ and $\gamma_m(t)$ units, radiation derivatives with payoff function $h_m(R_{t,m})$, zero coupon bonds with face value $Calendar_m(t)$. Then, solving GAM (1) yields minimum variance hedging with forwards and derivatives and $\epsilon_{t,m}$ gives a hedge error.

3. EMPIRICAL BACKTESTS

In this section, we apply our proposed minimum variance hedging for power generators (or equivalently, the supply aggregator), in which we estimate optimal spline functions and other required parameters in (1) based on the in-sample data to evaluate its out-of-sample performance using the out-of-sample data. The data periods are given as follows:

In-sample: April 1st, 2016, to December 31st, 2020.
Out-of-sample: January 1st to December 31st, 2021.

In this study, GAMs were estimated using R 4.0.5 (https://www.R-project.org/) and the package mgcv (Wood (2021)) to obtain the series of smoothing spline functions, wherein the smoothing parameter is calculated by the generalized cross-validation criterion. All figures are plotted using MATLAB 2021a (MathWorks, Inc., Natick, MA, USA).

We have estimated smooth functions and coefficients of GAM (1) using the data of in-sample-period, and executed out-of-sample simulations by substituting the data observed in the out-of-sample period into the regression equation to compute predicted values of GAM (1). Such predicted values do not necessarily provide forecast values obtained in the past period because they contain explanatory variables to be measured at the same time as the target value is observed. However, plotting the predicted values of GAM together with the realized values of $V_{t,m}S_{t,m}$ may help us intuitively grasp how the hedge is performed in the out-of-sample period. The blue and red lines in Figure 2 denote the realized and predicted values of $V_{t,m}S_{t,m}$ for $m = 13$ (1-2 pm) in the out-of-sample period, although they seem to be almost overlapped in these plots. Note that, around 1-2 pm, the electricity demand tended to take its maximum in a day, whereas the electricity price was not the highest due to the effect of solar power generation. In the current electricity market, the 30 minutes electricity price tends to take its highest value early evening. This is because the electricity demand still remains high, but the solar power generation almost disappears around that time. In fact, the spot electricity price recorded extremely high values around 4-9pm in the middle of January 2021 (which were about 25 times higher than monthly average price of January 2020). Such an extreme movement was observed in Figure 2 in that period.

As mentioned earlier in this section, although the predicted values given by regression equation in the right-hand side of (1) are not forecast values determined in the in-sample period,

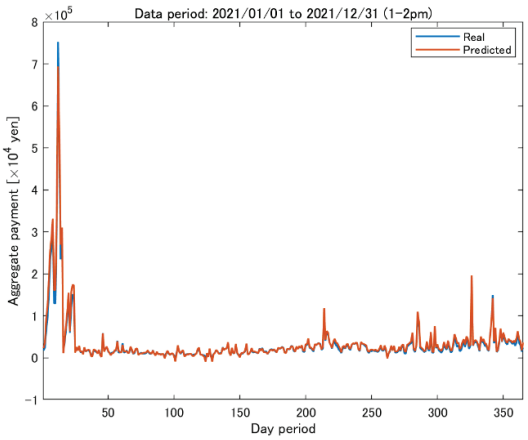

Figure 2. Realized vs. Predicted values of $V_{t,m}S_{t,m}$ in the out-of-sample period when $m = 14$ (1-2pm).

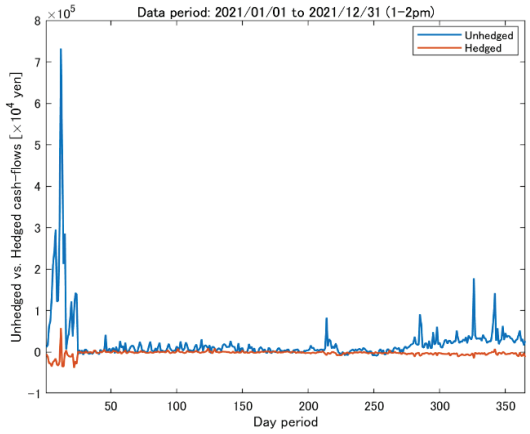

Figure 3. Unhedged vs. Hedged cash-flows in the out-of-sample period when (1-2pm).

the gap of two lines in Figure 2 provides hedge errors between $V_{t,m}S_{t,m}$ and the value of hedge portfolio consisting of forwards, derivatives, and bonds. To understand the effects of forwards and derivatives against the cash-flow fluctuation without these products, we consider a reference model using calendar trend only using GAM as

$$V_{t,m}S_{t,m} = Calendar_m(t) + \epsilon_{t,m}^{ref} \qquad (3)$$

where $\epsilon_{t,m}^{ref}$ is a residual satisfying zero mean condition, $\overline{\epsilon_{t,m}^{ref}} = 0$. In (3), $Calendar_m(t)$ may be thought of the face value of zero-coupon bond maturing on day t corresponding to the payment of debt from the income $V_{t,m}S_{t,m}$ for power generators. If the gap between $V_{t,m}S_{t,m}$ and $Calendar_m(t)$ is large, they may suffer from finding another source of financing. This is the idea to introduce financial instruments where the cash-flow fluctuations defined the residual terms are minimized using forwards and derivatives based on GAMs.

The blue and the red lines in Figure 3 compare unhedged vs. hedged cash-flows in the out-of-sample period for $m = 13$ (1-2pm). These lines were obtained by substituting the observed variables in (1) and (3) and plotting the residuals $\epsilon_{t,m}$ and $\epsilon_{t,m}^{ref}$ in the out-of-sample period for the hedged (red line) and the unhedged (blue line) cash-flows, respectively. Compared to the unhedged cash-flows, we see that the fluctuations of hedged cash-flows are significantly reduced by combining derivatives and forwards in these out-of-sample simulations.

3.3 Performance evaluation

We investigate the accuracy of the hedge in terms of the following Variance Reduction Rates (VRRs) and Normalized Mean Absolute Errors (NMAEs) for out-of-sample data:

$$VRR := \frac{\mathrm{Var}\left[\epsilon_{t,m}^{out}\right]}{\mathrm{Var}\left[\epsilon_{t,m}^{ref}\right]}, \qquad NMAE := \frac{\overline{\left|\epsilon_{t,m}^{out}\right|}}{\overline{\left|\epsilon_{t,m}^{ref}\right|}} \qquad (4)$$

where $\epsilon_{t,m}^{out}$ and $\epsilon_{t,m}^{ref}$ denote hedge errors corresponding to the residual of GAMs (1) and (3) with out-of-sample data. In (4), VRR and NMAE are defined by the ratios for improvement by applying derivatives and forwards compared to unhedged errors in the out-of-sample case. The bottom blue lines in Figures 4 and 5 provide VRRs and NMAEs for different values of $m = 0,1,\dots,23$ using hedged cash-flows with electricity and temperature forwards and radiation derivatives, i.e., the out-of-sample hedge errors for GAM (1). The red lines are the ones with electricity and temperature forwards and the yellow with electricity forwards only. Note that the radiation derivatives were applied for $m = 8,\dots,15$ (8am-4pm), the blue and the red lines take the same values outside this range. From these figures, we see that the introduction of temperature forwards reduced the cash-flow fluctuation early morning and daytime significantly, whereas the improvement in the evening was not observed almost at all. On the other hand, the introduction of radiation derivatives always improves the hedge performance.

4. CONCLUSION

In this paper, we have considered hedging of thermal power generators and provided mixed positions of forwards and derivatives on electricity price and weather indexes. The key findings of our analysis are summarized below.

1. Although unhedged cash-flows for power generators were unstable and had extreme price and volume fluctuations, they were shown to be stabilized by using financial instruments of our study. The fluctuations of hedged cash-flows were significantly improved by combining derivatives and forwards even in the out-of-sample simulations.

2. In contrast with power retailers' volume, the thermal generators' volume does not only depend on consumers' demand but also on the renewable power generation and others. The larger the amount of solar radiation, the lower the electricity price and the volume for thermal power generators (when demand is fixed). Our analysis showed that the radiation derivative is effective to reduce the cash-flow fluctuation resulting from uncertainty in solar power generation.

3. The cyclic trends in the units of electricity and the temperature forwards possessed in the hedge portfolio were modelled by combining cyclic splines with by-variables in GAMs and were shown to provide significant

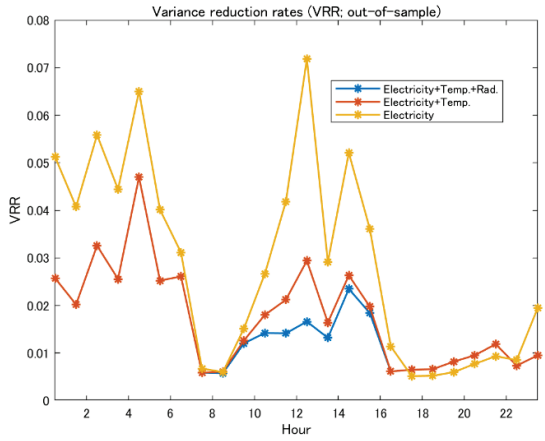

Figure 4. VRRs in the out-of-sample period.

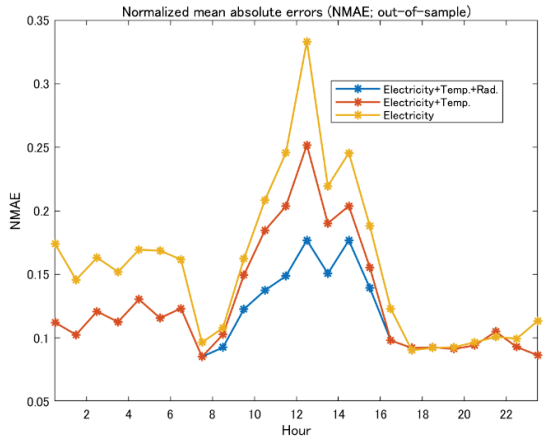

Figure 5. Normalized MAEs in the out-of-sample period.

hedge effects in terms of out-of-sample VRRs and NMAEs. Since electricity and temperature forwards are considered standardized products, showing their effectiveness is particularly important.

Compared to other electricity utility businesses, there is a variety of risks for thermal generators other than wholesale electricity price-volume fluctuations and the uncertainty of solar power generation. For example, volatility of fossil fuel energy prices is extremely high and the energy prices including oil and natural gas have increased currently (see e.g., https://www.eia.gov/, accessed on February 14th, 2022). Also, further investments in thermal power plants are becoming more difficult due to the regulations for controlling global warming gas emissions and many countries have been promoting a renewable energy policy. However, it is still fair to say that majority of electricity power generation depend on fossil fuel thermal power, and we need to consider risk management techniques for power generators from a cash-flow management perspective as well. In this sense, it is important to develop financial instruments and related strategy for reducing financial risk for power generators, which may lead to a smoother transition to renewable power as a core supply technology.

In practice, the interpretability of results is often important as well as accuracy, and we have taken a statistical approach based on GAM in this study, rather than other machine learning techniques. In this context, we have discussed the effectiveness of GAM for PV forecast in Matsumoto and Yamada (2021b), in comparison with four machine learning techniques and shown that the GAM-based PV forecast model flexibly express the tangled trend structure inherent in time series data and has an advantage not only in interpretability but also in improving forecast accuracy. A further investigation including a comparison of hedging models based on other machine learning techniques is interesting for future study.

Abstract: We present a novel targeted exploration strategy for the application of robust dual control. Unlike common greedy random exploration strategies considered in the related dual control literature, we introduce a targeted strategy in which the exploration inputs are a linear combination of sinusoids whose amplitudes are optimized based on an exploration criterion. Specifically, we leverage recent results on persistence of excitation using spectral lines to show how a (high probability) lower bound on the resultant persistence of excitation of the exploration data can be established. These results can be used to provide a priori lower bounds on the remaining model uncertainty after exploration. Given this exploration strategy and the corresponding uncertainty bounds, tools from robust control and gain-scheduling can be used to design a robust dual controller.

Keywords: Identification for control, Learning for control, Dual control

1. INTRODUCTION

Control inputs to an uncertain system should have a 'directing effect' to control the dynamical system and achieve a certain goal. Furthermore, the inputs should also have a 'probing' effect to learn the uncertainty in the system. In close association with these effects, simultaneous learning and control of uncertain dynamic systems has garnered research interest with the establishment of the *dual control* paradigm (Feldbaum, 1960). A detailed survey of dual control methods are provided by Filatov and Unbehauen (2000), and Mesbah (2018).

An approach to the dual control problem is to sequentially apply some probing input or exploration, and then a stabilizing controller informed by the gathered data. Recent methods by Umenberger et al. (2019), Barenthin and Hjalmarsson (2008), Ferizbegovic et al. (2019), and Iannelli et al. (2020) focus on *targeted* exploration and perform better than methods that use common greedy exploration. In particular, these methods consider that exploration should be targeted in the sense that the resulting uncertainty reduction in the model facilitates achieving a control goal and performance objective. The work of Umenberger et al. (2019) introduces a targeted exploration strategy that excites the system to reduce uncertainty specifically in a way that it minimizes the worst-case cost. This approach relies on a high probability uncertainty bound on system parameters which can be approximately predicted and thus optimized depending on the exploration input. Developing on the works of Barenthin and Hjalmarsson (2008), and Umenberger et al. (2019), a dual control strategy is proposed by Ferizbegovic et al. (2019) that minimizes the worst-case cost achieved by a robust controller that is synthesized with reduced model uncertainty. The approach by Iannelli et al. (2020) extends the exploration strategy by Umenberger et al. (2019) to a more realistic finite horizon problem setting that captures the trade-offs between exploration and exploitation better.

The exploration methods proposed by Venkatasubramanian et al. (2020), Barenthin and Hjalmarsson (2008), Umenberger et al. (2019), Ferizbegovic et al. (2019), and Iannelli et al. (2020), rely on state-feedback and an additional optimized Gaussian noise term for exploration. To tractably compute the predicted uncertainty bound associated with the parameter estimates after exploration, the empirical covariance is approximated by the worst-case state covariance. These approximations fail to provide a priori guarantees of excitation on the exploration inputs. Hence, we propose harmonic exploration inputs in the form of a linear combination of sinusoids of specific frequencies and reduce uncertainty in a targeted fashion with the goal of guaranteed control performance. This choice is also supported in literature, where it was established that the robust optimal control input can be expressed with appropriately chosen amplitudes and frequencies of the sinusoids (Rojas et al., 2007). Additionally, by suitably

influencing the spectral content of inputs, these inputs provide the advantage of guaranteed persistence of excitation (Sarker et al., 2020). The spectral information of the exploration inputs can be used to determine a lower uncertainty bound on the persistence of excitation of the exploration data, which can in turn be used to design a robust controller that provides some desired performance guarantees. Regarding the application of targeted exploration in dual control, our exploration strategy can be employed in our recently proposed gain-scheduling based dual control approach (Venkatasubramanian et al., 2020). The gain scheduling based approach gives rise to a linear matrix inequality (LMI) based design with closed-loop performance guarantees.

2. PROBLEM FORMULATION

Notation The transpose of a matrix $A \in \mathbb{R}^{n\times m}$ is denoted by $A^\top$. The positive definiteness of a matrix $A \in \mathbb{R}^{n\times n}$ is denoted by $A = A^\top \succ 0$. The conjugate transpose of a matrix $A \in \mathbb{C}^{n\times m}$ with complex entries is denoted by A^{H}. The operator $\mathrm{vec}(A)$ stacks the columns of A to form a vector. The operator $\mathrm{diag}(A_1, ..., A_n)$ creates a block diagonal matrix by aligning the input matrices $A_1, ..., A_n$ along the diagonal starting with A_1 in the upper left corner. The critical value of the Chi-squared distribution with n degrees of freedom and probability p is denoted by $\chi^2_n(p)$. The space of square-summable sequences is denoted by ℓ_2. A unit sphere of dimension d is denoted by $\mathcal{S}^{d-1}$. The expected value of a random variable X is denoted by $\mathbb{E}[X]$. Given a sequence $\{x_k\}_{k=0}^{T-1}$, the discrete Fourier transform (DFT) of the sequence is denoted by $\mathbf{x}(e^{j\omega}) = \sum_{k=0}^{T-1} x_k e^{-j2\pi k\omega}$ where $\omega \in \Omega_T$ and $\Omega_T := \{0, 1/T, ..., (T-1)/T\}$. For a vector $x \in \mathbb{R}^n$, the Euclidean norm is denoted by $\|x\| = \sqrt{x^\top x}$. For a matrix $M \in \mathbb{C}^{m\times n}$, the largest singular value is denoted by $\|M\|$. A random variable $X \in \mathbb{R}^d$ that is normally distributed with mean μ and variance Σ is denoted by $X \sim \mathcal{N}(\mu, \Sigma)$. A random variable $X \in \mathbb{R}$ is said to be sub-Gaussian with variance proxy σ^2, i.e., $X \sim \mathsf{subG}(\sigma^2)$, if $\mathbb{E}[X] = 0$ and its moment generating function satisfies $\mathbb{E}[e^{sX}] \leq e^{\left(\frac{\sigma^2 s^2}{2}\right)}, \quad \forall s \in \mathbb{R}$. A random vector $X \in \mathbb{R}^d$ is said to be sub-Gaussian with variance proxy σ^2, i.e., $X \sim \mathsf{subG}(\sigma^2)$, if $\mathbb{E}[X] = 0$ and $u^\top X$ is sub-Gaussian with variance proxy σ^2 for any unit vector $u \in \mathcal{S}^{d-1}$.

Setting: Consider a discrete-time linear time-invariant dynamical system of the form

$$x_{k+1} = A_{\mathrm{tr}} x_k + B_{\mathrm{tr}} u_k + w_k, \quad w_k \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma_w^2 I) \qquad (1)$$

where $x_k \in \mathbb{R}^{n_x}$ is the state, $u_k \in \mathbb{R}^{n_u}$ is the control input, and $w_k \in \mathbb{R}^{n_x}$ is the normally distributed process noise. It is assumed that the realizations of w_k are independent and identially distributed (i.i.d.) and the state x_k is directly measurable. The true values of the system dynamics, A_{tr} and B_{tr}, are unknown.

Control goal and outline: The overarching goal of the proposed dual control strategy is to design a stabilizing state-feedback controller $u_k = Kx_k$ which ensures that the closed-loop system is stable while also satisfying some desired quadratic performance specifications, e.g., ℓ_2-gain with high probability (Scherer, 2001; Veenman and Scherer, 2014). Additionally, an initial estimate of the system parameters is available with potentially large uncertainty. Correspondingly, we propose a sequential dual control approach wherein a targeted exploration strategy is implemented first and is followed by the implementation of the parametrized state-feedback controller. The primary challenge is to encapsulate the dual effect of performance improvement through the process of exploration, and to tailor the exploration in a manner that is pertinent to performance improvement. Therefore, we simultaneously design a targeted exploration strategy and a parametrized state-feedback controller for the system in (1) in dependence of the future parameters/model estimate. The new parameter estimate, which influences the state-feedback control law K, is interpreted as a scheduling variable using tools from gain-scheduling (Venkatasubramanian et al., 2020). The preliminaries regarding uncertainty bounds for parameter estimation based on time-series data and spectral information are provided in Section 3. The exploration strategy and the corresponding uncertainty bound on the data obtained during exploration are elaborated in Section 4. The dual control strategy is summarized in Section 5.

3. UNCERTAINTY BOUND

This section discusses preliminary results that provide a data-dependent uncertainty bound on the parameter estimates, and a lower uncertainty bound on the resultant persistence of excitation based on spectral information, by Umenberger et al. (2019) and Sarker et al. (2020), respectively.

3.1 Data-dependent uncertainty bound

Given observed data $\mathcal{D} = \{x_k, u_k\}_{k=0}^{N-1}$ of length N, denote $\phi_k = \begin{bmatrix} x_k^\top & u_k^\top \end{bmatrix}^\top \in \mathbb{R}^{n_\phi}$ where $n_\phi = n_x + n_u$. The least squares estimate of the unknown parameters A_{tr} and B_{tr} is computed as:

$$(\hat{A}, \hat{B}) = \underset{A,B}{\arg\min} \sum_{k=0}^{N-1} ||x_{k+1} - Ax_k - Bu_k||_2^2. \qquad (2)$$

The following lemma provides a high probability credibility region for the uncertain system matrices.

Lemma 1. (Umenberger et al., 2019, Lemma 3.1) Given data set $\mathcal{D}$ and $0 < \delta < 1$, let $D = \frac{1}{\sigma_w^2 c_\delta} \sum_{k=1}^{N-1} \phi_k \phi_k^\top$ with $c_\delta = \chi^2_{n_x^2 + n_x n_u}(\delta)$. Suppose we have a uniform prior over the parameters (A, B), i.e., given $\theta = \mathrm{vec}([A, B])$, $p(\theta) \propto 1$. Then, $[A_{\mathrm{tr}}, B_{\mathrm{tr}}] \in \Theta$ with probability $1 - \delta$, where

$$\Theta := \left\{ A, B : \begin{bmatrix} (\hat{A} - A)^\top \\ (\hat{B} - B)^\top \end{bmatrix}^\top D \begin{bmatrix} (\hat{A} - A)^\top \\ (\hat{B} - B)^\top \end{bmatrix} \preceq I \right\}. \qquad (3)$$

The result of Lemma 1 is a data-dependent uncertainty bound that can be utilized to synthesize robust controllers similar to approaches by Umenberger et al. (2019), Ferizbegovic et al. (2019), Iannelli et al. (2020), and Venkatasubramanian et al. (2020). In Section 4, we use this to derive a suitable targeted exploration strategy. Since the dynamics are unknown in this setup, we compute an initial error bound of the form given in Lemma 1 from the following assumption.

Assumption 1. The parameters (A, B) have a uniform prior. Furthermore, an initial data set $\mathcal{D}_0 = \{\phi_k\}_{k=-T_0}^{-1}$ is available such that

$$D_0 \coloneqq \frac{1}{\sigma_w^2 c_\delta} \sum_{k=-T_0}^{-1} \phi_k \phi_k^\top \succ 0. \tag{4}$$

Initial estimates of the system parameters $\hat{A}_0$ and $\hat{B}_0$ can be derived from the data $\mathcal{D}_0$. The matrix D_0 quantifies the robust bound associated with these initial estimates for a given probability $1-\delta$ (cf. Lemma 1), and can be determined from $\mathcal{D}_0$ as given in (4). This initial data can be acquired through some random persistently exciting input. Through the targeted exploration process for T time steps (cf. Section 4), data $\mathcal{D}_T = \{\phi_k\}_{k=0}^{T-1}$ will be observed. The new estimates $\hat{A}_T$ and $\hat{B}_T$ will be computed from data $\mathcal{D}_0 \cup \mathcal{D}_T$ and made available at time T. The matrix $D_T \coloneqq D_0 + \frac{1}{\sigma_w^2 c_\delta} \sum_{k=0}^{T-1} \phi_k \phi_k^\top$ will quantify the uncertainty associated with the estimates $\hat{A}_T$ and $\hat{B}_T$ (cf. Lemma 1).

3.2 Finite excitation based on the theory of spectral lines

This subsection discusses parameter estimation results based on the theory of spectral lines (Bai and Sastry, 1985; Sarker et al., 2020), which deals with the analysis of frequency domain information that can be derived from time-series data. The finite-data uncertainty bounds in Lemma 1 are based on the matrix D, which corresponds to the following notion of finite excitation.

Definition 1. (Finite Excitation (Sarker et al., 2020)) A sequence $\{\phi_k\}_{k\geq 0,\dots T-1}$ is said to be finitely exciting from $k=0$ to $T-1$ if there exist constants $0 < \rho_1 \leq \rho_2$ such that

$$\rho_2 I \succeq \sum_{k=0}^{T-1} \phi_k \phi_k^\top \succeq \rho_1 I. \tag{5}$$

With finite data in the stochastic setting, the notion of a sub-Gaussian spectral line is introduced.

Definition 2. (Sub-Gaussian Spectral Line (Sarker et al., 2020)) A stochastic sequence $\{\phi_k\}_{k\geq 0,\dots T-1}$ is said to have a sub-Gaussian spectral line from $k=0$ to $T-1$ at a frequency $\omega_0 \in \Omega_T$ of amplitude $\bar{\phi}(\omega_0) \in \mathbb{C}^{n_\phi}$ and a radius $R > 0$ if

$$\frac{1}{T} \sum_{k=0}^{T-1} \phi_k e^{-j2\pi\omega_0 k} - \bar{\phi}(\omega_0) \sim \mathsf{subG}(R^2/T). \tag{6}$$

In order to establish the relationship between the spectral content of the input and finite excitation, the expected information matrix is first defined.

Definition 3. (Expected Information Matrix (Sarker et al., 2020)) Given a sequence $\{\phi_k\}_{k\geq 0}$ with L sub-Gaussian spectral lines at frequencies $\{\omega_1, ..., \omega_L\}$ from $k=0$ to $T-1$ with amplitudes $\{\bar{\phi}(\omega_1), ..., \bar{\phi}(\omega_L)\}$, the information matrix $\bar{\Phi}$ is defined as

$$\bar{\Phi} = \begin{bmatrix} | & \dots & | \\ \bar{\phi}(\omega_1) & \dots & \bar{\phi}(\omega_L) \\ | & \dots & | \end{bmatrix}. \tag{7}$$

In deterministic system identification, fast estimation of unknown parameters is made possible if $\bar{\Phi}$ is full rank and numerically well conditioned. Note that we consider n_ϕ spectral lines for simplicity, which is the smallest number required for finite excitation and results in a square matrix $\bar{\Phi}$. Subsequently, since $\omega_i \in \Omega_T$, $i = 1, ..., n_\phi$, we set $T \geq n_\phi$ and select n_ϕ frequencies from Ω_T. Furthermore, whether an input signal is finitely exciting or not can be ascertained from its spectral content. The following lemma, inspired by (Sarker et al., 2020, Proposition 2), presents a clear relationship between the spectral content of the signal and finite excitation by utilizing the expected information matrix.

Lemma 2. If a sequence $\{\phi_k\}_{k\geq 0,\dots T-1}$ has n_ϕ spectral lines at frequencies $\omega_1, ..., \omega_{n_\phi}$ from $k=0$ to $T-1$ with amplitudes $\{\bar{\phi}(\omega_1), ..., \bar{\phi}(\omega_{n_\phi})\}$, then, for any $\epsilon \in (0,1)$, ϕ_k satisfies

$$\frac{1}{T} \sum_{k=0}^{T-1} \phi_k \phi_k^\top \geq \frac{1}{n_\phi} \left((1-\epsilon) \bar{\Phi}^\top \bar{\Phi} + \left(1 - \frac{1}{\epsilon}\right) \tilde{W}^\top \tilde{W} \right). \tag{8}$$

Here, $\tilde{W}$ is a random matrix for which each column is sub-Gaussian with properties as derived in Section 4.2. $\tilde{W}$ captures the effect of the disturbances w in a suitably defined manner. Inequality (8) can be used to determine a lower bound $\overline{D}_T$ on the *informativity* of the exploration data before the process of exploration. Such bounds are crucial for robust dual strategies (cf. Venkatasubramanian et al. (2020)). Note that this lower bound depends on the information matrix $\bar{\Phi}$, which contains the amplitudes of the harmonic signals (cf. (7)), as well as on the size of the noise.

4. TARGETED EXPLORATION

In this section, we propose a targeted exploration strategy and the corresponding uncertainty bound on the data obtained through the process of exploration. Unlike strategies based on greedy random exploration, we introduce a targeted exploration strategy in the form of a linear combination of sinusoids in specific frequencies that explicitly allow for the shaping of model uncertainty. Furthermore, a lower bound on finite excitation of the exploration data can be achieved using spectral information of the exploration inputs (cf. Lemma 2). This lower bound is pivotal in the design of a robust dual controller (cf. Section 5).

4.1 Exploration strategy

The exploration input takes the form

$$u_k = \sum_{i=1}^{n_\phi} a_i \cos(\omega_i k), \quad (a_i \in \mathbb{R}^{n_u}),\ k = 0, ..., T-1 \tag{9}$$

where T is the exploration time and a_i is the amplitude of the sinusoidal input with frequency ω_i. The amplitude of the sub-Gaussian spectral line at frequency ω_i is denoted as $\overline{u}(\omega_i)$. Since the input is sinusoidal and deterministic, the amplitude of the spectral line is $|\overline{u}(\omega_i)| = a_i/2$, and the radius of the spectral line is 0. Denote $U_\mathrm{e} = \mathrm{diag}(U_1, ..., U_{n_\phi})$ where $U_i = \overline{u}(\omega_i)$. The exploration input is computed such that it excites the system sufficiently with minimal control energy based on the initial parameter estimates, i.e., $U_\mathrm{e}^\top U_\mathrm{e} \preceq \gamma_\mathrm{e}$ where the bound γ_e is desired to be small.

4.2 Parameter estimation bounds

For the system evolving under the exploration input as given in (9), the uncertainty bound on the parameters can be computed from the expected information matrix $\bar{\Phi}$ of the input. As a requisite to compute the uncertainty bound, it is necessary to establish the relationship between the spectral content of the observed state and the input. The transfer function from u_k to ϕ_k can be written as,

$$\boldsymbol{\phi}(e^{j\omega}) = \begin{bmatrix} (e^{j\omega}I - A_{\mathrm{tr}})^{-1}B_{\mathrm{tr}} \\ I_{n_u} \end{bmatrix} \mathbf{u}(e^{j\omega}) + \begin{bmatrix} (e^{j\omega}I - A_{\mathrm{tr}})^{-1} \\ 0 \end{bmatrix} \mathbf{w}(e^{j\omega}). \tag{10}$$

Given u_k as in (9) and from (Sarker et al., 2020, Lemma 1), ϕ_k has a sub-Gaussian spectral line from 0 to $T-1$ at frequency $\omega_0 \in \Omega_T$ with amplitude

$$\bar{\phi}(\omega_0) = \begin{bmatrix} (e^{j\omega_0}I - A_{\mathrm{tr}})^{-1}B_{\mathrm{tr}} \\ I_{n_u} \end{bmatrix} \bar{u}(\omega_0). \tag{11}$$

Denote

$$V_i = \begin{bmatrix} (e^{j\omega_i}I - A_{\mathrm{tr}})^{-1}B_{\mathrm{tr}} \\ I_{n_u} \end{bmatrix},\ V_{\mathrm{tr}} = [V_1, \cdots, V_{n_\phi}],$$
$$Y_i = \begin{bmatrix} (e^{j\omega_i}I - A_{\mathrm{tr}})^{-1} \\ 0 \end{bmatrix},\ Y_{\mathrm{tr}} = [Y_1, \cdots, Y_{n_\phi}],$$
$$W = \mathrm{diag}(\bar{w}(\omega_1), ..., \bar{w}(\omega_{n_\phi})).$$

Then,

$$\bar{\Phi} = [V_1U_1, \cdots, V_{n_\phi}U_{n_\phi}] = V_{\mathrm{tr}}U_{\mathrm{e}}.$$

One can show that Lemma 2 holds with $\tilde{W} = Y_{\mathrm{tr}}W$ and $\epsilon > 0$ from (10):

$$\frac{1}{T}\sum_{k=0}^{T-1}\phi_k\phi_k^\top \succeq \frac{1}{n_\phi}\left((1-\epsilon)U_{\mathrm{e}}^\top V_{\mathrm{tr}}^{\mathsf{H}}V_{\mathrm{tr}}U_{\mathrm{e}} + \left(1-\frac{1}{\epsilon}\right)\tilde{W}^\top\tilde{W}\right) \succeq \overline{D}_T \tag{12}$$

from which we can derive a lower bound on the parameter uncertainty. Recall that we want to derive a lower bound on the information in the exploration data D_T which involves the term $\sum_{k=0}^{T-1}\phi_k\phi_k^\top$. Here, V_{tr} is unknown, however, we can compute an estimate $\hat{V}$ using an estimate of the system parameters $\hat{A}_0$, $\hat{B}_0$. By suitably bounding $|V_{\mathrm{tr}} - \hat{V}|$, a valid lower bound $\overline{D}_T$ satisfying (12) can be computed. Hence, we can compute a lower bound on finite excitation as defined in (5) only from terms that are known to us. By appropriately choosing the input U_e, we can guarantee a certain finite excitation in the future.

5. ROBUST DUAL CONTROL

The proposed harmonic targeted exploration strategy with the associated lower bound in (12) can be combined with the dual control paradigm suggested by Venkatasubramanian et al. (2020). The exploration strategy and a robust state-feedback controller can be simultaneously designed such that applying the feedback after exploration ensures the satisfaction of some performance specifications with high probability. Initial estimates of the system parameters, with potentially large uncertainty, are available. During the process of exploration, the estimates $\hat{A}$ and $\hat{B}$ change due to new data. We utilize this information by modeling the true system in (1) as a linear parameter varying (LPV) system, where the estimates $\hat{A}$, $\hat{B}$ are measured online. Given uncertainty bounds on the initial estimates and the estimates obtained after exploration, the dual control problem can now be interpreted as a gain-scheduling problem as described by Venkatasubramanian et al. (2020). The new parameter estimates obtained after exploration are selected as a scheduling variable which influences the control law K, thereby encapsulating the dual effect of performance improvement through the process of exploration. The resulting dual controller with targeted harmonic exploration strategy can provide (high-probability) a priori performance bounds by utilizing the excitation guarantees derived in (12). Further details including a theoretical analysis of the proposed dual control strategy can be found in (Venkatasubramanian et al., 2022).

k k

This article is a resubmission of the full paper that was accepted for the presentation at the MTNS 2020. This article reports error analysis and asymptotic variance of a closed-loop subspace model identification method for a system described with the output-error state-space representation. For details, since the procedure of the identification method includes the QR factorization of stacked data Hankel matrices, this study investigates asymptotic properties of block entries of the triangular matrix obtained from the QR factorization. The set of the block entries is separated into two components, namely, the signal-based component and the noise-based component. The contributions are to derive asymptotic properties of both components and to obtain the asymptotic covariance matrix of the vectorization of the noise-based component.

System identification, subspace methods, closed-loop identification, asymptotic properties, covariance matrices

1. INTRODUCTION

The authors have proposed a closed-loop subspace model identification method for a system described with the output-error state-space representation (Oku et al., 2006a,b). Since it utilizes the QR-factorization and its procedure resembles the procedure of the "MOESP" family very much, for convenience it is called CL-MOESP for the rest of this paper. A superiority of CL-MOESP is that it can directly estimate a system to be identified in closed-loop even when it is contaminated with the arbitrary colored output-error noise. Practical usefulness has been demonstrated by closed-loop system identification experiments on a cart-inverted-pendulum system (Oku and Ushida, 2009), a coaxial miniature helicopter (Matsuba et al., 2012; Kojio et al., 2014) and a quadrotor drone (Nakayama and Oku, 2018). Asymptotic properties and optimality of CL-MOESP have been discussed in part by Oku (2010). However, the analysis of consistency of the estimate and error, as well as the analysis of the asymptotic variance, is an important open problem.

With respect to the error analysis of CL-MOESP, this paper studies the estimation error of the triangular matrix obtained by the QR factorization of a stack of data Hankel matrices defined later. In details, focusing on significant block entries of the triangular matrix that are used to estimate the extended observability matrix and the coefficient matrices, the set of the block matrices is described using data Hankel matrices, and then it is separated into two components, namely, the signal-based component and the noise-based component. The contributions are as follows: 1) to prove that the signal-based component converges in probability to the matrix composed of meaningful structured matrices, each of which consists of the Markov parameters of the closed-loop system to be handled, 2) to prove that the noise-based component converges in probability to zero, and finally, 3) to derive the asymptotic covariance matrix of the vectorization of the noise-based component.

2. BRIEF REVIEW OF CL-MOESP

In this section, CL-MOESP in a general framework is briefly reviewed (Oku et al., 2006a,b).

Let us consider a closed-loop system depicted in Fig. 1. Suppose the plant P, which is to be identified, be a discrete-time linear time-invariant system described by the following minimal realization:

$$x_{k+1} = Ax_k + Bu_k, \qquad y_k = Cx_k + v_k, \tag{1}$$

where $x_k \in \mathbb{R}^n$ denotes the state vector. Note that the order of the system, n, is unknown and it is to be estimated. Note also that the coefficients (A, B, C) are unknown and to be estimated up to a similarity transform. The output signal $y_k \in \mathbb{R}^l$ is measurable but it is contaminated with the colored noise $v_k \in \mathbb{R}^l$. The input to P, $u_k \in \mathbb{R}^m$, is generated by subtraction of the output filtered by a stabilizing controller, $K = K(q)$, from the external excitation signal r_k, that is,

$$u_k = r_k - K(q)y_k, \tag{2}$$

where q denotes the forward shift operator.

Let us assume the set point $d_k \equiv 0$. Then, $K(q)$ is not necessarily known [1].

⋆ This article is a resubmission of the full paper that was accepted at the MTNS 2020, with more concise notations adopted. This work was supported by JSPS KAKENHI Grant Number 18K04217.

[1] Also for the case where d is a constant reference signal, $K(q)$ is not necessarily known when the output is redefined as $y - d$.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

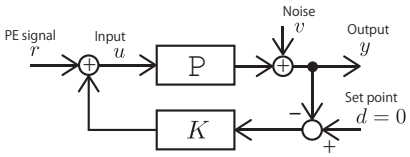

Fig. 1. Closed-loop system

Assume that, for $\forall k$ and $\forall i \geq 0$, x_k is independent of r_{k+i}. It means that the state at the current instant is influenced by the external excitation at relatively past instants. $\{r_k\}$ and $\{v_k\}$ are assumed to be uncorrelated each other in the sense that for $\forall i, \forall j \in \mathbb{Z}$, $\lim_{M\to\infty} \frac{1}{M} \sum_{k=1}^{M} v_{i+k} r_{j+k}^{\mathsf{T}} = 0$.

Given a sequence $\{u_k\}$, the block Hankel matrix, $\mathcal{U}_{i,s,j} \in \mathbb{R}^{ms\times j}$, is defined as

$$\mathcal{U}_{i,s,j} := \begin{bmatrix} u_i & u_{i+1} & \cdots & u_{i+j-1} \\ u_{i+1} & u_{i+2} & \cdots & u_{i+j} \\ \vdots & \vdots & & \vdots \\ u_{i+s-1} & u_{i+s} & \cdots & u_{i+s+j-2} \end{bmatrix}, \tag{3}$$

where the first subscript, i, is the same as the subscript on the top-left block element, and the others, s and j, mean that $\mathcal{U}_{i,s,j} \in \mathbb{R}^{ms\times j}$ is of s block rows and j columns. Note that $s > 0$ is a user-defined parameter which is chosen to be sufficiently larger than n. For sequences $\{y_k\}$, $\{r_k\}$ and $\{v_k\}$, the block Hankel matrices $\mathcal{Y}_{i,s,j}$, $\mathcal{R}_{i,s,j}$ and $\mathcal{V}_{i,s,j}$ are respectively defined in a manner similar to (3). These matrices are called the data Hankel matrices for the rest of this paper. For brevity's sake, the following notations with respect to the data Hankel matrices are introduced: for an integer N that is sufficiently larger than s,

$$\mathcal{R}_f := \mathcal{R}_{0,s,N}, \quad \mathcal{U}_f := \mathcal{U}_{0,s,N}, \quad \mathcal{Y}_f := \mathcal{Y}_{0,s,N},$$
$$\mathcal{R}_p := \mathcal{R}_{-s,s,N}, \quad \mathcal{U}_p := \mathcal{U}_{-s,s,N}.$$

Note that the subscriptions "f" and "p" respectively represents that the data Hankel matrices are made of relatively "future" and "past" data, respectively. Define $\mathcal{R} := \begin{bmatrix} \mathcal{R}_p^{\mathsf{T}} & \mathcal{R}_f^{\mathsf{T}} \end{bmatrix}$. For a sequence $\{x_k\}$, define

$$\mathcal{X}_{i,j} := \begin{bmatrix} x_i & x_{i+1} & \cdots & x_{i+j-1} \end{bmatrix}. \tag{4}$$

Given a quadruple of matrices (E, F, G, H) of appropriate sizes, define the notations as follows (Ikeda, 2014):

$$\mathcal{O}_i(G, E) := \begin{bmatrix} G^{\mathsf{T}} & (GE)^{\mathsf{T}} & \cdots & (GE^{i-1})^{\mathsf{T}} \end{bmatrix}^{\mathsf{T}}, \tag{5}$$

$$\mathcal{L}_i(E, F) := \begin{bmatrix} E^{i-1}F & \cdots & EF & F \end{bmatrix}, \tag{6}$$

$$\mathcal{T}_i(E, F, G, H) := \begin{bmatrix} H & & & 0 \\ GF & H & & \\ \vdots & \ddots & \ddots & \\ GE^{i-2}F & \cdots & GF & H \end{bmatrix}. \tag{7}$$

Using these notations, the extended observability matrix, $\mathcal{O}$, and the block-Toeplitz matrix made of the Markov parameters, $\mathcal{T}$, can be denoted as, respectively,

$$\mathcal{O} := \mathcal{O}_s(C, A), \qquad \mathcal{T} := \mathcal{T}_s(A, B, C, D).$$

Notice that from (1) $D = 0$ throughout this paper.

CL-MOESP is a solution to the following closed-loop subspace model identification problem.

Consider a closed-loop system depicted by Fig. 1. The problem is to estimate the order n of P to be identified and obtain the minimal realization (A, B, C) of P up to a similarity transform from the measurements of $\{r_k\}$, $\{u_k\}$ and $\{y_k\}$.

The procedure of CL-MOESP is as follows (Oku et al., 2006a,b):

(CL-MOESP). Suppose that a set of sampled data sequences $\{r_k\}$, $\{u_k\}$ and $\{y_k\}$ be obtained from a system identification experiment of the closed-loop system as depicted in Fig. 1. Then, a state-space model which represents the input/output relation of P can be obtained according to the procedures as follows:

1. Execute the QR factorization of the following matrix:
$$\begin{bmatrix} \mathcal{R} \\ \mathcal{U}_p \\ \mathcal{U}_f \\ \mathcal{Y}_f \end{bmatrix} = \begin{bmatrix} L_{11} & & & \\ L_{21} & L_{22} & & \\ L_{31} & L_{32} & L_{33} & \\ L_{41} & L_{42} & L_{43} & L_{44} \end{bmatrix} \begin{bmatrix} Q_1^{\mathsf{T}} \\ Q_2^{\mathsf{T}} \\ Q_3^{\mathsf{T}} \\ Q_4^{\mathsf{T}} \end{bmatrix} \tag{8}$$
2. Compute P and $\Upsilon^{\frac{1}{2}}$ as follows:
$$P := L_{21} - L_{21}L_{31}^{\mathsf{T}} \left(L_{31}L_{31}^{\mathsf{T}}\right)^{-1} L_{31} \tag{9}$$
$$\Upsilon^{\frac{1}{2}} := L_{41}P^{\mathsf{T}} \left(PP^{\mathsf{T}}\right)^{-\frac{1}{2}} \tag{10}$$
3. To estimate the extended observability matrix, $\mathcal{O}$, up to a similarity transform, execute singular value decomposition (SVD) of $\Upsilon^{\frac{1}{2}}$ and we have
$$\Upsilon^{\frac{1}{2}} = \begin{bmatrix} \hat{U} & \hat{U}^{\perp} \end{bmatrix} \begin{bmatrix} \hat{\Sigma} & \\ & \hat{\Sigma}^{\perp} \end{bmatrix} \begin{bmatrix} \hat{V}^{\mathsf{T}} \\ \left(\hat{V}^{\perp}\right)^{\mathsf{T}} \end{bmatrix},$$
where the diagonal matrix $\hat{\Sigma} \in \mathbb{R}^{n\times n}$ has n dominant singular values as its diagonal entries. Namely, the number of the dominant singular values can estimate the order of P. Note that the orthogonal matrix $\hat{U}$ is an estimate of $\mathcal{O}$ up to a similarity transform.
4. The set of estimates of the coefficients of a state-space representation of P, i.e., $(\hat{A}, \hat{B}, \hat{C}, \hat{D})$, can be obtained according to the procedure similar in the paper of Verhaegen and Dewilde (1992). See appendix A of the literature (Oku and Ikeda, 2021) for the details.

3. PROBLEM SETTING AND NOTATIONS

The aim of this article is to study error analysis of the triangular matrix obtained from the QR factorization (8). Especially, since from (8), (9) and (10) the matrix with 3 significant block entries

$$\begin{bmatrix} L_{21}^{\mathsf{T}} & L_{31}^{\mathsf{T}} & L_{41}^{\mathsf{T}} \end{bmatrix}^{\mathsf{T}} \tag{11}$$

plays a key role in derivation of $\Upsilon^{\frac{1}{2}}$ and the subsequent procedures of CL-MOESP, we will investigate error analysis of (11) and derivation of its asymptotic covariance matrix.

Let us consider a closed-loop system depicted by Fig. 2. To simplify the problem, a constant gain feedback case will be considered. Let $u_k, r_k \in \mathbb{R}^m$ denote the input and the external excitation signal, respectively. $y_k, e_k \in \mathbb{R}^l$ denote the output and noise, respectively. The set point is assumed to be $d_k \equiv 0$ for $\forall k$. Suppose that P to be

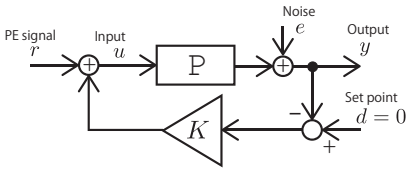

Fig. 2. A closed-loop system with constant gain feedback

identified is a n-th order LTI system of m inputs and l outputs with a minimal realization described by

$$x_{k+1} = Ax_k + Bu_k, \tag{12a}$$
$$y_k = Cx_k + e_k. \tag{12b}$$

where $x_k \in \mathbb{R}^n$ denotes the state vector of P. The input u_k is generated by subtraction of the output y_k multiplied by a constant feedback gain K from the external excitation signal r_k, that is,

$$u_k = r_k - Ky_k. \tag{13}$$

Suppose the closed-loop system be internally stable.

For the rest of the paper, adopt the following assumptions:

A1. $|\lambda_i(\bar{A})| < 1$, where $\bar{A} := A - BKC$.
A2. The noise $\{e_k\}$ is an unknown discrete-time Gaussian process with the mean $\mathrm{E}[e_k] = 0$ and the covariance $\mathrm{E}[e_k e_l^\mathsf{T}] = \Omega_{ee}\delta_{kl}$, which is not measurable.
A3. The external excitation signal $\{r_k\}$ is a known discrete-time Gaussian process with the mean $\mathrm{E}[r_k] = 0$ and the covariance $\mathrm{E}[r_k r_l^\mathsf{T}] = \Omega_{rr}\delta_{kl}$.
A4. $\{r_k\}$ and $\{e_k\}$ are uncorrelated with each other in the sense that, for $\forall i, \forall j \in \mathbb{Z}$, $\lim_{M\to\infty} \frac{1}{M}\sum_{k=1}^{M} e_{i+k} r_{j+k}^\mathsf{T} = 0$.
A5. For $\forall i \geq 0$, $\forall k$, x_k and r_{k+i} are independent of each other.
A6. The signals $\{x_k\}$, $\{r_k\}$, $\{u_k\}$, $\{y_k\}$ and $\{e_k\}$ are ergodic stationary processes.

The following notations are adopted: given i-successive sampled data of u from k, i.e., $\{u_k, \cdots, u_{k+i-1}\}$, define

$$u_i(k) := \begin{bmatrix} u_k^\mathsf{T} & \cdots & u_{k+i-1}^\mathsf{T} \end{bmatrix}^\mathsf{T}. \tag{14}$$

Note that $r_i(k)$, $y_i(k)$ and $e_i(k)$ are also defined in a similar manner to (14).

4. ERROR ANALYSIS OF CL-MOESP

x

Substitution of (13) into (12a) yields

$$x_{k+1} = \bar{A}x_k + Br_k + B_e e_k, \tag{15}$$

where $B_e := -BK$. Recursive use of (15) gives, for $i \geq 1$,

$$x_{k+i} = \bar{A}^i x_k + \mathcal{L}_i(\bar{A}, B) r_i(k) + \mathcal{L}_i(\bar{A}, B_e) e_i(k). \tag{16}$$

Let an integer s be sufficiently greater than n. Using the output equation (12b) and (16),

$$y_{k+i} = C\bar{A}^i x_k + C\mathcal{L}_i(\bar{A}, B) r_i(k) + C\mathcal{L}_i(\bar{A}, B_e) e_i(k) + e_{k+i} \tag{17}$$

is derived for $i = 0, \cdots, s-1$. Then, stack (17) for $i = 0, \cdots, s-1$, and we have the following equation:

$$y_s(k) = \mathcal{O}_y x_k + \mathcal{T}_y r_s(k) + \mathcal{H}_y e_s(k), \tag{18}$$

where $\mathcal{O}_y := \mathcal{O}_s(C, \bar{A})$, $\mathcal{T}_y := \mathcal{T}_s(\bar{A}, B, C, 0)$, $\mathcal{H}_y := \mathcal{T}_s(\bar{A}, B_e, C, I)$. Moreover, place (18) for $k = 0, \cdots, N$ side by side, and we obtain the following matrix IO equation:

$$\mathcal{Y}_f = \mathcal{O}_y \mathcal{X}_f + \mathcal{T}_y \mathcal{R}_f + \mathcal{H}_y \mathcal{E}_f \tag{19}$$

where define $\mathcal{X}_f := \mathcal{X}_{0,N}$ and the error matrix $\mathcal{E}_f := \mathcal{E}_{0,s,N}$.

Follow the same context discussed above, and we have the following equation with respect to $u_s(k)$:

$$u_s(k) = \mathcal{O}_u x_k + \mathcal{T}_u r_s(k) + \mathcal{H}_u e_s(k) \tag{20}$$

where $H := -KC$, and $\mathcal{O}_u := \mathcal{O}_s(H, \bar{A})$, $\mathcal{T}_u := \mathcal{T}_s(\bar{A}, B, H, 0)$, $\mathcal{H}_u := \mathcal{T}_s(\bar{A}, B_e, H, -K)$. Then, place (20) for $k = 0, \cdots, N$ side by side, and we derive the following matrix input-output equation:

$$\mathcal{U}_f = \mathcal{O}_u \mathcal{X}_f + \mathcal{T}_u \mathcal{R}_f + \mathcal{H}_u \mathcal{E}_f. \tag{21}$$

Now, recursive use of (16) toward the past gives the s-step ahead state equation between x_k and x_{k-s} as follows:

$$x_k = \bar{A}^s x_{k-s} + \mathcal{L}_r r_s(k-s) + \mathcal{L}_e e_s(k-s), \tag{22}$$

where $\mathcal{L}_r := \mathcal{L}_s(\bar{A}, B)$ and $\mathcal{L}_e := \mathcal{L}_s(\bar{A}, B_e)$. Then, place (22) for $k = 0, \cdots, N$ side by side, and we have the s-step ahead matrix state equation as follows:

$$\mathcal{X}_f = \bar{A}^s \mathcal{X}_p + \mathcal{L}_r \mathcal{R}_p + \mathcal{L}_e \mathcal{E}_p \tag{23}$$

where $\mathcal{X}_p := \mathcal{X}_{-s,N}$ and $\mathcal{E}_p := \mathcal{E}_{-s,s,N}$.

Finally, substitute (19) and (21) into (23) and notice an analogy between $\mathcal{U}_p$ and $\mathcal{U}_f$ with respect to (21), and we have the following matrix input-output equations:

$$\begin{bmatrix} \mathcal{U}_p \\ \mathcal{U}_f \\ \mathcal{Y}_f \end{bmatrix} = \begin{bmatrix} \mathcal{O}_u \\ \mathcal{O}_u\bar{A}^s \\ \mathcal{O}_y\bar{A}^s \end{bmatrix} \mathcal{X}_p + \begin{bmatrix} \mathcal{T}_u & 0 \\ \mathcal{O}_u\mathcal{L}_r & \mathcal{T}_u \\ \mathcal{O}_y\mathcal{L}_r & \mathcal{T}_y \end{bmatrix} \mathcal{R} + \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u\mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y\mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \mathcal{E}, \tag{24}$$

where $\mathcal{E} := \begin{bmatrix} \mathcal{E}_p^\mathsf{T} & \mathcal{E}_f^\mathsf{T} \end{bmatrix}^\mathsf{T}$.

L x k

With respect to the 3 block entries of the L-matrix, i.e., (11), the following lemma is derived from (8) directly:

Assume that the matrix $\mathcal{R}$ is of full row rank. Then, it holds that

$$\begin{bmatrix} L_{21} \\ L_{31} \\ L_{41} \end{bmatrix} = \begin{bmatrix} \mathcal{U}_p \\ \mathcal{U}_f \\ \mathcal{Y}_f \end{bmatrix} \mathcal{R}^\mathsf{T} L_{11}^{-\mathsf{T}} \tag{25}$$

P **f** From (8), we obtain

$$\begin{bmatrix} \mathcal{U}_p \\ \mathcal{U}_f \\ \mathcal{Y}_f \end{bmatrix} \mathcal{R}^\mathsf{T} = \begin{bmatrix} L_{21} \\ L_{31} \\ L_{41} \end{bmatrix} L_{11}^\mathsf{T}.$$

The invertibility of L_{11}^T is ensured by the assumption of the full row rankness of $\mathcal{R}$, and it completes the proof. □

Now, notice that $\mathcal{R}\mathcal{R}^\mathsf{T} = L_{11}L_{11}^\mathsf{T}$. Substitution of (24) into (25) yields

$$\begin{bmatrix} L_{21} \\ L_{31} \\ L_{41} \end{bmatrix} = \mathcal{S}_N + \mathcal{N}_N,$$

where $\mathcal{S}_N$ and $\mathcal{N}_N$ are called, respectively, the signal-based component and the noise-based component of (11), defined respectively as follows:

$$\mathcal{S}_N := \begin{bmatrix} \mathcal{O}_u \\ \mathcal{O}_u \bar{A}^s \\ \mathcal{O}_y \bar{A}^s \end{bmatrix} \mathcal{X}_p \mathcal{R}^\mathsf{T} L_{11}^{-\mathsf{T}} + \begin{bmatrix} \mathcal{T}_u & 0 \\ \mathcal{O}_u \mathcal{L}_r & \mathcal{T}_u \\ \mathcal{O}_y \mathcal{L}_r & \mathcal{T}_y \end{bmatrix} L_{11}, \quad (26)$$

$$\mathcal{N}_N := \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \mathcal{E} \mathcal{R}^\mathsf{T} L_{11}^{-\mathsf{T}}. \quad (27)$$

The lower triangular matrix $\boldsymbol{L}_r$ is defined as the Cholesky factor, up to a sign matrix, of the following asymptotic covariance matrix:

$$\boldsymbol{L}_r \boldsymbol{L}_r^\mathsf{T} := \lim_{N\to\infty} \frac{1}{N} \mathcal{R}\mathcal{R}^\mathsf{T} = \text{block-diag}(\Omega_{rr}, \cdots, \Omega_{rr}).$$

For the rest of the paper, let us assume that the sign matrix is determined compatibly with the context.

The following theorem is for the probability convergence property of the signal-based component $\mathcal{S}_N$:

Under the assumptions from **1** to **6**,

$$\frac{1}{\sqrt{N}} \mathcal{S}_N \longrightarrow \mathcal{S}_\infty := \begin{bmatrix} \mathcal{T}_u & 0 \\ \mathcal{O}_u \mathcal{L}_r & \mathcal{T}_u \\ \mathcal{O}_y \mathcal{L}_r & \mathcal{T}_y \end{bmatrix} \boldsymbol{L}_r \quad \text{i.p. for } N \to \infty.$$

P f $\|\cdot\|_F$ denotes the Frobenius norm. For $\forall \varepsilon > 0$,

$$\begin{aligned} &\mathrm{P}\left[\left\| \frac{1}{\sqrt{N}} \mathcal{S}_N - \mathcal{S}_\infty \right\|_F > \varepsilon \right] \\ &\le \mathrm{P}\left[\left\| \begin{bmatrix} \mathcal{O}_u \\ \mathcal{O}_u \bar{A}^s \\ \mathcal{O}_y \bar{A}^s \end{bmatrix} \frac{1}{N} \mathcal{X}_p \mathcal{R}^\mathsf{T} \cdot \left(\frac{1}{\sqrt{N}} L_{11} \right)^{-\mathsf{T}} \right\|_F \right. \\ &\quad \left. + \left\| \begin{bmatrix} \mathcal{T}_u & 0 \\ \mathcal{O}_u \mathcal{L}_r & \mathcal{T}_u \\ \mathcal{O}_y \mathcal{L}_r & \mathcal{T}_y \end{bmatrix} \left(\frac{1}{\sqrt{N}} L_{11} - \boldsymbol{L}_r \right) \right\|_F > \varepsilon \right] \\ &\longrightarrow 0, \quad \text{as } N \to \infty. \end{aligned}$$

Note that $\lim_{N\to\infty} \frac{1}{N} \mathcal{X}_p \mathcal{R}^\mathsf{T} = 0$ holds from **5**. □

The following theorem is for the probability convergence property of the noise-based component $\mathcal{N}_N$:

Under the assumptions from **1** to **6**,

$$\frac{1}{\sqrt{N}} \mathcal{N}_N \longrightarrow 0 \quad \text{i.p. for } N \to \infty.$$

P f The assumption **4** gives $\lim_{N\to\infty} \frac{1}{N} \mathcal{E}\mathcal{R}^\mathsf{T} = 0$ Then, for $\forall \varepsilon > 0$, it holds that

$$\lim_{N\to 0} \mathrm{P}\left[\left\| \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \left(\frac{1}{N} \mathcal{E}\mathcal{R}^\mathsf{T} \right) \cdot \left(\frac{1}{\sqrt{N}} L_{11} \right)^{-\mathsf{T}} \right\|_F \ge \varepsilon \right] = 0$$

□

The vectorization of the noise-based component yields

$$\mathrm{vec}\,(\mathcal{N}_N) = \left(Q_1^\mathsf{T} \otimes \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \right) \mathrm{vec}\,(\mathcal{E}).$$

We introduce the notations: $\Phi(i) := \lim_{N\to\infty} Q_1^\mathsf{T} J_N^i Q_1$,

$$I_\nu := \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & & \\ \vdots & & \ddots & \\ 0 & 0 & & 1 \end{bmatrix} \in \mathbb{R}^{\nu\times\nu}, \quad J_\nu := \begin{bmatrix} 0 & & & 0 \\ 1 & 0 & & \\ & \ddots & \ddots & \\ 0 & & 1 & 0 \end{bmatrix} \in \mathbb{R}^{\nu\times\nu},$$

The following theorem is for the asymptotic covariance matrix of $\mathrm{vec}(\mathcal{N}_N)$:

Under the assumptions from **1** to **6**, $\mathrm{vec}\,(\mathcal{N}_N)$ converges in distribution to the Gaussian distribution with zero mean and the covariance given by

$$\begin{aligned} &\lim_{N\to\infty} \mathrm{E}\left[\mathrm{vec}\,(\mathcal{N}_N)\, \mathrm{vec}\,(\mathcal{N}_N)^\mathsf{T} \right] \\ &= I_{2ms} \otimes \left(\begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} (I_{2s} \otimes \Omega_{ee}) \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix}^\mathsf{T} \right) \\ &\quad + \sum_{i=1}^{2s-1} \Phi(i) \otimes \left(\begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \left(\left(J_{2s}^\mathsf{T} \right)^i \otimes \Omega_{ee} \right) \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix}^\mathsf{T} \right) \\ &\quad + \sum_{i=1}^{2s-1} \Phi(i)^\mathsf{T} \otimes \left(\begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix} \left(J_{2s}^i \otimes \Omega_{ee} \right) \begin{bmatrix} \mathcal{H}_u & 0 \\ \mathcal{O}_u \mathcal{L}_e & \mathcal{H}_u \\ \mathcal{O}_y \mathcal{L}_e & \mathcal{H}_y \end{bmatrix}^\mathsf{T} \right) \end{aligned}$$

P f The proof is omitted. See the literature (Oku and Ikeda, 2021). □

Abstract: We prove that a network of input-to-state stable infinite-dimensional systems is input-to-state stable, provided that the gain operator of the network satisfies the monotone limit property. This property is equivalent to the strong small-gain condition in the case of finite networks. We prove our small-gain theorem for a very general class of networks, including networks of nonlinear partial and delay differential equations. It also recovers the classical nonlinear small-gain theorems for finitely many finite-dimensional systems as a special case.

Keywords: large-scale systems, nonlinear control systems, small-gain theorems, input-to-state stability, distributed parameter systems.

1. INTRODUCTION

Stability of large-scale and infinite networks has attracted a lot of attention during the last decades.

A prominent place is occupied by the theory of linear spatially invariant systems Bamieh et al. (2002); Bamieh and Voulgaris (2005); Besselink and Johansson (2017); Curtain et al. (2009) whose applications range from microelectromechanical systems to control of car platoons. In these works, it is assumed that an infinite number of control systems are connected with each other by means of the same pattern. This nice geometrical structure, together with the linearity of subsystems, allowed the development of powerful criteria for the stability of infinite interconnections.

For finite networks consisting of nonlinear systems, groundbreaking results have been obtained within the framework of input-to-state stability (ISS), initiated for finite-dimensional systems in Sontag (1989), see also Sontag (2008), and recently extended to the infinite-dimensional setting, see Karafyllis and Krstic (2019); Mironchenko and Prieur (2020) for an overview of this topic. In this approach, the influence of any subsystem on other subsystems of a network is characterized by so-called gain functions. The gain operator constructed from these functions characterizes the interconnection structure of the network. The small-gain theorems for couplings of $n \in \mathbb{N}$ input-to-state stable systems of ordinary differential equations (ODEs) Jiang et al. (1994, 1996); Dashkovskiy et al. (2007, 2010) state that if the gains are small enough (i.e., the gain operator satisfies the small-gain condition), the network is stable. These results have been extended to finite networks of time-delay, and PDE systems Polushin et al. (2006); Tiwari et al. (2012); Dashkovskiy and Mironchenko (2013).

Very recently, a significant effort has been devoted to the development of small-gain theorems for infinite networks of ISS systems. In Dashkovskiy and Pavlichkov (2020) nonlinear small-gain theorems have been obtained under the assumption that all the gains are uniformly less than identity, which is a very strong assumption. In Kawan et al. (2021), tight small-gain theorems have been obtained for the networks of exponentially ISS systems with linear gains, while in Dashkovskiy et al. (2019), it is shown that ISS of a network can be guaranteed provided that there is a linear path of strict decay for the gain operator.

In this work, which is a conference version of the journal paper Mironchenko et al. (2021), we provide nonlinear ISS small-gain theorems for infinite networks with infinite-dimensional components. We do not impose any linearity and/or contractivity assumption for the gains, which makes the result truly nonlinear. Moreover, our result applies to networks of ODE systems, delay systems, PDE networks, and well-posed multi-physics systems. We derive our small-gain theorems in the trajectory formulation, in contrast to the papers Dashkovskiy et al. (2019); Dashkovskiy and Pavlichkov (2020); Kawan et al. (2021), where they have been shown in the Lyapunov formulation.

More precisely, we show that an infinite network consisting of ISS systems is ISS provided that the discrete-time system induced by the gain operator has the so-called *monotone limit property*. This property concerns the input-to-state behavior of the discrete-time control system $x(k+1) \leq \Gamma(x(k))+u(k)$ defined via the gain operator Γ on the positive cone of the gain space. For finite networks, this property is equivalent to the strong small-gain condition used in Dashkovskiy et al. (2007, 2010). Hence, our result fully covers the classical nonlinear small-gain theorems developed in Dashkovskiy et al. (2007, 2010).

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

In this note, we omit all proofs and only present the main result. For much more on this topic, we refer the reader to the journal version of this paper Mironchenko et al. (2021). In the same paper, the relationships of the monotone limit property to various types of small-gain conditions have been studied, and a UGS small-gain theorem has been provided. For finitely many systems, our small-gain result has been shown in Mironchenko (2021), and we refer to this paper for the detailed discussion of the relationships between our main result and the available small-gain theorems for various classes of control systems, as well as for the other versions of small-gain theorems (e.g., small-gain theorems in maximum formulations).

Notation. We write $\mathbb{R}$ for the real numbers, $\mathbb{Z}$ for the integers, and $\mathbb{N}$ for natural numbers $1, 2, \ldots$. $\mathbb{R}_+$ and $\mathbb{Z}_+$ denote the sets of nonnegative reals and integers, respectively.

For a set U, we let $U^{\mathbb{R}_+}$ denote the space of all maps from $\mathbb{R}_+$ to U. By $\|w\|_{[0,t]}$ we denote the sup-norm of a bounded function $w : [0,t] \to W$, i.e., $\|w\|_{[0,t]} = \sup_{s\in[0,t]} \|w(s)\|_W$. Given a nonempty set I, we write $\ell_\infty(I)$ for the Banach space of all $x \in \mathbb{R}^I$ with $\|x\|_{\ell_\infty(I)} := \sup_{i\in I} |x(i)| < \infty$. Moreover, $\ell_\infty(I)^+ := \{x \in \ell_\infty(I) : x(i) \geq 0 \text{ for all } i \in I\}$. If $I = \mathbb{N}$, we simply write ℓ_∞ and ℓ_∞^+, respectively.

Throughout the paper, all considered vector spaces are vector spaces over $\mathbb{R}$. We use the standard classes $\mathcal{K}$, $\mathcal{K}_\infty$, $\mathcal{L}$, $\mathcal{KL}$ of comparison functions, see Kellett (2014).

2. CONTROL SYSTEMS AND THEIR STABILITY

In this paper, we define systems as follows.

Definition 2.1. Consider a triple $\Sigma = (X, \mathcal{U}, \phi)$ consisting of the following:

(i) A normed vector space $(X, \|\cdot\|_X)$, called the *state space*.

(ii) A vector space U of *input values* and a normed vector *space of inputs* $(\mathcal{U}, \|\cdot\|_\mathcal{U})$, where $\mathcal{U}$ is a linear subspace of $U^{\mathbb{R}_+}$. We assume that the following axioms hold:
- *The axiom of shift invariance*: for all $u \in \mathcal{U}$ and all $\tau \geq 0$, the time-shifted function $u(\cdot + \tau)$ belongs to $\mathcal{U}$ with $\|u\|_\mathcal{U} \geq \|u(\cdot + \tau)\|_\mathcal{U}$.
- *The axiom of concatenation*: for all $u_1, u_2 \in \mathcal{U}$ and for all $t > 0$ the concatenation of u_1 and u_2 at time t, defined by
$$u_1 \underset{t}{\diamondsuit} u_2(\tau) := \begin{cases} u_1(\tau) & \text{if } \tau \in [0,t], \\ u_2(\tau - t) & \text{otherwise} \end{cases}$$
belongs to $\mathcal{U}$.

(iii) A map $\phi : D_\phi \to X$, $D_\phi \subseteq \mathbb{R}_+ \times X \times \mathcal{U}$, called *transition map*, so that for all $(x,u) \in X \times \mathcal{U}$ it holds that $D_\phi \cap (\mathbb{R}_+ \times \{(x,u)\}) = [0, t_m) \times \{(x,u)\}$, for a certain $t_m = t_m(x,u) \in (0, +\infty]$. The corresponding interval $[0, t_m)$ is called the *maximal domain of definition* of the mapping $t \mapsto \phi(t,x,u)$, which we call a *trajectory* of the system.

The triple Σ is called a *(control) system* if it satisfies the following axioms:

(Σ1) *The identity property:* for all $(x,u) \in X \times \mathcal{U}$, it holds that $\phi(0,x,u) = x$.

(Σ2) *Causality:* for all $(t,x,u) \in D_\phi$ and $\tilde{u} \in \mathcal{U}$ such that $u(s) = \tilde{u}(s)$ for all $s \in [0,t]$, it holds that $[0,t] \times \{(x,\tilde{u})\} \subset D_\phi$ and $\phi(t,x,u) = \phi(t,x,\tilde{u})$.

(Σ3) *Continuity:* for each $(x,u) \in X \times \mathcal{U}$, the trajectory $t \mapsto \phi(t,x,u)$ is continuous on its maximal domain of definition.

(Σ4) *The cocycle property:* for all $x \in X$, $u \in \mathcal{U}$ and $t, h \geq 0$ so that $[0, t+h] \times \{(x,u)\} \subset D_\phi$, we have $\phi(h, \phi(t,x,u), u(t+\cdot)) = \phi(t+h, x, u)$.

We call the Σ *forward complete* if $D_\phi = \mathbb{R}_+ \times X \times \mathcal{U}$, i.e., $\phi(t,x,u)$ is defined for all $(t,x,u) \in \mathbb{R}_+ \times X \times \mathcal{U}$.

This class of systems encompasses control systems generated by ordinary differential equations, switched systems, time-delay systems, many classes of PDEs, important classes of boundary control systems, etc.

For the prolongation of trajectories of control systems, the following notion is of importance (Karafyllis and Jiang, 2011, Def. 1.4).

Definition 2.2. We say that a system Σ satisfies the *boundedness-implies-continuation (BIC) property* if for each $(x,u) \in X \times \mathcal{U}$ such that the maximal existence time $t_m = t_m(x,u)$ is finite, for any given $M > 0$ there exists $t \in [0, t_m)$ with $\|\phi(t,x,u)\|_X > M$.

Next, we introduce the input-to-state stability property, which unifies the classical asymptotic stability concept with the input-output stability notion, and is one of the cornerstones of nonlinear control theory as argued in Kokotović and Arcak (2001); Sontag (2008).

Definition 2.3. A system $\Sigma = (X, \mathcal{U}, \phi)$ is called *(uniformly) input-to-state stable (ISS)* if there exist $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}_\infty$ such that for all $(t,x,u) \in D_\phi$
$$\|\phi(t,x,u)\|_X \leq \beta(\|x\|_X, t) + \gamma(\|u\|_\mathcal{U}).$$

3. INFINITE INTERCONNECTIONS

This section introduces (feedback) interconnections of an arbitrary number of control systems, indexed by some nonempty set I. For each $i \in I$, let $(X_i, \|\cdot\|_{X_i})$ be a normed vector space which serves as the state space of a control system Σ_i. Before we can specify the space of inputs for Σ_i, we first have to construct the overall state space. Below, we use the sequence notation $(x_i)_{i\in I}$ for functions with domain I. The overall state space is then defined as
$$X := \left\{(x_i)_{i\in I} : x_i \in X_i,\ \forall i \in I \text{ and } \sup_{i\in I} \|x_i\|_{X_i} < \infty\right\}$$
and becomes a normed vector space with the norm
$$\|x\|_X := \sup_{i\in I} \|x_i\|_{X_i}.$$

We also define for each $i \in I$ the normed vector space $X_{\neq i}$ by the same construction as above, but for the restricted index set $I \setminus \{i\}$.

Now consider for each $i \in I$ a control system of the form
$$\Sigma_i = (X_i, \mathrm{PC}_b(\mathbb{R}_+, X_{\neq i}) \times \mathcal{U}, \bar{\phi}_i),$$
where $\mathrm{PC}_b(\mathbb{R}_+, X_{\neq i})$ is the space of all globally bounded piecewise continuous functions $w : \mathbb{R}_+ \to X_{\neq i}$, with the norm $\|w\|_\infty = \sup_{t\geq 0} \|w(t)\|_{X_{\neq i}}$. The norm on $\mathrm{PC}_b(\mathbb{R}_+, X_{\neq i}) \times \mathcal{U}$ is defined by

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$$\|(w,u)\|_{\mathrm{PC}_b(\mathbb{R}_+,X_{\neq i})\times\mathcal{U}} := \max\{\|w\|_\infty, \|u\|_\mathcal{U}\}. \quad (1)$$

Here we assume that $\mathcal{U} \subset U^{\mathbb{R}_+}$ for some vector space U, and $\mathcal{U}$ satisfies the axioms of shift invariance and concatenation. Then, by the definition of $\mathrm{PC}_b(\mathbb{R}_+, X_{\neq i})$ and the norm (1), these axioms are also satisfied for the product space $\mathrm{PC}_b(\mathbb{R}_+, X_{\neq i}) \times \mathcal{U}$.

Definition 3.1. Given the control systems Σ_i ($i \in I$) as above, we call a control system of the form $\Sigma = (X, \mathcal{U}, \phi)$ a *(feedback) interconnection* of the systems Σ_i if the following holds:

(i) The components ϕ_i of the transition map $\phi : D_\phi \to X$ satisfy
$$\phi_i(t,x,u) = \bar{\phi}_i(t, x_i, (\phi_{\neq i}, u)) \quad \text{for all } (t,x,u) \in D_\phi,$$
where $\phi_{\neq i}(\cdot) = (\phi_j(\cdot, x, u))_{j\in I\setminus\{i\}}$ for all $i \in I$. [1]

(ii) Σ has the BIC property.

We then call $X_{\neq i}$ the space of *internal input values*, $\mathrm{PC}_b(\mathbb{R}_+, X_{\neq i})$ the space of *internal inputs*, and $\mathcal{U}$ the space of *external inputs* of the system Σ_i. Moreover, we call Σ_i the *i-th subsystem* of Σ.

Let us define the concept of input-to-state stability for subsystems of a network.

Definition 3.2. Given the spaces $(X_j, \|\cdot\|_{X_j})$, $j \in I$, and the system Σ_i for a fixed $i \in I$, we say that Σ_i is *input-to-state stable (ISS) (in semimaximum formulation)* if Σ_i is forward complete and there are $\gamma_{ij}, \gamma_j \in \mathcal{K} \cup \{0\}$ for all $j \in I$, and $\beta_i \in \mathcal{KL}$ such that for all initial states $x_i \in X_i$, all internal inputs $w_{\neq i} = (w_j)_{j\in I\setminus\{i\}} \in \mathrm{PC}_b(\mathbb{R}_+, X_{\neq i})$, all external inputs $u \in \mathcal{U}$ and $t \geq 0$ it holds that
$$\|\bar{\phi}_i(t,x_i,(w_{\neq i},u))\|_{X_i} \leq \beta_i(\|x_i\|_{X_i}, t) + \sup_{j\in I}\gamma_{ij}(\|w_j\|_{[0,t]}) + \gamma_i(\|u\|_\mathcal{U}).$$

Here we assume that the functions γ_{ij} satisfy $\sup_{j\in I}\gamma_{ij}(r) < \infty$ for every $r \geq 0$ (implying that rhs is finite) and $\gamma_{ii} = 0$.

The functions γ_{ij} and γ_i in this definition are called *(nonlinear) gains*. For notational simplicity, we allow the case $\gamma_{ij} = 0$ for $j \neq i$.

Assuming that all systems Σ_i, $i \in I$, are ISS in semimaximum formulation, define a nonlinear monotone operator $\Gamma_\otimes : \ell_\infty(I)^+ \to \ell_\infty(I)^+$ from the gains γ_{ij} as follows:
$$\Gamma_\otimes(s) := \big(\sup_{j\in I}\gamma_{ij}(s_j)\big)_{i\in I}, \quad s = (s_i)_{i\in I} \in \ell_\infty(I)^+. \quad (2)$$

$\Gamma_\otimes$ is well-defined iff the following assumption holds.

Assumption 3.1. For every $r > 0$, we have
$$\sup_{i,j\in I}\gamma_{ij}(r) < \infty.$$

Also, observe that $\Gamma_\otimes$ is a monotone operator:
$$s^1 \leq s^2 \quad \Rightarrow \quad \Gamma_\otimes(s^1) \leq \Gamma_\otimes(s^2) \quad \text{for all } s^1, s^2 \in \ell_\infty(I)^+.$$

4. SMALL-GAIN THEOREM

We consider the system
$$x(k+1) \leq \Gamma_\otimes(x(k)) + u(k), \quad k \in \mathbb{Z}_+, \quad (3)$$
where $u \in \ell_\infty(\mathbb{Z}_+, \ell^+_\infty(I)) := \{u = (u(k))_{k\in\mathbb{Z}_+} : u(k) \in \ell^+_\infty(I),\ \|u\|_\infty := \sup_{k\in\mathbb{Z}_+}\|u(k)\|_X < \infty\}$.

As we will see, the stability properties of the interconnection will depend on the stability properties of the discrete-time system (3) induced by the gain operator.

Definition 4.1. System (3) has the *monotone limit property (MLIM)* if there is $\xi \in \mathcal{K}_\infty$ such that for every $\varepsilon > 0$ and $u \in \ell_\infty(\mathbb{Z}_+, \ell^+_\infty(I))$ and any solution $x(\cdot) = (x(k))_{k\in\mathbb{Z}_+}$ of (3) with $x(k+1) \leq x(k)$ for all $k \in \mathbb{Z}_+$, there exists $N = N(\varepsilon, u, x(\cdot)) \in \mathbb{Z}_+$ with
$$\|x(N)\|_X \leq \varepsilon + \xi(\|u\|_\infty).$$

Now we can state our main result.

Theorem 4.1. **(Nonlinear ISS small-gain theorem)** Let I be an arbitrary nonempty index set, $(X_i, \|\cdot\|_{X_i})$, $i \in I$ be normed spaces and $\Sigma_i = (X_i, \mathrm{PC}_b(\mathbb{R}_+, X_{\neq i}) \times \mathcal{U}, \bar{\phi}_i)$ be forward complete control systems. Assume that the interconnection $\Sigma = (X, \mathcal{U}, \phi)$ of the systems Σ_i is well-defined. Furthermore, let the following be satisfied:

(i) Each system Σ_i is ISS in the sense of Definition 3.2 with $\beta_i \in \mathcal{KL}$ and nonlinear gains $\gamma_{ij}, \gamma_i \in \mathcal{K} \cup \{0\}$.

(ii) There are $\beta_{\max} \in \mathcal{KL}$ and $\gamma_{\max} \in \mathcal{K}$ so that $\beta_i \leq \beta_{\max}$ and $\gamma_i \leq \gamma_{\max}$ pointwise for all $i \in I$.

(iii) Assumption 3.1 holds and the discrete-time system
$$w(k+1) \leq \Gamma_\otimes(w(k)) + v(k), \quad (4)$$
with $w(\cdot), v(\cdot)$ taking values in $\ell_\infty(I)^+$ has the MLIM property.

Then Σ is ISS.

If all interconnection gains γ_{ij} are linear, the small-gain condition in our theorem can be formulated more directly in terms of the gains, as the following corollary shows.

Corollary 4.1. **(Linear ISS small-gain theorem)** Given an interconnection $(\Sigma, \mathcal{U}, \phi)$ of systems Σ_i as in Theorem 4.1, additionally to the assumptions (i) and (ii) of this theorem, assume that all gains γ_{ij} are linear functions (and hence can be identified with nonnegative real numbers), $\Gamma_\otimes$ is well-defined and the following condition holds:
$$\lim_{n\to\infty}\Big(\sup_{j_1,\dots,j_{n+1}\in I}\gamma_{j_1j_2}\cdots\gamma_{j_nj_{n+1}}\Big)^{1/n} < 1. \quad (5)$$
Then Σ is ISS.

As an example, consider an infinite interconnection
$$\dot{x}_i = -x_i^3 + \max\{ax_{i-1}^3, bx_{i+1}^3, u\}, \quad i \in \mathbb{Z}, \quad (6)$$
where $a, b > 0$. Each Σ_i is a scalar system with the state $x_i \in \mathbb{R}$, internal inputs x_{i-1}, x_{i+1} and an external input u, belonging to the input space $\mathcal{U} := L_\infty(\mathbb{R}_+, \mathbb{R})$. Let the state space for the interconnection Σ be $X := \ell_\infty(\mathbb{Z})$.

It is not hard to show that this interconnection is well-posed. The stability of this network follows from:

Proposition 4.1. The coupled system (6) is ISS if and only if $\max\{a, b\} < 1$.

Proof. "⇒": For any $a, b > 0$ consider the scalar equation
$$\dot{z} = -(1 - \max\{a, b\})z^3,$$
subject to an initial condition $z(0) = x^*$. The function $y : t \mapsto (z(t))_{i\in\mathbb{Z}}$ is a solution of (6) subject to an initial

[1] By the causality axiom, we can assume that $\phi_{\neq i}$ is globally bounded, since $\bar{\phi}_i(t, x_i, (\phi_{\neq i}, u))$ does not depend on the values $\phi_{\neq i}(s)$ with $s > t$, and on the compact interval $[0, t]$, $\phi_{\neq i}$ is bounded because it is continuous.

condition $(x^*)_{i\in\mathbb{Z}}$ and input $u \equiv 0$. This shows that if $\max\{a, b\} \geq 1$, then the system (6) is not ISS.

"$\Leftarrow$": Consider x_{i-1}, x_{i+1} and u as inputs to the x_i-subsystem of (6) and define $q := \max\{ax_{i-1}^3, bx_{i+1}^3, u\}$. The derivative of $|x_i(\cdot)|$ along the trajectory satisfies for almost all t the following inequality:

$$\frac{\mathrm{d}}{\mathrm{d}t}|x_i(t)| \leq -|x_i(t)|^3 + q(t) \leq -|x_i(t)|^3 + \|q\|_\infty.$$

For any $\varepsilon > 0$, if $\|q\|_\infty \leq \frac{1}{1+\varepsilon}|x_i(t)|^3$, we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}|x_i(t)| \leq -\frac{\varepsilon}{1+\varepsilon}|x_i(t)|^3.$$

Arguing as in the proof of direct Lyapunov theorems ($x_i \mapsto |x_i|$ is an ISS Lyapunov function for the x_i-subsystem), see, e.g., (Sontag and Wang, 1995, Lem. 2.14), we obtain that there is $\beta \in \mathcal{KL}$ such that for all $t \geq 0$ it holds that

$$\begin{aligned}
&|x_i(t)| \leq \beta(|x_i(0)|, t) + \big((1+\varepsilon)\|q\|_\infty\big)^{\frac{1}{3}} \\
&= \beta(|x_i(0)|, t) + \max\{a_1\|x_{i-1}\|_\infty, b_1\|x_{i+1}\|_\infty, (1+\varepsilon)^{\frac{1}{3}}\|u\|_\infty^{\frac{1}{3}}\} \\
&\leq \beta(|x_i(0)|, t) + \max\{a_1\|x_{i-1}\|_\infty, b_1\|x_{i+1}\|_\infty\} + (1+\varepsilon)^{\frac{1}{3}}\|u\|_\infty^{\frac{1}{3}},
\end{aligned}$$

where $a_1 = (1+\varepsilon)^{\frac{1}{3}}a^{\frac{1}{3}}$, $b_1 = (1+\varepsilon)^{\frac{1}{3}}b^{\frac{1}{3}}$.

This shows that the x_i-subsystem is ISS in semimaximum formulation with the corresponding homogeneous gain operator $\Gamma : \ell_\infty^+(\mathbb{Z}) \to \ell_\infty^+(\mathbb{Z})$ given for all $s = (s_i)_{i\in\mathbb{Z}}$ by $\Gamma(s) = (\max\{a_1 s_{i-1}, b_1 s_{i+1}\})_{i\in\mathbb{Z}}$.

Previous computations are valid for all $\varepsilon > 0$. Now pick $\varepsilon > 0$ such that $a_1 < 1$ and $b_1 < 1$, which is possible as $a \in (0, 1)$ and $b \in (0, 1)$. The ISS of the network follows by Corollary 4.1. □

Distributed control barrier function-based control scheme for multi-agent systems under a collective constraint ⋆

Xiao Tan * **Dimos V. Dimarogonas** *

* *School of EECS, KTH Royal Institute of Technology, Sweden*
(e-mail: xiaotan, dimos@kth.se*)*

Abstract: In this work, we consider multi-agent systems (MAS) operating under a collective constraint, i.e., a constraint that involves the collective states of MAS, using control barrier function (CBF) technique. CBF-based control design usually consists of designing a task-achieving controller, and modifying it minimally in a quadratic program (QP) to satisfy the state constraint. Despite its success for single-agent systems, most existing CBF-based control designs for MAS are either centralized or sub-optimal. Our proposed distributed CBF-based control scheme guarantees that the optimal to the QP control signals are obtained in finite time, and the collective constraint is satisfied for all time. The result is valid for a large class of MAS (linear or nonlinear, homogeneous or heterogeneous), underlying tasks (consensus, formation, coverage, etc), and collective constraints. We also analyze another scheme with some comparative remarks. Several numerical examples are shown.

Keywords: Multi-agent systems, constrained control, control barrier functions, distributed control, distributed optimization

1. INTRODUCTION

Control designs for dynamical systems under state/output constraints have been under extensive investigations in the literature. Many nonlinear control techniques are proposed, including potential fields, barrier-Lyapunov functions, and prescribed performance control. A recent technique called control barrier functions (CBF) (Xu et al. (2015); Tan et al. (2021)) has gained new attention. CBF provides a point-wise linear inequality condition on the system input, and by enforcing this condition at every state, the forward invariance of the safety set is guaranteed. This technique goes hand-in-hand with a computationally efficient, modular implementation leveraging quadratic programs that renders a pre-designed nominal controller to be safe in a minimal invasive manner. This methodology has been widely investigated and applied with practical success for single-agent systems.

Constraints considered for MAS are mainly defined locally in the literature, i.e., the satisfaction/violation of the constraints can be determined based on local information. These constraints are agent-wise and edge-wise state constraints; the later includes, e.g., collision avoidance, connectivity maintenance (see, e.g., Panagou et al. (2015)) and transient bounds of relative distances. In comparison, collective constraints are defined over the collective state of the MAS and cannot be evaluated to be violated or not using only local information. Some examples of collective constraints are the global connectivity maintenance (Capelli and Sabattini (2020)) and collective state boundedness constraint. Enforcing collective constraints in a distributed manner is in general more challenging since every agent can only obtain local information and make a decision based on it, while not knowing whether the constraint is satisfied. One common practice to enforce a collective constraint is to conservatively decompose it into several local ones.

There are many attempts extending the CBF framework to multi-agent systems. Rather straightforwardly, the CBF technique gives out a quadratic program with coupling constraints. In most works along this direction, the quadratic program is either solved in a centralized manner (Capelli and Sabattini (2020)), i.e, by a central module that has access to the states of every agent, or using a pre-allocation scheme (Wang et al. (2017)) that distributes the linear constraint among the agents involved. With the pre-allocation scheme, the optimality of the original quadratic program is generally lost. One could tackle this problem from a distributed optimization (Chen et al. (2020); Santilli et al. (2020)) perspective, which however no theoretical guarantees can be asserted regarding the satisfaction of the safety-certifying conditions during the solution iterations. This can potentially lead to unsafe behaviors. In general, a distributed implementation of CBF conditions is lacking.

In this extended abstract, we consider multi-agent systems under a collective constraint using control barrier function techniques. We propose two distributed implementations: one consists of local quadratic programs and an adaptive auxiliary variable that connects the local QPs. We show that, using this implementation scheme, the optimality

condition of the original quadratic program will be fulfilled in finite time and the CBF condition is satisfied for all time. Main results have been reported in Tan and Dimarogonas (2021), yet some interesting but unmentioned aspects are identified here. Another implementation is more straightforward and leverages on average tracking algorithms, which, however, cannot guarantee the satisfaction of CBF condition for all time. Applications to a formation control problem with collective state boundedness constraint are demonstrated for both schemes.

2. PROBLEM FORMULATION

Consider a multi-agent system with N agents indexed by $\mathcal{I} = \{1, 2, ..., N\}$ whose communication graph $\mathcal{G} = (\mathcal{I}, E)$ is connected and undirected. $(i, j) \in E$ represents that the agents i, j can communicate with each other. The associated Laplacian matrix is denoted as L and the neighborhood set of agent i is defined as $N_i := \{j \in \mathcal{I} : (i, j) \in E\}$. The dynamics of agent $i \in \mathcal{I}$ is given by $\dot{\boldsymbol{x}}_i = \mathfrak{f}_i(\boldsymbol{x}_i) + \mathfrak{g}_i(\boldsymbol{x}_i)\boldsymbol{u}_i$, where the state $\boldsymbol{x}_i \in \mathbb{R}^{n_i}$, and the control input $\boldsymbol{u}_i \in \mathbb{R}^{m_i}$, $\mathfrak{f}_i(\boldsymbol{x}_i)$, $\mathfrak{g}_i(\boldsymbol{x}_i)$ are locally Lipschitz functions in $\boldsymbol{x}_i$. We denote the stacked state $\boldsymbol{x} := (\boldsymbol{x}_1^\top, \boldsymbol{x}_2^\top, ..., \boldsymbol{x}_N^\top)^\top \in \mathbb{R}^n, n := \sum_{i\in\mathcal{I}} n_i$, the stacked control input $\boldsymbol{u} := (\boldsymbol{u}_1^\top, \boldsymbol{u}_2^\top, ..., \boldsymbol{u}_N^\top)^\top \in \mathbb{R}^m, m = \sum_{i\in\mathcal{I}} m_i$, the stacked vector fields $\mathfrak{f} = (\mathfrak{f}_1^\top, \mathfrak{f}_2^\top, ..., \mathfrak{f}_N^\top)^\top$ and $\mathfrak{g} = \text{blk}(\mathfrak{g}_1, \mathfrak{g}_2, ..., \mathfrak{g}_N)$. Thus, the stacked dynamics is

$$\dot{\boldsymbol{x}} = \mathfrak{f}(\boldsymbol{x}) + \mathfrak{g}(\boldsymbol{x})\boldsymbol{u}. \tag{1}$$

We denote the stacked locally available state to agent i as $\boldsymbol{x}_{loc,i} := (\boldsymbol{x}_i^\top, \boldsymbol{x}_{j_1}^\top, ..., \boldsymbol{x}_{j_{|N_i|}}^\top)^\top, j_k \in N_i$, for $k \in \{1, 2, ..., |N_i|\}$.

In this work, we consider collective constraints for MAS, i.e., the stacked state $\boldsymbol{x}$ is expected to evolve within a safety set, denoted as a superlevel set of a differentiable function $h : \mathbb{R}^n \to \mathbb{R}$:

$$\mathscr{C} = \{\boldsymbol{x} \in \mathbb{R}^n : h(\boldsymbol{x}) \geq 0\}. \tag{2}$$

Definition 1. (CBF). $h(\boldsymbol{x})$ in (2) is a control barrier function (CBF) for MAS (1) if there exists a locally Lipschitz extended class $\mathcal{K}$ function α such that:

$$\sup_{\boldsymbol{u}\in\mathbb{R}^m} [L_{\mathfrak{f}} h(\boldsymbol{x}) + L_{\mathfrak{g}} h(\boldsymbol{x})\boldsymbol{u} + \alpha(h(\boldsymbol{x}))] \geq 0, \ \forall \boldsymbol{x} \in \mathbb{R}^n \tag{3}$$

Xu et al. (2015); Tan et al. (2021) showed that any locally Lipschitz control input $\boldsymbol{u}$ that satisfies the CBF condition (3) renders the set $\mathscr{C}$ forward invariant and, if $\mathscr{C}$ is compact, asymptotically stable.

Assumption 1. The parameters in the CBF condition (3) are locally obtainable, i.e, the argument of (3) can be written in the form of

$$\sum_{i\in\mathcal{I}} \boldsymbol{a}_i^\top(\boldsymbol{x}_{loc,i})\boldsymbol{u}_i + \sum_{i\in\mathcal{I}} b_i(\boldsymbol{x}_{loc,i}) \leq 0. \tag{4}$$

This assumption admits a variety of collective constraints including, but not limited to, the examples below:

(1) $h(\boldsymbol{x}) = \sum_{i\in\mathcal{I}} h_i(\boldsymbol{x}_i)$ with h_i differentiable. One example is the collective state boundedness constraint: $h(\boldsymbol{x}) = \sum_{i\in\mathcal{I}}(r^2 - \|\boldsymbol{x}_i\|^2)$ for some constant $r > 0$.
(2) $h(\boldsymbol{x}) = \sum_{l\in\mathscr{L}} h_l(\boldsymbol{x}_{l_i}, \boldsymbol{x}_{l_j})$, $\mathscr{L} \subset \mathbb{N}$ with $h_l(\cdot, \cdot)$ differentiable, $(l_i, l_j) \in E$. This could encode, for example, a least collective interaction level among all connected agents $h(\boldsymbol{x}) = \sum_{(i,j)\in E}(e^{-r_0\|\boldsymbol{x}_i - \boldsymbol{x}_j\|^2} - r_1)$ for some constants $0 < r_0, 0 < r_1 < 1$.

Remark 1. Assumption 1 indeed excludes some possible CBFs. However, the assumption could serve as a design principle for the communication topology of MAS if a particular collective constraint is given and, from Assumption 1, we know which communication links are relevant.

Assuming that nominal controllers are obtained by some distributed coordination protocol, i.e, $\boldsymbol{u}_{nom,i}(\boldsymbol{x}_{loc,i})$, we straightforwardly obtain the CBF-induced QP given as

$$\begin{aligned} &\min_{\boldsymbol{u}\in\mathbb{R}^m} \sum_{i\in\mathcal{I}} \frac{1}{2}\|\boldsymbol{u}_i - \boldsymbol{u}_{nom,i}(\boldsymbol{x}_{loc,i})\|^2 \\ &s.t. \ \sum_{i\in\mathcal{I}} \boldsymbol{a}_i^\top(\boldsymbol{x}_{loc,i})\boldsymbol{u}_i + \sum_{i\in\mathcal{I}} b_i(\boldsymbol{x}_{loc,i}) \leq 0. \end{aligned} \tag{5}$$

The intuition behind this QP is that the control signal is obtained by modifying the nominal controller subject to the safety condition in a minimum invasive manner. In the following we denote for brevity $\boldsymbol{a}_i, b_i, \boldsymbol{u}_{nom,i}$ when no ambiguity occurs. Defining $\bar{\boldsymbol{a}} = (\boldsymbol{a}_1^\top, \boldsymbol{a}_2^\top, ..., \boldsymbol{a}_N^\top)^\top$, $\bar{b} = \sum_{i\in\mathcal{N}} b_i$ and $\boldsymbol{u}_{nom} = (\boldsymbol{u}_{nom,1}^\top, \boldsymbol{u}_{nom,2}^\top, ..., \boldsymbol{u}_{nom,N}^\top)^\top$.

Remark 2. Here we assume agent dynamics to be control affine which encapsulates linear dynamics and a large class of nonlinear dynamics. Moreover, the agent dynamics and even the dimensions of state variables can be different among the agents. The distributed coordination protocol, which relates to the underlying tasks of the MAS, is designed independently.

Note that $\boldsymbol{a}_i, b_i, \boldsymbol{u}_{nom,i}$ are defined along the system trajectory, thus their values evolve with time. In the following we analyze the frozen-time optimality condition and provide two schemes that both guarantee the convergence to the time-varying solution optimal to QP in (5) in finite time.

3. MAIN RESULT

In this section, we will analyze the explicit solution to the QP in (5) and a distributed, yet equivalent QP, and then propose a distributed implementation that solves the original QP online while always enforcing the coupling constraint. We will also analyze another distributed implementation with some comparative remarks. Proofs of all the claims in Sec. 3.1 and Sec. 3.2 can be found in Tan and Dimarogonas (2021).

3.1 Explicit solution analysis and an equivalent QP

If the QP in (5) is feasible, then the optimal solution is explicitly given as

$$\boldsymbol{u}_i^\star = \boldsymbol{u}_{nom,i} - \max(0, (\bar{\boldsymbol{a}}^\top \boldsymbol{u}_{nom} + \bar{b})/\|\bar{\boldsymbol{a}}\|^2)\boldsymbol{a}_i, \forall i \in \mathcal{I}. \tag{6}$$

Although $\boldsymbol{u}_{nom,i}$ and $\boldsymbol{a}_i$ in (6) only require local information, the calculation of $(\bar{\boldsymbol{a}}^\top \boldsymbol{u}_{nom} + \bar{b})/\|\bar{\boldsymbol{a}}\|^2$ requires global information.

The QP problem in (5) can be equivalently given by

$$\begin{aligned} &\min_{(\boldsymbol{u},\boldsymbol{y})\in\mathbb{R}^{m+N}} \sum_{i\in\mathcal{I}} \frac{1}{2}\|\boldsymbol{u}_i - \boldsymbol{u}_{nom,i}\|^2 \\ &s.t. \ \boldsymbol{a}_i^\top \boldsymbol{u}_i + \sum_{j\in N_i} (y_i - y_j) + b_i \leq 0, \ \forall i \in \mathcal{I}, \end{aligned} \tag{7}$$

where $\boldsymbol{y} = (y_1, y_2, ..., y_N) \in \mathbb{R}^N$ is an auxiliary decision variable. One could relate y_i with agent i and view $(\boldsymbol{x}_i, y_i)$ as an extended state of agent i. By analyzing its Lagrangian and KKT condition, we obtain, as expected, the optimal $\boldsymbol{u}_i^\star, i \in \mathcal{I}$, to (7) is the same as (6).

For the optimality condition for $\boldsymbol{y}^\star$, one observation is that $\boldsymbol{y}^\star$ is not unique: suppose $(\boldsymbol{u}^\star, \boldsymbol{y}')$ is an optimal solution to (7), then $(\boldsymbol{u}^\star, \boldsymbol{y}' + \beta \mathbf{1}_N), \beta \in \mathbb{R}$ is also an optimal solution. One sufficient condition on the optimal $\boldsymbol{y}^\star$ is

$$\boldsymbol{a}_i^\top \boldsymbol{u}_{nom,i} + \boldsymbol{l}_i \boldsymbol{y}^\star + b_i = c \boldsymbol{a}_i^\top \boldsymbol{a}_i, \ \forall i \in \mathcal{I} \tag{8}$$

with $c = (\bar{\boldsymbol{a}}^\top \boldsymbol{u}_{nom} + \bar{b})/\|\bar{\boldsymbol{a}}\|^2$.

3.2 Distributed Implementation

We propose a distributed implementation scheme that combines an adaptive law that locally updates y_i and a local QP with only the decision variable $\boldsymbol{u}_i$. Specifically, for each agent i, $\forall i \in \mathcal{I}$, we solve

$$\begin{aligned} &\min_{\boldsymbol{u}_i \in \mathbb{R}^{m_i}} \frac{1}{2}\|\boldsymbol{u}_i - \boldsymbol{u}_{nom,i}\|^2 \\ &s.t. \ \boldsymbol{a}_i^\top \boldsymbol{u}_i + \sum_{j \in N_i} (y_i - y_j) + b_i \le 0, \end{aligned} \tag{9}$$

and y_i is updated locally that will be derived later.

Proposition 1. If the local QPs given in (9) are feasible, i.e, $\sum_{j \in N_i}(y_i - y_j) + b_i \le 0$ whenever $\boldsymbol{a}_i = \mathbf{0}, \forall i \in \mathcal{I}$, then the solution $\bar{\boldsymbol{u}}^\star = (\boldsymbol{u}_1^\star, \boldsymbol{u}_2^\star, ..., \boldsymbol{u}_N^\star)$ to the local QPs satisfies $\bar{\boldsymbol{a}}^\top \bar{\boldsymbol{u}}^\star + \bar{b} \le 0$ for any value of $\boldsymbol{y}$.

This property is of interest because it states that whatever $\boldsymbol{y}$ is chosen, the safety guarantee is enforced whenever the local QPs are feasible.

Proposition 2. Assume that $\boldsymbol{a}_i \neq \mathbf{0}$ for all $i \in \mathcal{I}$. Define $c_i = \frac{1}{\boldsymbol{a}_i^\top \boldsymbol{a}_i}(\boldsymbol{l}_i \boldsymbol{y} + \boldsymbol{a}_i^\top \boldsymbol{u}_{nom,i} + b_i), i \in \mathcal{I}$ If $\boldsymbol{y}$ is chosen such that $c_i = c_j$ for any $i, j \in \mathcal{I}$, then the condition in (8) is satisfied.

In the following, an adaptive law for $\boldsymbol{y}$ is derived such that $\boldsymbol{c} = (c_1, c_2, ..., c_N)$ reaches a consensus in finite time even in the presence of slowly time-varying $\boldsymbol{a}_i, \boldsymbol{u}_{nom,i}, \boldsymbol{b}_i$. We note that the consensus algorithm is inspired by Franceschelli et al. (2014).

Proposition 3. Assume that $\boldsymbol{a}_i, \boldsymbol{u}_{nom,i}, \boldsymbol{b}_i$ are slowly time-varying in the sense that $\sum_{i \in \mathcal{I}} |\frac{d}{dt}(\boldsymbol{a}_i^\top \boldsymbol{a}_i) c_i(t) + \frac{d}{dt}(\boldsymbol{a}_i^\top \boldsymbol{u}_{nom,i} + b_i)| \le D$ for some $D > 0$ and $a_{min} \le \boldsymbol{a}_i^\top \boldsymbol{a}_i \le a_{max}$ for some positive constants a_{min}, a_{max} for all $i \in \mathcal{I}$. If the discontinuous adaptive law

$$\dot{\boldsymbol{y}} = -k_0 \text{sign}(L\boldsymbol{c}), \tag{10}$$

is applied, and the gain k_0 satisfies

$$k_0 \ge a_{max}(2\delta_{max} D / a_{min} + \epsilon), \tag{11}$$

where $\delta_{max} := \max_{i \in \mathcal{I}} |N_i|$, ϵ is a positive constant, then $c_i = c_j, \forall i, j \in \mathcal{I}$, within a finite time $t_r \le \frac{\|L\boldsymbol{c}(0)\|_1}{\epsilon}$.

Now we summarize the theoretical guarantees.

Theorem 1. Consider the CBF-induced quadratic program in (5). Assume that the conditions in Proposition 3 hold. Then the solution to the local QPs in (9) with $\boldsymbol{y}$ locally updated according to (10) solves the QP (5) in finite time. Moreover, the coupling constraint in (5) is satisfied for all time.

Remark 3. Instead of solving N local QPs as in (9) online, we could apply analytical solutions to the local QPs that are given by $\boldsymbol{u}_i = \boldsymbol{u}_{nom,i} - \max(0, c_i)\boldsymbol{a}_i, \ \forall i \in \mathcal{I}$.

3.3 Another distributed implementation

Taking a further look at the centralized optimal solution (6), we observe that the only variable that needs global information is $\frac{\sum_{i \in \mathcal{I}} \boldsymbol{a}_i^\top \boldsymbol{u}_{nom,i} + b_i}{\sum_{i \in \mathcal{I}} (\boldsymbol{a}_i^\top \boldsymbol{a}_i)}$. In this subsection, we propose another distributed implementation. For notational brevity, let $d_i(t) := \boldsymbol{a}_i^\top \boldsymbol{u}_{nom} + b_i$ and $e_i(t) := \boldsymbol{a}_i^\top \boldsymbol{a}_i$. Viewing $d_i(t)$ and $e_i(t)$ as two reference signals, we utilize distributed average tracking algorithms such that each agent tracks $\sum_{i \in \mathcal{I}} d_i/N$ and $\sum_{i \in \mathcal{I}} e_i/N$, respectively. Once each agent has the accurate averages, a local division between them gives $\sum_{i \in \mathcal{I}} d_i / \sum_{i \in \mathcal{I}} e_i$. More technical details are given below.

The scheme is implemented as follows. For agent i, define two extra local variables $p_i(t), q_i(t) \in \mathbb{R}$ whose dynamics are given by

$$\begin{aligned} \dot{z}_{1,i} &= \beta \sum_{j \in N_i} \text{sign}(p_j - p_i), z_{1,i}(0) = 0, \\ p_i(t) &= z_{1,i}(t) + d_i(t) \end{aligned} \tag{12}$$

and

$$\begin{aligned} \dot{z}_{2,i} &= \beta \sum_{j \in N_i} \text{sign}(q_j - q_i), z_{2,i}(0) = 0 \\ q_i(t) &= z_{2,i}(t) + e_i(t), \end{aligned} \tag{13}$$

where $z_{1,i}, z_{2,i}$ are local internal states. The input of agent i is chosen as

$$\boldsymbol{u}_i = \begin{cases} \boldsymbol{u}_{nom,i} - \max(0, p_i/q_i)\boldsymbol{a}_i, & \text{if } q_i \neq 0; \\ \boldsymbol{u}_{nom,i}, & \text{otherwise} \end{cases} \forall i \in \mathcal{I}. \tag{14}$$

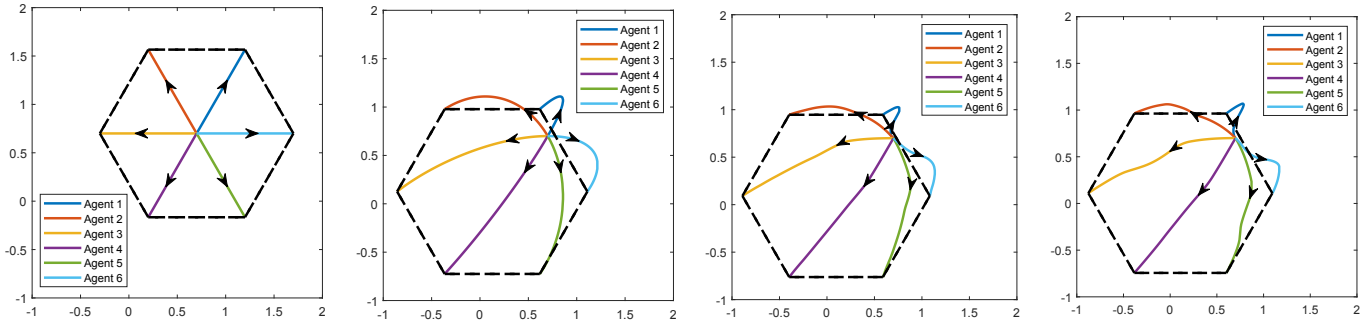
Theorem 2. Assume that $\sup_{t \in [0,\infty)} \max(|\dot{d}_i(t)|, |\dot{e}_i(t)|) \le \bar{d}$ for all $i \in \mathcal{I}$ and some positive constants $\bar{d}$, and $\sum_{i \in \mathcal{I}} e_i(t) > 0, \forall t > 0$. If we choose $\beta > \bar{d}$, then the agent input in (14) is optimal to the QP in (5) after time $T = \max\{\sum_{i \in \mathcal{I}} \sum_{j \in N_i} |p_j(0) - p_i(0)|, \sum_{i \in \mathcal{I}} \sum_{j \in N_i} |q_j(0) - q_i(0)|\}/2(\beta - \bar{d})$.

Proof. From Theorem 1 of Chen et al. (2012), since $\beta > \bar{d}$, $p_i(t), q_i(t)$ accurately tracks $\sum_{i \in \mathcal{I}} d_i/N$ and $\sum_{i \in \mathcal{I}} e_i/N$, respectively in finite time T. In view of $\boldsymbol{u}_i^\star$ given in (6), the input signal in (14) coincide with $\boldsymbol{u}_i^\star$ after T.

Remark 4. Both implementations assume slow dynamics of $\boldsymbol{a}_i, \boldsymbol{u}_{nom,i}$ and b_i, and use non-smooth analysis arguments to obtain a finite-time convergence result. One notable difference is that the implementation in Sec. 3.3 relaxes the requirement that $\boldsymbol{a}_i(t) \neq \mathbf{0}$ for all $i \in \mathcal{I}, t > 0$, which could be advantageous in many applications. However, it also fails to guarantee the satisfaction of the CBF condition during $[0, T]$, while the other one in Sec. 3.2 guarantees.

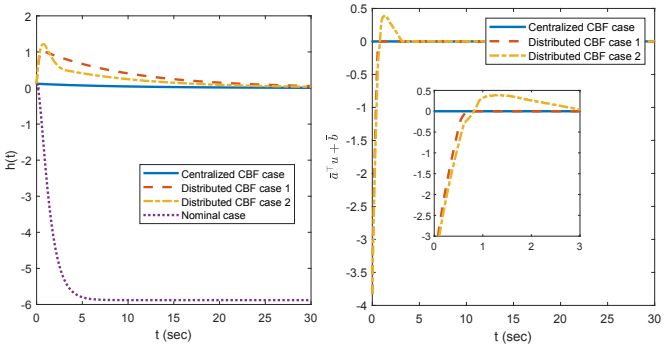
4. SIMULATIONS

In this section we demonstrate the efficacy of our proposed distributed schemes for a formation control problem under a collective state boundedness constraint. We consider 6 2-dimensional agents who has a simple single integrator dynamics. The MAS is tasked to form a star formation,



(a) Nominal case. (b) Centralized CBF case. (c) Distributed CBF case 1. (d) Distributed CBF case 2.

Fig. 1. MAS trajectories in four cases.



(a) CBF values. (b) CBF conditions.

Fig. 2. Time history of CBF values and CBF conditions.

i.e., the desired relative position $\boldsymbol{x}_d = (\boldsymbol{x}_{d,1}^\top, ..., \boldsymbol{x}_{d,6}^\top)^\top$ with $\boldsymbol{x}_{d,i} = (\cos(i\pi/3), \sin(i\pi/3)), i = 1, 2, ..., 6$. The communication graph is connected and undirected as shown in black dash lines in Fig. 1. All the agents start from $(0.7, 0.7)$ and the collective state is expected to evolve within the safety set $\{\boldsymbol{x} : h(\boldsymbol{x}) = 6 - \boldsymbol{x}^\top \boldsymbol{x} \geq 0\}$. Choose the extended class $\mathcal{K}$ function $\alpha(x) = 0.1x$. Straightforwardly, we obtain the CBF-induced QP in the form of (5) where $\boldsymbol{u}_{nom,i} = \sum_{i \in N_i}(\boldsymbol{x}_j - \boldsymbol{x}_{d,j} + \boldsymbol{x}_{d,i} - \boldsymbol{x}_i)$, $\boldsymbol{a}_i = 2\boldsymbol{x}_i, b_i = 0.1(\boldsymbol{x}_i^\top \boldsymbol{x}_i - 1)$.

We show the simulation results for the nominal case, where $\boldsymbol{u}_{nom,i}$ is used; the centralized CBF case, where $\boldsymbol{u}_i$ is obtained by solving the CBF-induced QP in a centralized way; the distributed CBF case 1, where $\boldsymbol{u}_i$ is obtained via the scheme in Sec. 3.2; and the distributed CBF case 2, where $\boldsymbol{u}_i$ is calculated as in Sec. 3.3. For a fair comparison, we choose both k_0 in (10) and β in (12) and (13) to be 1. The trajectories of the MAS are shown in Fig. 1. We observe that both distributed CBF cases have a very similar trajectory compared to that of the centralized CBF case. From Fig. 2(a), we also see that the collective boundedness constraint is fulfilled for all time in the centralized and distributed CBF cases. From Fig. 2(b), we observe that the CBF condition ($\bar{\boldsymbol{a}}^\top \boldsymbol{u} + \bar{b} \leq 0$) is always satisfied for the distributed scheme in Sec. 3.2, yet is temporally violated for the proposed scheme in Sec. 3.3.

5. CONCLUSION

In this work, we consider a CBF framework to control MAS under a collective constraint. In particular, two distributed implementation schemes to implement the CBF-induced quadratic programs are discussed. Under the assumption that the parameters of the coupling constraint are slowly time-varying, both proposed implementations solve the CBF-induced QP in finite time. One of them guarantees the satisfaction of the coupling constraint for all time, while the other one is applicable even when some coefficients of the agent inputs become zero.

Abstract: This extended abstract summarizes a series of recent works (Li et al., 2021a,b, 2022; Jiang et al., 2021) on the approximations theory of deep learning methods for time series modelling and analysis. The primary aim is to develop the mathematical foundations for modelling sequential relationships with neural networks, which guides the practical implementation and design of such architectures. In particular, we place on concrete mathematical footing on when and how certain architectures (recurrent neural networks, encoder-decoder structures, dilated convolutions, etc) can adapt to corresponding data structures in the temporal relationships to be learned (memory, rank, sparsity, etc). These form the first step towards principled neural network architecture design and selection for practical machine learning of temporal relationships.

Keywords: Approximation theory, time series analysis, deep learning.

1. INTRODUCTION

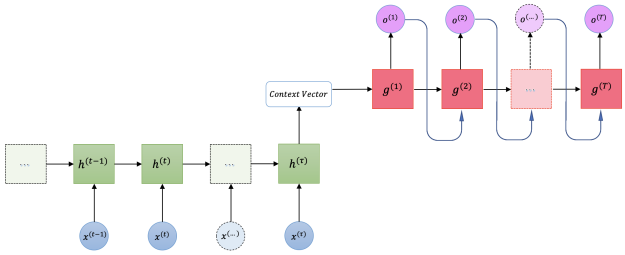

Fig. 1. A recurrent encoder-decoder architecture which maps a sequence into another sequence Cho et al. (2014).

The primary interest of this series of works is to analyze sequence to sequence (seq2seq) modelling, where the input and output are both time-series or sequences. Fig. 1 illustrates an example of a deep learning architecture for seq2seq modelling. There are various architectures that can achieve state-of-the-art performance in different tasks, e.g. the Transformers (Vaswani et al., 2017) in natural language processing (NLP) and the WaveNet (Oord et al., 2016) in audio signal processing, and Vision Transformers (Vit, Dosovitskiy et al. (2020)) in image classification. Our goal is to rigorously formulate the seq2seq problems and theoretically understand how these architectures fundamentally differ from each other. We developed a mathematical framework for analysing seq2seq problems, and this framework enables us to compare different architectures under the same regime. Currently, our work covers recurrent neural networks (RNNs), RNN encoder-decoders and convolutional neural networks (CNNs). Active research is also in process to include more architectures, including attention mechanism and Transformers.

This extended abstract is organised as follows. In Section 2, we will introduce the analysis framework including problem settings and notations. In the remaining sections, we will present and discuss the main results for different architectures.

2. GENERAL FORMULATION OF SEQ2SEQ MODELLING PROBLEM

2.1 Definition of sequences

We view a sequence $\boldsymbol{x} : \mathcal{I} \to \mathbb{R}^d$ as a function from a index set to real vectors. Based on specific settings, the index set $\mathcal{I}$ may be taken as (a subset of) $\mathbb{R}$ (continuous-time setting) or (a subset of) $\mathbb{Z}$ (discrete-time setting).

2.2 Formulation of temporal relationships

For seq2seq problems, we need to model mappings between two sequences. We denote the input and output space by $\mathcal{X}$ and $\mathcal{Y}$, respectively. The input space is usually taken as a normed vector space with some norm $\|\boldsymbol{x}\|_{\mathcal{X}}$. The mapping between $\boldsymbol{x}$ and $\boldsymbol{y}$ can be described by a sequence of functionals:

$$\{y(t) = H_t(\boldsymbol{x}) : t \in \mathcal{I}\}. \tag{1}$$

The output at each time depend on the entire input sequence through a time-dependent functional. The goal is to learn this sequence of functionals $\boldsymbol{H} := \{H_t : t \in \mathcal{I}\}$, which is called the target temporal relationship. The induced functional norm is defined as

$$\|H_t\| := \sup_{\boldsymbol{x}\in\mathcal{X},\|\boldsymbol{x}\|_{\mathcal{X}}\le 1} |H_t(\boldsymbol{x})|, \tag{2}$$

$$\|\boldsymbol{H}\| := \sup_{t\in\mathcal{I}} \|H_t\|. \tag{3}$$

We denote a temporal relationship built from a specific architecture/model by $\hat{\boldsymbol{H}}$. The hypothesis space and concept space is denoted by $\mathcal{H}$ and $\mathcal{C}$, respectively.

Here, we introduce an example to elaborate this functional formulation. The convolution can be considered as a seq2seq relation in the following sense. Suppose we have an input $\boldsymbol{x}$ and a convolution filter g, then the output at time t is given by $y_t = H_t(\boldsymbol{x}) = \int_{-\infty}^{\infty} g(s)x(t-s)ds$, hence the sequence of functionals $\boldsymbol{H} = \{H_t : t \in \mathbb{R}\}$ can be viewed as the entire output sequence $\boldsymbol{y}$.

We are interested in the approximation capabilities of different models, with the approximation error defined as

$$\|\boldsymbol{H} - \hat{\boldsymbol{H}}\|. \tag{4}$$

As is shown later, different models are good at approximating specific classes of target temporal relationships.

2.3 Properties of temporal relationships

We assume that the target temporal relationship (in a certain concept space $\mathcal{C}$) satisfy some specific properties. Below is a list of the related properties possibly used in our works.

P1. $H_t \in \boldsymbol{H}$ is a linear and continuous functional, if for any $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathcal{X}$ and $\lambda_1, \lambda_2 \in \mathbb{R}$,

$$\begin{aligned} H_t(\lambda_1\boldsymbol{x}_1 + \lambda_2\boldsymbol{x}_2) &= \lambda_1 H_t(\boldsymbol{x}_1) + \lambda_2 H_t(\boldsymbol{x}_2), \\ \|H_t\| &= \sup_{\boldsymbol{x}\in\mathcal{X},\|\boldsymbol{x}\|_{\mathcal{X}}\le 1} |H_t(\boldsymbol{x})| < \infty, \end{aligned} \tag{5}$$

$\boldsymbol{H}$ is linear and continuous if each H_t is linear and continuous.

P2. $H_t \in \boldsymbol{H}$ is regular, if for any sequence $\{\boldsymbol{x}_n : n \in \mathbb{N}\}$ such that $x_n(s) \to 0$ for almost every $s \in \mathcal{I}$, we have $\lim_{n\to\infty} H_t(\boldsymbol{x}_n) = 0$. $\boldsymbol{H}$ is regular if each H_t is regular.

P3. $\boldsymbol{H}$ is causal, if it does not depend on the future inputs. That is, for any $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathcal{X}$ and any $t \in \mathcal{I}$ such that $x_1(s) = x_2(s)$ for all $s \le t$, the output satisfies $H_t(\boldsymbol{x}_1) = H_t(\boldsymbol{x}_2)$.

P4. A sequence of functionals $\boldsymbol{H}$ is time-homogeneous, if for any $t, \tau \in \mathcal{I}$, $H_t(\boldsymbol{x}) = H_{t+\tau}(\boldsymbol{x}^{(\tau)})$ with $x^{(\tau)}(s) := x(s-\tau)$ for all $s \in \mathcal{I}$.

3. RECURRENT NEURAL NETWORKS

In the continuous-time setting, the simplest RNN (with skip connections and one linear readout layer) is given by

$$\begin{aligned} \frac{d}{dt}h(t) &= \sigma(Wh(t) + Ux(t)), \\ \hat{y}(t) &= c^\top h(t), \\ \text{with } c \in \mathbb{R}^m, W \in \mathbb{R}^{m\times m}, U &\in \mathbb{R}^{m\times d}. \end{aligned} \tag{6}$$

Here, $h \in \mathbb{R}^m$ is the hidden state and m denotes the width of RNNs, which determines the model complexity. If we assume the linearity, (6) defines a family of functionals

$$\mathcal{H}^{(m)}_{\text{RNN}} := \Big\{\hat{\boldsymbol{H}} : \hat{H}_t = \hat{y}(t) = \int_0^\infty c^\top e^{Ws} U x(t-s) ds\Big\}. \tag{7}$$

The hypothesis space for RNNs with arbitrary widths is defined as

$$\mathcal{H}_{\text{RNN}} := \bigcup_{m\in\mathbb{N}_+} \mathcal{H}^{(m)}_{\text{RNN}}. \tag{8}$$

The concept space we considered here is

$$\mathcal{C} = \{\boldsymbol{H} : \boldsymbol{H} \text{ satisfies P1, P2, P3, P4}\}. \tag{9}$$

We next present the main result.

3.1 Approximation rate (Li et al., 2021a, Theorem 4.2)

Let $y_i(t) = H_t(\boldsymbol{e}_i)$, $i = 1, \dots, d$, where $\boldsymbol{e}_i$ is a step constant signal. Suppose

- $y_i \in C^{(\alpha+1)}(\mathbb{R})$;
- $e^{\beta t} y_i^{(k)}(t) = o(1)$.

We have the estimate

$$\|\boldsymbol{H} - \hat{\boldsymbol{H}}\| \le \frac{C(\alpha)\gamma d}{\beta m^\alpha}, \tag{10}$$

where α measures the smoothness of the target, and β measures the memory/decay of the target. $C(\alpha)$ and γ are two positive universal constants depending on α, β. The smoothness and memory are characterised by y_i, i.e. the response of target functionals under (step) constant inputs.

This result implies that a target temporal relationship can be efficiently approximated by RNNs if it is smooth (large α) and decays fast (large β). Conversely, the target with sudden changes are difficult to be learned by RNNs.

4. RNN ENCODER-DECODER

The architecture with RNNs as both encoder and decoder can be formulated as

$$\begin{aligned} h_s &= \sigma_E(W_E h_{s-1} + U_E x_s + b_E), \quad & v &= h_\tau, \\ g_t &= \sigma_D(W_D g_{t-1} + b_D), & g_0 &= v, \\ o_t &= W_O g_t + b_O, \end{aligned} \tag{11}$$

where h_t, g_t are hidden states of the encoder and decoder, respectively. We take a linear, residual and continuous-time idealisation of (11):

$$\begin{aligned} \frac{d}{ds}h_s &= Wh_s + Ux_s, \quad & v &= Qh_0, \quad & s \le 0, \\ \frac{d}{dt}g_t &= Vg_t, & g_0 &= Pv, \\ y_t &= c^\top g_t, & t &\ge 0, \\ \text{with } W \in \mathbb{R}^{m_E\times m_E}, V &\in \mathbb{R}^{m_D\times m_D}, U \in \mathbb{R}^{m_E\times d}, \\ Q \in \mathbb{R}^{N\times m_E}, P &\in \mathbb{R}^{m_D\times N}. \end{aligned} \tag{12}$$

Here, m_E and m_D denote the width of encoder and decoder, respectively. N is the dimension of the coding vector v, and it can be also understood as the model rank. (12) defines a family of functionals

$$\mathcal{H}^{(m_E,m_D,N)}_{\text{EncDec}} := \Big\{\hat{\boldsymbol{H}} : \hat{H}_t = \int_0^\infty c^\top e^{Vt} P Q e^{Ws} U x_{-s} ds\Big\}. \tag{13}$$

The hypothesis space for RNN encoder-decoders with arbitrary widths is defined by

$$\mathcal{H}_{\text{EncDec}} := \bigcup_{m_E,m_D,N\in\mathbb{N}_+} \mathcal{H}^{(m_E,m_D,N)}_{\text{EncDec}}. \tag{14}$$

The concept space we considered here is

$$\mathcal{C} = \{\boldsymbol{H} : \boldsymbol{H} \text{ satisfies P1, P2}\} \tag{15}$$

We next present the main result.

4.1 Approximation rate (Li et al., 2021b, Theorem 4.3)

Let $y_i(t,s) = H_t(e_i \mathbf{1}_{(-\infty,-s]}),\ i = 1,\dots,d$. Suppose

- $y_i \in C^{(\alpha+1)}([0,\infty))$;
- $e^{\beta(t+s)} \frac{\partial^{k+l}}{\partial t^k \partial s^l} y_i(t,s) = o(1)$ as $\|(t,s)\| \to \infty$;
- $\{\sigma_n\}$ are singular values of ρ. Intuitively, we have $\rho(t,s) = \sum_{n=1}^{\infty} \sigma_n \varphi_n(t) \phi_n(s)$, where $\{\varphi_n\}$ and $\{\phi_n\}$ are orthonormal bases, and $\sigma_1 \geq \sigma_2 \geq \cdots \geq 0$ denote the singular values.

We have

$$\|\boldsymbol{H} - \hat{\boldsymbol{H}}\| \leq \frac{C(\alpha)\gamma d}{\beta^2} \Bigg\{ \left(1 + \sqrt{\bar{m} - N}\right) \cdot \left(\frac{1}{m_E^{\alpha}} + \frac{1}{m_D^{\alpha}}\right) + \left(\sum_{n=N+1}^{\bar{m}} \sigma_n^2\right)^{\frac{1}{2}} + \left(\sum_{n=N+1}^{\bar{m}} \sigma_n\right)^{\frac{1}{2}} \left(\frac{1}{m_E^{\alpha/2}} + \frac{1}{m_D^{\alpha/2}}\right) \Bigg\}, \tag{16}$$

where α measures the smoothness of the target, β measures the memory/decay of the target. $C(\alpha)$ and γ are two positive universal constants depending on α, β. A target can be efficiently approximated by RNN encoder-decoders if it is smooth (large α) and decays fast (large β). These are almost the same as RNNs.

New insights are presented as follows. Different from the RNN case where we only consider time-homogeneous target relationships, here we instead investigate time-inhomogeneous relationships. We have $\mathcal{H}_{\text{RNN}} \subseteq \mathcal{H}_{\text{EncDec}}$, which implies that the encoder-decoder is more general with the capability to learn time-inhomogeneity. In addition, the time-inhomogeneous temporal relationship considered here possesses a two parameter representation $\rho(t,s)$, leading to an extra characterisation which we called temporal product structure. Intuitively, we can decompose $\rho(t,s)$ along the input and output temporal direction, i.e. s and t, such that $\rho(t,s) = \sum_{n=1}^{\infty} \sigma_n \varphi_n(t) \phi_n(s)$, which is analogous to the singular value decomposition of matrices. We say $\rho(t,s)$ has a low "effective rank" if the singular values $\{\sigma_n\}$ decays fast. Our approximation rate shows that a target with low effective rank can be efficiently approximated by the encoder-decoder architecture with a small model rank N, which reduces the number of parameters needed to achieve the accuracy.

5. CONVOLUTIONAL NEURAL NETWORKS

For CNNs, we use the discrete-time setting. Inspired from the dilated convolution architecture in WaveNet (Oord et al., 2016), a dilated convolution-based temporal sequence model with K layers and M_k channels at layer k is given by

$$\begin{aligned} \boldsymbol{h}_{0,i} &= \boldsymbol{x}_i, \\ \boldsymbol{h}_{k+1,i} &= \sigma\left(\sum_{j=1}^{M_k} \boldsymbol{w}_{kji} *_{d_k} \boldsymbol{h}_{k,j}\right), \\ \hat{\boldsymbol{y}} &= \boldsymbol{h}_K. \end{aligned} \tag{17}$$

Here, $*_{d_k}$ denotes the dilated convolution operator with the dilation rate equalling to d_k, $\boldsymbol{x}_i$ is the i^{th} dimension of $\boldsymbol{x}$, and $\boldsymbol{w}_{kji}$ is the filter from channel j at layer k to channel i at layer $k+1$. All the filters have a size $l \geq 2$. If σ is linear, we have

$$\mathcal{H}_{\text{CNN}}^{(l,K,\{M_k\})} := \left\{ \hat{\boldsymbol{H}} : \hat{H}_t(\boldsymbol{x}) = \sum_{s \in \mathbb{N}} \rho^{(\hat{\boldsymbol{H}})}(s)^{\top} x(t-s) \right\}, \tag{18}$$

where $\rho^{(\hat{\boldsymbol{H}})}$ is a finite-supported vector. The hypothesis space for CNNs with arbitrary depths and number of channels is defined as

$$\mathcal{H}_{\text{CNN}}^{(l)} = \bigcup_{K \in \mathbb{N}_+} \bigcup_{\{M_k\} \in \mathbb{N}_+^K} \mathcal{H}_{\text{CNN}}^{(l,K,\{M_k\})}. \tag{19}$$

The concept space we considered here is

$$\mathcal{C} = \{\boldsymbol{H} : \boldsymbol{H} \text{ satisfies P1, P2, P3, P4}\}. \tag{20}$$

We next present the main result.

5.1 Approximation rate (Jiang et al., 2021, Theorem 4)

Define the complexity measure of $\boldsymbol{H}$ by

$$\begin{aligned} &\mathrm{C}^{(l,g)}(\boldsymbol{H}) \\ &= \inf\left\{ c : \left(\sum_{i=s+K}^{lK} |\sigma_i^{(K)}|^2\right)^{\frac{1}{2}} \leq c g(s),\ s \geq 0, K \in \mathbb{N}_+ \right\}, \end{aligned} \tag{21}$$

where $\sigma_1^{(K)} \geq \sigma_2^{(K)} \geq \cdots \geq \sigma_{lK}^{(K)} \geq 0$ denote the singular values of the tensorisation of $\boldsymbol{\rho}^{(\boldsymbol{H})}$, and g is a non-increasing function with zero limit at positive infinity. For any $\boldsymbol{H} \in \mathrm{C}^{(l,g)}$ and any set of parameters $(K, \{M_k\})$, we have

$$\|\boldsymbol{H} - \hat{\boldsymbol{H}}\| \leq d\ g(KM^{\frac{1}{K}} - K)\, \mathrm{C}^{(l,g)}(\boldsymbol{H}) + \|\boldsymbol{\rho}^{(\boldsymbol{H})}_{[l^K,\infty)}\|_2, \tag{22}$$

where $M := \frac{1}{d}(\sum_{k=2}^{K} M_k M_{k-1} - lK)$ denotes the "effective" number of filters.

In terms of approximation, CNNs are different from the former recurrent architectures. Our approximation rate shows that a target with low effective (tensor) rank can be easily approximated by CNNs with fewer channels $\{M_k\}$, which controls the model (tensor) rank. The target with sparsity is a special case, which is also low rank and easy to be approximated (since CNNs can construct each non-zero value individually).

Different from RNNs (possessing an infinite long filter), the CNN has a finite-supported filter (despite with exponentially large receptive fields). Hence, if the target has long tails, more parameters are required for CNNs to learn it.

6. DISCUSSION

In this section, we discuss the relations between different architectures. First, RNNs and RNN encoder-decoders are similar with each other, since both of them possess recurrent architectures. When an RNN encoder-decoder is required to be time-homogeneous, it becomes an RNN. In particular, we have $\mathcal{H}_{\text{RNN}} \subseteq \mathcal{H}_{\text{EncDec}}$. Similar with RNNs, it is also difficult for RNN encoder-decoders to handle targets with long-term memories or sudden changes.

In addition, RNNs and CNNs are both causal and time-homogeneous, but they have different underlying structures. The RNN uses a power sum filter, which is good at approximating targets with fast decayed structures, but not efficient to handle sudden changes or long-term memories. While the CNN uses a finite-supported filter, which works well for targets with low (effective) ranks or fast decayed singular values. The approximation can become inefficient if the tail error is significant, or the finite-supported part does not possess this low (effective) rank structure.

Finally, we want to clarify that the rank concept appeared in CNNs and encoder-decoders are totally different. In the CNN setting, the rank corresponds to tensors after certain tensorisation. While for encoder-decoders, the rank is related with the temporal product structure.

Construction of a Lyapunov function for linear coupled impulsive systems

Ivan Atamas, **Sergey Dashkovskiy**, **Vitalii Slynko**

Institute of Mathematics, University of Würzburg Germany, (e-mail: ivan.atamas, sergey.dashkovskiy, vitalii.slynko@uni-wuerzburg.de)

Abstract: We propose an approach to construct a Lyapunov function for a linear coupled impulsive system consisting of two time-invariant subsystems. In contrast to various variants of small-gain stability conditions for coupled systems, the asymptotic stability property of independent subsystems is not assumed. To analyze the asymptotic stability of a coupled system, the direct Lyapunov method is used in combination with the discretization method. The periodic case and the case when the Floquet theory is not applicable at all are considered separately.

Keywords: Impulsive systems, time-varying systems, coupled systems, Lyapunov methods

1. INTRODUCTION AND PROBLEM STATEMENT

Impulsive differential equations can model mechanical systems subjected to shocks. Instantaneous changes in holonomic or nonholonomic constraints imposed on the system and changes in the parameters of the system in time lead to the need to study stability of impulsive systems with variable coefficients. It is important to obtain stability conditions that are robust with respect to small variations in the sequence of moments of impulse action. A possible approach is to construct a matrix-valued Lyapunov function Djordjevic (1983); Martynyuk (1985). In Martynyuk and Slynko (2003) for linear time-variant coupled systems with time-invariant subsystems a construction of a matrix-valued Lyapunov function is proposed. For linear impulsive systems with variable coefficients the problem of choosing the elements of the matrix-valued Lyapunov function has not been studied.

The use of the discretization method to construct approximate solutions of the Lyapunov matrix differential equations has led to significant advances in the theory of stability of linear hybrid systems with constant parameters, see Allerhand and Shaked (2010). Discretization method for a construction of a Lyapunov function allows to obtain estimates of dwell-times that guarantee the stability of a linear hybrid system or conditions of robust stability.

We propose to apply the discretization method to construct matrix-valued Lyapunov functions for linear impulsive systems with periodic coefficients. We assume that independent subsystems are time-invariant and for the dwell-times two possible cases are considered: they are constant or subject to two-sided estimates. The elements of the matrix-valued Lyapunov function are constructed in the bilinear forms with time-variable matrices. The proposed construction of Lyapunov functions admits a numerical implementation.

Let $\mathbb{R}^n$ be the n-dimensional Euclidian space with standard dot product, $\mathbb{R}^{n\times m}$ be linear space of $n\times m$ matrices. For a matrix $A\in\mathbb{R}^{n\times n}$, $\sigma(A)$ denotes its spectrum, $r_\sigma(A)$ denotes spectral radius of A and norm $\|A\|=\lambda_{\max}^{1/2}(A^{\mathrm{T}}A)$. If $\sigma(A)\subset\mathbb{R}$, then $\lambda_{\min}(A)$ and $\lambda_{\max}(A)$ are its smallest and largest eigenvalues respectively. For any symmetric matrices P and Q the notation $P\succeq Q$ means that $P-Q$ is a positive semidefinite matrix and $P\succ Q$ means that $P-Q$ is a positive definite matrix. We will use the Cauchy–Bunyakovskii inequality $|x^{\mathrm{T}}y|\le\|x\|\|y\|$ for $x,y\in\mathbb{R}^n$.

Consider a coupled linear system of impulsive differential equations consisting of two subsystems

$$\begin{aligned}\dot{x}_1(t)&=A_{11}x_1(t)+A_{12}(t)x_2(t),\quad t\neq\tau_k\\ \dot{x}_2(t)&=A_{21}(t)x_1(t)+A_{22}x_2(t),\quad t\neq\tau_k,\\ x_1(t^+)&=B_{11}x_1(t)+B_{12}x_2(t),\quad t=\tau_k,\\ x_2(t^+)&=B_{21}x_1(t)+B_{22}x_2(t),\quad t=\tau_k\end{aligned}\tag{1}$$

where $x_i\in\mathbb{R}^{n_i}$, $i=1,2$, $A_{ij}:\mathbb{R}\to\mathbb{R}^{n_i\times n_j}$ are piecewise continuous maps, $i,j=1,2$, A_{ii} are constant matrices and $A_{ij}(t)$, $i\neq j$ are θ-periodic functions, i.e., $A_{ij}(t+\theta)=A_{ij}(t)$ for all $t\in\mathbb{R}$, $\{\tau_k\}_{k=0}^{\infty}$ is a sequence of moments of impulse action, such that $\theta=\tau_k-\tau_{k-1}$, $k\ge1$. $B_{ij}\in\mathbb{R}^{n_i\times n_j}$ are constant matrices. We denote $x=(x_1^{\mathrm{T}},x_2^{\mathrm{T}})^{\mathrm{T}}$ and $n=n_1+n_2$. We will study the asymptotic stability of (1) in the sense of the following

Definition 1. *The linear impulsive system* (1) *is called*

1) stable if $\forall\varepsilon>0$, $t_0\in\mathbb{R}$ *there exists* $\delta=\delta(\varepsilon,t_0)>0$ *such that* $\|x_0\|<\delta\ \Rightarrow\ \|x(t,t_0,x_0)\|<\varepsilon$ *for all* $t\ge t_0$*;*

2) uniformly stable if $\forall\varepsilon>0\ \exists\delta=\delta(\varepsilon)>0$ *s.t.* $\forall\, t_0\in\mathbb{R}$ *we have* $\|x_0\|<\delta\ \Rightarrow\ \|x(t,t_0,x_0)\|<\varepsilon$ *for all* $t\ge t_0$*;*

3) asymptotically stable (AS) if it is stable and for all (t_0,x_0) *it holds that* $\lim\limits_{t\to+\infty}\|x(t,t_0,x_0)\|=0$.

Here, $x(t,t_0,x_0)$ is the solution to (1) with the initial condition $x(t_0,t_0,x_0)=x_0$, $x_0=(x_{10}^{\mathrm{T}},x_{20}^{\mathrm{T}})^{\mathrm{T}}\in\mathbb{R}^n$.

The aim of this work is to construct a Lyapunov function for (1). For simplicity we assume that $t_0=0$. Let

$$\mathbb{V}(t,x)=(v_{ij}(t,\cdot,\cdot))_{i,j=1,2}$$

be a matrix-valued Lyapunov function (MFL) Djordjevic (1983); Martynyuk (1985). We choose the diagonal elements of this function in the quadratic form $v_{ii}(t,x_i)=x_i^{\mathrm{T}}P_{ii}(t)x_i$, where $P_{ii}:\mathbb{R}\to\mathbb{R}^{n_i\times n_i}$, $P_{ii}(t)\succ0$, $i=1,2$ are continuous on the left θ-periodic maps, and off-diagonal elements in the form $v_{ij}(t,x_i,x_j)=x_i^{\mathrm{T}}P_{ij}(t)x_j$, where $P_{ij}:\mathbb{R}\to\mathbb{R}^{n_i\times n_j}$ are continuous on the left θ-periodic maps, $P_{ij}(t)=P_{ji}^{\mathrm{T}}(t)$. It is enough to define these functions $P_{ij}(t)$, $i,j=1,2$ on the period $(0,\theta]$.

2. MATRIX-VALUED LYAPUNOV FUNCTIONS

Discretization parameters are the number of nodes $N \in \mathbb{N}$ and the discretization step length $h = \frac{\theta}{N}$. Let $P_0 = (P_{ij}^{(0)})_{i,j=1,2}$ be a positive definite symmetric block matrix, $P_{ij}^{(0)} \in \mathbb{R}^{n_i \times n_j}$, $P_{ij}^{(0)} = (P_{ji}^{(0)})^{\mathrm{T}}$. We define recursively

$$P_{ij}^{(m)}, \quad P_{ji}^{(m)} = (P_{ij}^{(m)})^{\mathrm{T}}, \quad i,j = 1,2$$

as follows

$$P_{ii}^{(m+1)} = e^{-A_{ii}^{\mathrm{T}} h}(P_{ii}^{(m)} - \int_{mh}^{(m+1)h} (P_{ij}^{(m)} A_{ji}(s) + A_{ji}^{\mathrm{T}}(s) P_{ji}^{(m)})\, ds) e^{-A_{ii}h}, \quad i \neq j, \tag{2}$$

$$P_{12}^{(m+1)} = e^{-A_{11}^{\mathrm{T}} h}(P_{12}^{(m)} - \int_{mh}^{(m+1)h} (P_{11}^{(m)} A_{12}(s) + A_{21}^{\mathrm{T}}(s) P_{22}^{(m)})\, ds) e^{-A_{22}h}. \tag{3}$$

Next, define matrices $P_{ij}(t)$, $i,j = 1,2$, $P_{ij}(t) = P_{ji}^{\mathrm{T}}(t)$ on the intervals $(mh, (m+1)h]$ by setting

$$P_{ii}(t) = e^{-A_{ii}^{\mathrm{T}}(t-mh)}(P_{ii}^{(m)} - \int_{mh}^{t} (P_{ij}^{(m)} A_{ji}(s) + A_{ji}^{\mathrm{T}}(s) P_{ji}^{(m)})\, ds) e^{-A_{ii}(t-mh)}, \quad i \neq j, \tag{4}$$

$$P_{12}(t) = e^{-A_{11}^{\mathrm{T}}(t-mh)}(P_{12}^{(m)} - \int_{mh}^{t} (P_{11}^{(m)} A_{12}(s) + A_{21}^{\mathrm{T}}(s) P_{22}^{(m)})\, ds) e^{-A_{22}(t-mh)}. \tag{5}$$

We define an MLF $\mathbb{V}(t, x_1, x_2) = (v_{ij}(t, ., .))_{i,j=1,2}$, by $v_{ii}(t, x_i) = x_i^{\mathrm{T}} P_{ii}(t) x_i$, $i = 1,2$, $v_{ij}(t, x_i, x_j) = x_i^{\mathrm{T}} P_{ij}(t) x_j$, $i \neq j$, $P_{ij}(t) = P_{ji}^{\mathrm{T}}(t)$, $i,j = 1,2$. Using $\mathbb{V}$ we construct the scalar Lyapunov function Djordjevic (1983)

$$v(t, x_1, x_2) = v_{11}(t, x_1) + 2v_{12}(t, x_1, x_2) + v_{22}(t, x_2). \tag{6}$$

Assumption 1. *Let $\gamma_{12}^{(m)}$, $\gamma_{21}^{(m)}$, $m = 0, 1, \ldots, N-1$ be positive constants such that the following inequalities hold*

$$\sup_{s \in (mh, (m+1)h]} \|A_{12}(s)\| \leq \gamma_{12}^{(m)}, \quad \sup_{s \in (mh, (m+1)h]} \|A_{21}(s)\| \leq \gamma_{21}^{(m)}$$

There exists real constants μ_i, δ_i, M_i, N_i, such that for matrices A_{ii} the following estimates Gil (1993) holds

$$\|e^{sA_{ii}}\| \leq M_i e^{s\mu_i}, \quad \|e^{-sA_{ii}}\| \leq N_i e^{s\delta_i}, \quad s \geq 0.$$

To verify the positive-definiteness of the proposed LF and to construct the impulsive scalar equation we use

Lemma 1. *Let $z_{1m} = e^{-A_{11}(t-mh)} x_1$, $z_{2m} = e^{-A_{22}(t-mh)} x_2$, $t \in (mh, (m+1)h]$. Then,*

$$\lambda_{\min}(\Pi_m)\|z_m\|^2 \leq v(t, x_1, x_2) \leq \lambda_{\max}(\Xi_m)\|z_m\|^2, \quad \text{for all} \quad t \in (mh, (m+1)h], \quad m = 0, \ldots, N-1, \tag{7}$$

where $z_m = (z_{1m}^{\mathrm{T}}, z_{2m}^{\mathrm{T}})^{\mathrm{T}}$, $\|z_m\|^2 = \|z_{1m}\|^2 + \|z_{2m}\|^2$, $\Xi_m = (\xi_{ij}^{(m)})_{i,j=1,2}$ is some block matrix and $\Pi_m = (\pi_{ij}^{(m)})_{i,j=1,2}$ is block matrix with the elements

$$\pi_{11}^{(m)} = P_{11}^{(m)} - h(2\gamma_{21}^{(m)}\|P_{12}^{(m)}\| + (\gamma_{12}^{(m)}\|P_{11}^{(m)}\| + \gamma_{21}^{(m)}\|P_{22}^{(m)}\|))I_{n_1},$$
$$\pi_{22}^{(m)} = P_{22}^{(m)} - h(2\gamma_{12}^{(m)}\|P_{12}^{(m)}\| + (\gamma_{12}^{(m)}\|P_{11}^{(m)}\| + \gamma_{21}^{(m)}\|P_{22}^{(m)}\|))I_{n_2},$$
$$\pi_{12}^{(m)} = P_{12}^{(m)}, \quad \pi_{21}^{(m)} = P_{21}^{(m)}$$

For $i = 1, 2$, $i \neq j$ we denote

$$\eta_{ii}^{(m)} := \sqrt{\|P_{ii}^{(m)}\|^2 + \|P_{ij}^{(m)}\|^2} + \|P_{ij}^{(m)}\|,$$
$$\eta_{ij}^{(m)} := \frac{1}{2}(\|P_{ii}^{(m)}\|\gamma_{ij}^{(m)} + \|P_{jj}^{(m)}\|\gamma_{ji}^{(m)} + \sqrt{(\|P_{ii}^{(m)}\|\gamma_{ij}^{(m)} + \|P_{jj}^{(m)}\|\gamma_{ji}^{(m)})^2 + 16(\gamma_{ji}^{(m)})^2\|P_{ij}^{(m)}\|^2}).$$
$$\alpha_{11}^{(m)} := \gamma_{12}^{(m)}\|A_{22}\|N_1 M_2 \eta_{11}^{(m)}, \alpha_{12}^{(m)} := \gamma_{12}^{(m)}\|A_{11}\|N_1\eta_{11}^{(m)},$$
$$\alpha_{21}^{(m)} := \gamma_{21}^{(m)}\|A_{11}\|N_2 M_1 \eta_{22}^{(m)}, \alpha_{22}^{(m)} := \gamma_{21}^{(m)}\|A_{22}\|N_2\eta_{22}^{(m)},$$

$$\Theta_m(h) := \frac{\alpha_{11}^{(m)}}{\mu_2}\Big(\frac{e^{(\mu_2+\delta_1)h} - 1}{\mu_2 + \delta_1} - \frac{e^{\delta_1 h} - 1}{\delta_1}\Big) + \frac{\alpha_{12}^{(m)}}{\delta_1}\Big(\frac{e^{h\delta_1} - 1}{\delta_1} - h\Big) + \frac{\alpha_{21}^{(m)}}{\mu_1}\Big(\frac{e^{(\mu_1+\delta_2)h} - 1}{\mu_1 + \delta_2} - \frac{e^{\delta_2 h} - 1}{\delta_2}\Big) + \frac{\alpha_{22}^{(m)}}{\delta_2}\Big(\frac{e^{h\delta_2} - 1}{\delta_2} - h\Big) + \tag{8}$$
$$+2\Big(\gamma_{12}^{(m)}\eta_{12}^{(m)} N_1 M_2\Big(\frac{he^{(\mu_2+\delta_1)h}}{\mu_2 + \delta_1} - \frac{e^{(\mu_2+\delta_1)h} - 1}{(\mu_2 + \delta_1)^2}\Big) + \gamma_{21}^{(m)}\eta_{21}^{(m)} N_2 M_1\Big(\frac{he^{(\mu_1+\delta_2)h}}{\mu_1 + \delta_2} - \frac{e^{(\mu_1+\delta_2)h} - 1}{(\mu_1 + \delta_2)^2}\Big)\Big).$$

Lemma 2. *Suppose that for all $m = 0, \ldots, N-1$, the matrices Π_m are positive definite. Then*

$$v((m+1)h, x_1((m+1)h), x_2((m+1)h)) \leq e^{\frac{\Theta_m(h)}{\lambda_{\min}(\Pi_m)}} v(mh + 0, x_1(mh + 0), x_2(mh + 0)). \tag{9}$$

We establish sufficient conditions for (1) to be AS using the above $\mathbb{V}(t, x_1, x_2)$ and Lemma 2.

Theorem 1. *Let N be a positive natural number and $P_0 > 0$ be such that for $m = 0, \ldots, N-1$ the matrices Π_m are positive definite and it holds that*

$$Q := \sum_{m=0}^{N-1} \frac{\Theta_m(h)}{\lambda_{\min}(\Pi_m)} + \ln \lambda_{\max}(P_N^{-1} B^{\mathrm{T}} P_0 B) < 0.$$

Then the system (1) is asymptotically stable.

3. APPLICATION AND COMPARISON OF RESULTS

Here we compare Theorem 1 with known stability conditions for coupled time-varying systems. We restrict ourselves to a special case of high-frequency periodic functions that is θ is sufficiently small. The value of this parameter we obtain from Theorem 1, applied to the case $N = 1$. We will compare our results with small-gain conditions obtained on the basis of the ISS theory and the Lyapunov vector function. Moreover, we will also consider the case when one of the independent subsystems is not stable, and the known approaches from the theory of stability of coupled systems are not applicable.

Consider (1) and denote $\widehat{A}_{ij} = \frac{1}{\theta}\int_0^\theta A_{ij}(t)\,dt$ for $i \neq j$. Let $B = (B_{ij})_{i,j=1,2}$, $\widehat{A} = \begin{pmatrix} 0 & \widehat{A}_{12} \\ \widehat{A}_{21} & 0 \end{pmatrix}$ be block matrices. Consider the system of linear matrix inequalities

$$\begin{aligned} &\operatorname{diag}\{e^{\theta A_{11}^{\mathrm{T}}}, e^{\theta A_{22}^{\mathrm{T}}}\} B^{\mathrm{T}} P_0 B \operatorname{diag}\{e^{\theta A_{11}}, e^{\theta A_{22}}\} \\ &\qquad \prec P_0 - \theta(\widehat{A}^{\mathrm{T}} P_0 + P_0 \widehat{A}). \end{aligned} \tag{10}$$

Suppose it has a solution $P_0 = (P_{ij}^{(0)})_{i,j=1,2}$ in the form of a symmetric positive-definite matrix, i.e. $P_{ij}^{(0)} = (P_{ji}^{(0)})^{\mathrm{T}}$.

Let us define matrices

$$\pi_{11}^{(0)} = P_{11}^{(0)} - \theta(2\gamma_{21}^{(0)}\|P_{12}^{(0)}\| + (\gamma_{12}^{(0)}\|P_{11}^{(0)}\| + \gamma_{21}^{(0)}\|P_{22}^{(0)}\|))I_{n_1},$$
$$\pi_{22}^{(0)} = P_{22}^{(0)} - \theta(2\gamma_{12}^{(0)}\|P_{12}^{(0)}\| + (\gamma_{12}^{(0)}\|P_{11}^{(0)}\| + \gamma_{21}^{(0)}\|P_{22}^{(0)}\|))I_{n_2},$$
$$\pi_{12}^{(0)} = P_{12}^{(0)}, \quad \pi_{21}^{(0)} = P_{21}^{(0)}$$

and block matrix $P_1 = (P_{ij}^{(1)})_{i,j=1,2}$, $(P_{ij}^{(1)})^{\mathrm{T}} = P_{ji}^{(1)}$ with the blocks

$$P_{11}^{(1)} = e^{-A_{11}^{\mathrm{T}}\theta}(P_{11}^{(0)} - \theta(P_{12}^{(0)}\widehat{A}_{21} + \widehat{A}_{21}^{\mathrm{T}}P_{21}^{(0)}))e^{-A_{11}\theta}, \tag{11}$$

$$P_{22}^{(1)} = e^{-A_{22}^{\mathrm{T}}\theta}(P_{22}^{(0)} - \theta(\widehat{A}_{12}^{\mathrm{T}}P_{12}^{(0)} + P_{21}^{(0)}\widehat{A}_{12}))e^{-A_{22}\theta} \tag{12}$$

$$P_{12}^{(1)} = e^{-A_{11}^{\mathrm{T}}\theta}(P_{12}^{(0)} - \theta(P_{11}^{(0)}\widehat{A}_{12} + \widehat{A}_{21}^{\mathrm{T}}P_{22}^{(0)})))e^{-A_{22}\theta}. \tag{13}$$

Corollary 1. *If* $Q{:=}\frac{\Theta_0(\theta)}{\lambda_{\min}(\Pi_0)} + \ln\lambda_{\max}(P_1^{-1}B^{\mathrm{T}}P_0B) < 0$, $\Pi_0 = (\pi_{ij}^{(0)})_{i,j=1,2} > 0$, *then* (1) *is asymptotically stable.*

Example 1.

$$\begin{aligned} \dot{x}_1(t) &= 0.01x_1(t) - 0.2\sin^2\frac{2\pi t}{\theta}x_2(t), \\ \dot{x}_2(t) &= -0.1x_2(t) + 0.2\cos^2\frac{2\pi t}{\theta}x_1(t) \end{aligned} \tag{14}$$

Choose $\theta = 0.09$, $P_{11}^{(0)} = 18$, $P_{12}^{(0)} = P_{21}^{(0)} = -7$, $P_{22}^{(0)} = 12$. *It is obvious that* $\mu_1 = 0.01$, $\mu_2 = -0.1$, $\delta_1 = -0.01$, $\delta_2 = 0.1$, $\gamma_{12}^{(0)} = \gamma_{21}^{(0)} = 0.2$. *By direct calculations we get*

$$\Pi_0 = \begin{pmatrix} 17.208 & -7 \\ -7 & 11.208 \end{pmatrix},$$
$$P_1 = \begin{pmatrix} 18.09340255 & -7.002491081 \\ -7.002491081 & 12.08966719 \end{pmatrix}$$

and $\eta_{11}^{(0)} = 26.31320792$, $\eta_{22}^{(0)} = 20.89244399$, $\eta_{12}^{(0)} = 7.103656905$, $\eta_{21}^{(0)} = 7.103656905$, $\alpha_{11}^{(0)} = 0.5262641584$, $\alpha_{12}^{(0)} = 0.052626641584$, $\alpha_{21}^{(0)} = 0.04178488798$, $\alpha_{22}^{(0)} = 0.4178488798$, $Q = -0.00004279 < 0$. *Therefore, the system is asymptotically stable.*

At the same time, the first independent system is unstable, which makes it impossible to apply the small-gain theorem.

3.1 Comparison with the small-gain conditions

Consider (1), assuming $\int_0^\theta A_{ij}(t)\,dt = 0$ for $i \neq j$. Since the Lyapunov vector functions or small-gain results are only applicable when the independent subsystems are AS, we assume $r_\sigma(e^{\theta A_{ii}}B_{ii}) < 1$, $i = 1, 2$. Then (10) reduces to

$$e^{\theta A_{ii}^{\mathrm{T}}} B_{ii}^{\mathrm{T}} P_{ii} B_{ii} e^{\theta A_{ii}} \prec P_{ii}, \quad i = 1, 2. \tag{15}$$

To apply Theorem 1, we assume that $P_{ii}^{(0)} = P_{ii}$, $i = 1, 2$ $P_{12}^{(0)} = 0$, then from (11)–(13) we obtain $P_{12}^{(1)} = 0$ and

$$P_{11}^{(1)} = e^{-\theta A_{11}^{\mathrm{T}}} P_{11} e^{-\theta A_{11}}, \quad P_{22}^{(1)} = e^{-\theta A_{22}^{\mathrm{T}}} P_{22} e^{-\theta A_{22}}.$$

Let us define the matrix

$$\begin{aligned} \Phi = &\begin{pmatrix} e^{\theta A_{11}}P_{11}^{-1}e^{\theta A_{11}^{\mathrm{T}}} & 0 \\ 0 & e^{\theta A_{22}}P_{22}^{-1}e^{\theta A_{22}^{\mathrm{T}}} \end{pmatrix} \begin{pmatrix} B_{11}^{\mathrm{T}} & B_{21}^{\mathrm{T}} \\ B_{12}^{\mathrm{T}} & B_{22}^{\mathrm{T}} \end{pmatrix} \\ &\times \begin{pmatrix} P_{11} & 0 \\ 0 & P_{22} \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} \end{aligned}$$

A consequence of Theorem 1 is the following Proposition.

Proposition 1. *Let us assume that for the system* (1) $\int_0^\theta A_{ij}(t)\,dt = 0$ *for* $i \neq j$ *and* $r_\sigma(\Phi) < 1$, *the conditions of Assumption 1 and the following inequalities hold*

$$\begin{aligned} &\theta < \min\Big\{\frac{\lambda_{\min}(P_{11})}{\varrho}, \frac{\lambda_{\min}(P_{22})}{\varrho}\Big\}, \\ &\frac{\Theta_0(\theta)}{\min\{\lambda_{\min}(P_{11}) - \theta\varrho, \lambda_{\min}(P_{22}) - \theta\varrho\}} \\ &\qquad < -\ln\lambda_{\max}(\Phi), \end{aligned} \tag{16}$$

where $\varrho = \gamma_{12}\|P_{11}\| + \gamma_{21}\|P_{22}\|$, *then* (1) *is AS.*

To compare the obtained results with known ones obtained on the basis of the ISS approach or Lyapunov vector function (small-gain conditions), we consider (1) without impulsive action, i.e. $B_{ii} = I$, $i = 1, 2$, $B_{ij} = 0$ for $j = 1, 2$, $i \neq j$ under the same assumption $\int_0^\theta A_{ij}(t)\,dt = 0$ for $i \neq j$.

Since the Lyapunov vector function or small-gain results are only applicable when the independent subsystems are asymptotically stable, we assume $\max\{\operatorname{Re}\lambda \,|\, \lambda \in \sigma(A_{ii})\} < 0$ for $i = 1, 2$. For given $Q_i \succ 0$, $i = 1, 2$ consider the linear algebraic Lyapunov equations

$$A_{ii}^{\mathrm{T}}P_{ii} + P_{ii}A_{ii} = -Q_i. \tag{17}$$

It is known that under our assumptions for the matrices A_{ii}, $i = 1, 2$ these equations have unique solutions in the form of symmetric positive-definite matrices P_{ii}.

Remark 1. *Solutions of matrix algebraic equations* (17) *satisfy linear matrix inequalities* (15), *up to* $O(\theta^2)$.

In this case matrix Φ is the following $\Phi = \operatorname{diag}\{e^{\theta A_{11}}P_{11}^{-1}e^{\theta A_{11}^{\mathrm{T}}}P_{11}, e^{\theta A_{22}}P_{22}^{-1}e^{\theta A_{22}^{\mathrm{T}}}P_{22}\}$. Since, θ is a small parameter, we can write

$$\Phi = I - \theta\operatorname{diag}\{P_{11}^{-1}Q_1, P_{22}^{-1}Q_2\} + O(\theta^2) \quad \Rightarrow$$

$$-\ln\lambda_{\max}(\Phi) = \theta\min\{\lambda_{\min}(P_{11}^{-1}Q_1), \lambda_{\min}(P_{22}^{-1}Q_2)\} + O(\theta^2)$$

is positive-defined for a sufficiently small $\theta > 0$. On the other hand, it is easy to show that $\Theta_0(\theta) = \frac{\Theta_0(\theta)}{\min\{\lambda_{\min}(P_{11}) - \theta\varrho, \lambda_{\min}(P_{22}) - \theta\varrho\}}$, hence $\exists\,\theta^* > 0$, such that for all $\theta \in (0, \theta^*)$ the conditions of Proposition 1 are satisfied.

Corollary 2. *For the system* (1) *without impulsive action with* $\int_0^\theta A_{ij}(t)\,dt = 0$ *exists* $\theta^* > 0$, *such that for all* $\theta \in (0, \theta^*)$ *the coupled system* (1) *is asymptotically stable.*

Note that θ^* is determined from the conditions (16).

We apply the same LF $V_1(x_1) = x_1^{\mathrm{T}}P_{11}x_1$, $V_2(x_2) = x_2^{\mathrm{T}}P_{22}x_2$ to study stability of (1) without impulsive action, using the small-gain theorem in Edwards et al. (2000). By Assumption 1 and the Cauchy-Bunyakovsky inequality we get the estimates of $\dot{V}_i$ along solutions of (1)

$$\begin{aligned} \dot{V}_i(x_i) &= -x_i^{\mathrm{T}}Q_ix_i + 2x_i^{\mathrm{T}}P_{ii}A_{ij}(t)x_j \\ &\le -\lambda_{\min}(P_{ii}^{-1}Q_i)V_i(x_i) \\ &+2\|P_{ii}\|^{1/2}\|P_{jj}\|^{-1/2}\gamma_{ij}V_i^{1/2}(x_i)V_j^{1/2}(x_j). \end{aligned} \tag{18}$$

Here $i \neq j$, $i, j = 1, 2$. To check the small-gain conditions from Edwards et al. (2000) (Theorem 4), we choose

$$\chi_i(r) = \Big(\frac{2\gamma_{ij}\|P_{ii}\|^{1/2}\|P_{jj}\|^{-1/2}}{\lambda_{\min}(P_{ii}^{-1}Q_i)} + \varepsilon\Big)^2 r.$$

This leads to the following sufficient condition for the asymptotic stability of (1) (small-gain condition)

$$\gamma_{12}\gamma_{21} < \frac{1}{4}\lambda_{\min}(P_{11}^{-1}Q_1)\lambda_{\min}(P_{22}^{-1}Q_2) \tag{19}$$

Remark 2. *The method of Lyapunov vector functions lead us to the same stability conditions. Indeed,* (18) *in the new variables* $y_i(t) = V_i^{1/2}(x_i(t))$ *leads to a linear system of differential inequalities*

$$\dot{y}_i(t) \le -\frac{1}{2}\lambda_{\min}(P_{ii}^{-1}Q_i)y_i(t) + \|P_{ii}\|^{1/2}\|P_{jj}\|^{-1/2}\gamma_{ij}y_j(t).$$

Application of the comparison principle leads to (19).

From (19) it follows that the small-gain conditions do not depend on θ. Therefore, it is possible to choose the parameters of the system (1), such that the conditions (19) are not satisfied, however, based on Corollary 1, this system is asymptotically stable for sufficiently small θ. We conclude that our approach leads to less conservative stability conditions than the known small-gain conditions.

Example 2. *Consider a second-order linear system*

$$\dot{x}_1(t) = -0.2x_1(t) + 0.15a_{12}(t)x_2(t),$$
$$\dot{x}_2(t) = -0.1x_2(t) + 0.2a_{21}(t)x_1(t)$$

where $a_{ij} \in C(\mathbb{R})$, $\|a_{ij}\|_{C[0,\theta]} = 1$, $\int_0^\theta a_{ij}(t)\,dt = 0$. *Here the small-gain condition* $0.03\|a_{12}\|_{C[0,\theta]}\|a_{21}\|_{C[0,\theta]} < 0.02$ *is not satisfied. We hvae* $\mu_1 = -0.2$, $\mu_2 = -0.1$, $\delta_1 = 0.2$, $\delta_2 = 0.1$.

Choose $\theta = 0.5$, $P_{11}^{(0)} = 2.5$, $P_{22}^{(0)} = 5$, $P_{12}^{(0)} = 0$, $M_1 = M_2 = N_1 = N_2 = 1$. *By direct calculation* $\gamma_{12}^{(0)} = 0.15$, $\gamma_{21}^{(0)} = 0.2$,

$$\Pi_0 = \begin{pmatrix} 1.8125 & 0 \\ 0 & 4.3125 \end{pmatrix}, P_1 = \begin{pmatrix} 3.053506895 & 0 \\ 0 & 5.525854586 \end{pmatrix}$$

Since $Q = -0.0050178428 < 0$, *the asymptotic stability of the considered system follows.*

4. EXAMPLES

Consider a linear fourth-order impulsive system (1) with

$$A_{11} = \begin{pmatrix} 0.1 & 0.05 \\ 0.05 & 0.1 \end{pmatrix}, \quad A_{22} = \begin{pmatrix} -1 & 0.01 \\ 0.01 & -1 \end{pmatrix},$$

$$A_{12}(t) = -2\sin^2(\omega t)I, \quad A_{21}(t) = 2\sin^2(\omega t)I,$$

$$B_{11} = \begin{pmatrix} 0.98 & 0 \\ 0 & 0.98 \end{pmatrix}, \quad B_{22} = \begin{pmatrix} 1.02 & 0 \\ -0.01 & 1.01 \end{pmatrix}$$
$$B_{12} = \begin{pmatrix} -0.01 & 0 \\ 0.02 & 0 \end{pmatrix}, \quad B_{21} = \begin{pmatrix} 0 & 0.01 \\ -0.05 & 0 \end{pmatrix}$$

Here, $\tau_{k+1} - \tau_k = \theta = 0.2$, $\omega = \frac{2\pi}{\theta}$. To check the asymptotic stability conditions obtained in Theorem 1, we choose $N = 50$, $P_{11}^{(0)} = 18I$, $P_{12}^{(0)} = -7I$, $P_{22}^{(0)} = 12I$. Then, $\min_{p=\overline{0,49}} \lambda_{\min}(\Pi_p) = 7.032226894$, $Q = -0.0464239887 < 0$. Therefore, the linear impulsive system (1) is asymptotically stable. Note that the independent subsystem

$$\dot{x}_2(t) = A_{22}x_2(t), \quad t \ne \tau_k,$$
$$x_2(t^+) = B_{22}x_2(t), \quad t = \tau_k, \tag{20}$$

is not stable due to the fact that $r_\sigma(e^{A_{22}\theta}B_{22}) > 1$.

Consider a linear impulsive system (1) with the matrices

$$A_{11} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}, \quad A_{22} = \begin{pmatrix} 0.1 & 0 \\ 0 & 0.1 \end{pmatrix}$$

$$A_{12}(t) = \begin{pmatrix} 0.2\cos(\omega t) & -0.2\sin(\omega t) \\ 0.2\sin(\omega t) & 0.2\cos(\omega t) \end{pmatrix},$$

$$A_{21}(t) = \begin{pmatrix} 0.1\cos(\omega t) & -0.1\sin(\omega t) \\ 0.1\sin(\omega t) & 0.1\cos(\omega t) \end{pmatrix}$$

$$B_{11} = \begin{pmatrix} 1.2 & 0.1 \\ -0.1 & 1.5 \end{pmatrix}, \quad B_{22} = \begin{pmatrix} 0.5 & 0.05 \\ -0.05 & -0.5 \end{pmatrix}$$
$$B_{12} = \begin{pmatrix} 0.04 & 0.1 \\ 0.1 & 0.04 \end{pmatrix}, \quad B_{21} = \begin{pmatrix} 0.05 & 0.1 \\ 0.2 & 0.05 \end{pmatrix}$$

Here, $\tau_{k+1} - \tau_k = \theta = 0.5$, $\omega = \frac{2\pi}{\theta}$. To check the asymptotic stability conditions obtained in Theorem 1, we choose $N = 3$, $P_{11}^{(0)} = I$, $P_{12}^{(0)} = 0$, $P_{22}^{(0)} = I$. Then,

$$P_3 = \begin{pmatrix} 2.7171 & 0 & -0.00098 & -0.0189 \\ 0 & 2.7171 & 0.0189 & -0.00098 \\ -0.00098 & 0.0189 & 0.9024 & 0 \\ -0.0189 & -0.00098 & 0 & 0.9024 \end{pmatrix},$$

$\min_{p=\overline{0,2}} \lambda_{\min}(\Pi_p) = 0.851$, $Q = -0.11333 < 0$. Therefore (1) is asymptotically stable. Consider separately the continuous dynamics of a linear impulsive system, which is described by a linear time-variant system of ODEs

$$\dot{x}_1(t) = A_{11}x_1(t) + A_{12}(t)x_2(t),$$
$$\dot{x}_2(t) = A_{21}(t)x_1(t) + A_{22}x_2(t), \tag{21}$$

We denote

$$U(\omega t) = \begin{pmatrix} \cos(\omega t) & -\sin(\omega t) \\ \sin(\omega t) & \cos(\omega t) \end{pmatrix}$$

and rewrite (21) as

$$\dot{x}_1(t) = -x_1(t) + 0.2U(\omega t)x_2(t),$$
$$\dot{x}_2(t) = 0.1U(\omega t)x_1(t) + 0.1x_2(t), \tag{22}$$

Consider the Lyapunov–Chetaev function $v(x_1, x_2) = 2\|x_2\|^2 - \|x_1\|^2$, the total derivative of which is

$$\dot{v}(x_1, x_2) = 2(0.2\|x_2\|^2 + \|x_1\|^2 + 0.4\sin(\omega t)x_1^T J x_2)$$
$$\ge 2(0.2\|x_2\|^2 + \|x_1\|^2 - 0.4\|x_1\|\|x_2\|) > 0,$$

for all $(x_1, x_2) \ne (0, 0)$, where $J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$.

Therefore, (22) is unstable. Its discrete dynamics is also unstable since $r_\sigma(B) = 1.472162$.

Keywords: Kron-based model reduction, moment at zero, single-species single substrate chemical network, Gramian-based approach.

1. KRON REDUCTION METHOD FOR OPEN CRN WITH MASS-ACTION KINETICS

In this extended abstract, we propose a Kron-based model reduction method for open chemical reaction networks (CRN) with constant inflow and proportional outflow, which guarantees the preservation of network structures and interlacing property of the reduced-order model. Kron reduction was originally introduced for reduction of electrical circuit, see Dofler and Bullo (2012). The concept of Kron reduction is similar with singular perturbation model reduction presented in Liu and Anderson (1989) in which the Schur complement is used.

Consider an open CRN with the dynamic given by

$$\left.\begin{aligned} \dot{x} &= ZDv(x) + ZD_{\text{in}}v_{\text{in}} - ZD_{\text{out}}v_{\text{out}}(x) \\ y &= C\text{Exp}(Z^T\text{Ln}x), \end{aligned}\right\} \tag{1}$$

where $Z \in \mathbb{R}_+^{n\times c}$ is the complex stoichiometric matrix of the network, $D \in \mathbb{R}^{c\times r}$ is the incidence matrix and $v(x) \in \mathbb{R}^r$ is the vector of reaction rates or fluxes, D_{in} and D_{out} are incidence matrices of the inflow and outflow that connect internal complexes to an additional "zero"-complex $\emptyset$, $v_{\text{in}} \in \mathbb{R}^c$ is the vector of inflow from the environment, $v_{\text{out}}(x) \in \mathbb{R}^d$ is gives the outflow kinetics and y is the measured output. We will assume throughout that the inflow v_{in} are constant inflow while the outflow kinetics $v_{\text{out}}(x)$ and the vector of reaction rates $v(x) \in \mathbb{R}^r$ are given by mass-action kinetics, as presented in van der Schaft et al. (2016), the reaction rates are given by

$$v(x) = K\text{Exp}(Z^T\text{Ln}x), \tag{2}$$

$$v_{\text{out}}(x) = K_{\text{out}}\text{Exp}(Z^T\text{Ln}x), \tag{3}$$

where the *outgoing co-incidence matrix* $K \in \mathbb{R}^{r\times c}$ is the matrix whose (j,σ)th element equals the j-th reaction rate constant $k_j > 0$ if the σ-th complex is the substrate complex for the j-th reaction and K_{out} is the *outgoing co-incidence matrix* for the outflow. This allow us to rewrite (1) into the form of

$$\left.\begin{aligned} \dot{x} &= -Z(L+R)\text{Exp}(Z^T\text{Ln}x) + ZD_{\text{in}}v_{\text{in}} \\ y &= C\text{Exp}(Z^T\text{Ln}x), \end{aligned}\right\} \tag{4}$$

where $L := -DK \in \mathbb{R}^{c\times c}$ defines a weighted Laplacian matrix which has non-negative diagonal elements and non-positive off-diagonal elements and $R = D_{\text{out}}K_{\text{out}}$. Let us use the partitions

$$Z = [Z_1 \ Z_2], \quad L = \begin{bmatrix} L_{11} & L_{12} \\ L_{21} & L_{22} \end{bmatrix},$$
$$R = \begin{bmatrix} R_{11} & 0 \\ 0 & R_{22} \end{bmatrix}, \text{ and } D_{\text{in}} = \begin{bmatrix} D_{\text{in},1} \\ D_{\text{in},2} \end{bmatrix}. \tag{5}$$

For ease of expression, we consider the following auxiliary dynamical system

$$\begin{bmatrix} \dot{\xi}_1 \\ \dot{\xi}_2 \end{bmatrix} = -\begin{bmatrix} L_{11}+R_{11} & L_{12} \\ L_{21} & L_{22}+R_{22} \end{bmatrix}\begin{bmatrix} w_1 \\ w_2 \end{bmatrix} + \begin{bmatrix} D_{\text{in},1}v_{\text{in}} \\ D_{\text{in},2}v_{\text{in}} \end{bmatrix}, \tag{6}$$

which corresponds to the dynamics of complexes in (4) with $w_1 = \text{Exp}(Z_1^T\text{Ln}x)$ and $w_2 = \text{Exp}(Z_2^T\text{Ln}x)$. By imposing the constraint $\dot{\xi}_2 = 0$, we obtain that the reduced network is given by

$$\left.\begin{aligned} \dot{x} &= -\hat{Z}\hat{L}\text{Exp}(\hat{Z}^T\text{Ln}x) + \hat{Z}\hat{D}_{\text{in}}v_{\text{in}} \\ y &= \hat{C}\text{Exp}(\hat{Z}^T\text{Ln}x), \end{aligned}\right\} \tag{7}$$

where $\hat{Z} = Z_1$, $\hat{L} = (L_{11}+R_{11}) - L_{12}(L_{22}+R_{22})^{-1}L_{21}$, $\hat{D}_{\text{in}} = D_{\text{in},1} - L_{12}(L_{22}+R_{22})^{-1}D_{\text{in},2}$, and $\hat{C} = C_1 - C_2(L_{22}+R_{22})^{-1}L_{21}$.

2. ANALYSIS OF KRON-REDUCED OPEN CRN

To gain further insight to the dynamics of Kron-reduced open CRN, we will investigate a number of dynamical properties that can be preserved or obtained by the resulting Kron-reduced open CRN. First, we will see the interlacing property, where, in van der Schaft et al. (2013), Rao et al. (2013) and Jayawardhana et al. (2015), it has been shown that the Kron reduction approach preserve the network structure of the original CRN. For instance, if

the original CRN is detailed-balanced or complex-balanced then the Kron-reduced CRN is again detailed-balanced or complex-balanced, respectively. Another network property that is inherited by the Kron-reduced CRN is the network spectrum interlacing property where the spectrum of weighted Laplacian matrix of the Kron-reduced CRN is interlaced with that of the original CRN. It follows that for a given detailed-balanced open CRN as in (4), consider the corresponding Kron-reduced open CRN as in (7). Then $\sigma(\hat{L})$ interlace with $\sigma(L+R)$, i.e. for every $i = 1, \ldots, \hat{c}$

$$0 < \lambda_i(L+R) \leq \lambda_i(\hat{L}) \leq \lambda_{i+c-\hat{c}}(L+R), \tag{8}$$

holds. The proof of the proposition follows the standard result for Kron reduction of a positive semi-definite Hermitian matrix as in Smith (1992) that is used for electrical networks in Dofler and Bullo (2012) or closed CRN in Jayawardhana et al. (2015).

The next thing that we will investigate is the steady-state or zero-moment matching property. Suppose that $\mathrm{Ker}(Z) = \emptyset$ and the underlying CRN graph $\mathcal{G}$ is undirected and connected. Then the zero-moment of reduced open CRN in (7) matches with the zero-moment of original open CRN in (4). Since Z has full column rank, the left-inverse (or Moore-Penrose inverse) of Z is given by $Z^\dagger = (Z^T Z)^{-1} Z^T$. Pre-multiplying the first equation in (4) by $Z^\dagger$, we have the zero-moment property that satisfies

$$\left.\begin{aligned} 0 &= -A\mathrm{Exp}(Z^T \mathrm{Ln} x) + D_{\mathrm{in}} v_{\mathrm{in}} \\ y &= C\mathrm{Exp}(Z^T \mathrm{Ln} x), \end{aligned}\right\} \tag{9}$$

where $A = L + R$. Similarly, for the reduced-order open CRN in (7), its zero-moment satisfies

$$\left.\begin{aligned} 0 &= -(A_{11} - A_{12}A_{22}^{-1}A_{21})\mathrm{Exp}(Z^T \mathrm{Ln} x) \\ &\quad + \Big(D_{\mathrm{in},1} - (A_{12})(A_{22})^{-1} D_{\mathrm{in},2}\Big) v_{\mathrm{in}} \\ y &= (C_1 - C_2(A_{22})^{-1}(A_{21}))\mathrm{Exp}(\hat{Z}^T \mathrm{Ln} x). \end{aligned}\right\} \tag{10}$$

By hypotheses of the proposition, the matrix A is invertible due to the connectedness of $\mathcal{G}$ and due to the fact that R is a diagonal matrix with at least one positive entry (see, for example, Lemma 3 in Ni and Cheng (2010)). It follows that

$$y = CA^{-1} D_{\mathrm{in}} v_{\mathrm{in}}. \tag{11}$$

For the Kron-reduced one in (10), we can have a similar expression as above. In which we will have

$$y = \hat{C}(A_{11} - A_{12}A_{22}^{-1}A_{21})^{-1} \hat{D}_{\mathrm{in}} v_{\mathrm{in}}, \tag{12}$$

where $\hat{C}$ and $\hat{D}_{in}$ are as in (7). By using matrix inversion lemma or Woodbury formula (see Riedel (1992)), it follows that (11) is equivalent to (12).

3. SELECTION OF REMOVED COMPLEXES OF OPEN SS CRN VIA GENERALIZED GRAMIANS

As shown in Rao et al. (2014), the selection of removed nodes using Kron reduction method in a closed CRN plays an important role in the quality of the approximation error. Correspondingly, Rao et al. (2014) has proposed the combined use of error integral and simulation to remove one node at a time in order to obtain the set of removed nodes. Since the computing resource that is needed to perform the said method is quite extensive, we will propose another method with the use of generalized Gramian to get the optimal set of removed nodes along with the model reduction error bound for a class of open detailed-balanced single-species single-substrate (which we will refer to as SS) CRN. The open SS CRN can be given by

$$\left.\begin{aligned} \dot{x} &= \underbrace{-(\overbrace{DK}^{=:L} + \overbrace{D_{\mathrm{out}}K_{\mathrm{out}}}^{=:R})}_{=:A} x + \underbrace{D_{\mathrm{in}}}_{=:B} u \\ y &= Cx \end{aligned}\right\} \tag{13}$$

where the matrices A, B and C are the usual matrices of linear systems.

Since $Z = I$ in this case, the partitioning of Z, L, R and D_{in} as above corresponds to the partitioning of matrices A, B and C in (13) as follows

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \quad B = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix}, \quad C = [C_1 \; C_2]. \tag{14}$$

Hence the application of Kron reduction method to (13) gives

$$\left.\begin{aligned} \dot{\hat{x}} &= \hat{A}\hat{x} + \hat{B}u \\ \hat{y} &= \hat{C}\hat{x}, \end{aligned}\right\} \tag{15}$$

where $\hat{A} = A_{11} - A_{12}A_{22}^{-1}A_{21}$, $\hat{B} = B_1 - A_{12}A_{22}^{-1}B_2$, and $\hat{C} = C_1 - C_2A_{22}^{-1}A_{21}$.

For linear systems, controllability and observability Gramians have been used to obtain reduced-order models, see, e.g. Antoulas (2005). These Gramians reveal the states of systems that are hard to control and observe. Instead of using the ordinary Gramian to get the controllability or observability Gramian, generalized Gramians can be defined to characterize state variables that are difficult to control or to observe. In particular, *generalized controllability Gramians* is defined as a solution of inequality

$$AP + PA^T + BB^T \leq 0, \tag{16}$$

and, similarly, *generalized observability Gramians* is a solution of inequality

$$A^T Q + QA + C^T C \leq 0. \tag{17}$$

Note that, the matrices P and Q in (16) and (17) are not unique and satisfy $P \geq P_0$ and $Q \geq Q_0$ with P_0 and Q_0 be the ordinary controllability and observability Gramian, respectively, which are the unique solutions of their corresponding Lyapunov equations. This non-uniqueness gives extra degree of freedom on their structure. Namely, we can force P and Q to have a specific structure, such as forcing P and Q to be diagonal.

In our method, we will have a slightly different definition of generalized Gramians. Namely, matrices $P \in \mathbb{R}_+^{n\times n}$ and $Q \in \mathbb{R}_+^{n\times n}$ are said to be *generalized controllability* and *observability Gramians of open SS CRN systems* (13) if they are diagonal and satisfy

$$AP + PA^T + BB^T \leq 0 \tag{18}$$

and

$$A^T Q + QA + A^T C^T CA \leq 0, \tag{19}$$

respectively, where A, B and C are as in (13).

We remark that the matrix inequality defined above is stronger than the one defined in (17). It can be verified that if Q^* is a solution of (17) then $A^T Q^* A$ is a solution of (19). The generalized Gramians of open SS CRN defined above will allow for the computation of error bounds below. In this regards, the computation of tight model reduction error bounds via (18) and (19) can be done by minimizing

trace(P) and trace(Q). Following this definition we can express the generalized Gramians as

$$P = \begin{bmatrix} \pi_1^c & & \\ & \ddots & \\ & & \pi_n^c \end{bmatrix} \quad \text{and} \quad Q = \begin{bmatrix} \pi_1^o & & \\ & \ddots & \\ & & \pi_n^o \end{bmatrix}. \tag{20}$$

Next, let us first consider a one step Kron reduction, where we only remove one complex that is deemed the least controllable and observable from generalized Gramian standpoint, as follows. Consider an open SS CRN system Σ as in (13) and its reduced-order model $\hat{\Sigma}_{n-1}$ via Kron reduction as in (15) by removing the n-th node so that the reduced system $\hat{\Sigma}_{n-1}$ are given by system matrices $\hat{A} = A_{11} - A_{12}A_{22}^{-1}A_{21}$, $\hat{B} = B_1 - A_{12}A_{22}B_2$ and $\hat{C} = C_1$. In this case, we assume that $C_2 = 0$. This corresponds to the assumption that we will not remove the nodes that are measured directly. Then

$$\hat{P}_1 = \begin{bmatrix} \pi_1^c & & \\ & \ddots & \\ & & \pi_{n-1}^c \end{bmatrix} \quad \text{and} \quad \hat{Q}_1 = \begin{bmatrix} \pi_1^o & & \\ & \ddots & \\ & & \pi_{n-1}^o \end{bmatrix}, \tag{21}$$

are generalized controllability and observability Gramians for system $\hat{\Sigma}_{n-1}$, respectively.

Moreover, we have also proven that the ignored entries of the Gramians can be used to compute an a priori upper bound of this one step model reduction error as follows. For any input function $u(\cdot) \in \mathcal{L}_2[0,\infty)$ and initial condition $x(0) = 0$ and $\hat{x}(0) = 0$, the outputs satisfy

$$\|y - \hat{y}\|_2 \leq 2M_{22}\sqrt{(\pi_n^c \pi_n^o)}\|u\|_2, \tag{22}$$

where the scalar $M_{22} > 0$ is a diagonal element of the partition matrix

$$M := \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix} = -A^{-1} = (L+R)^{-1}, \tag{23}$$

and π_n^c, π_n^o are the corresponding removed elements of the generalized Gramians P and Q as in (20). The proof of proposition is based on that of (Besselink et al., 2015, Theorem 11).

Based on the bound (22), we can order the complexes (or vertices of CRN) such that

$$M_{11}^2 \pi_1^c \pi_1^o \geq \cdots \geq M_{nn}^2 \pi_n^c \pi_n^o \geq 0. \tag{24}$$

Based on this order, we can consider the removal of complexes associated to smallest error bound. By removing the vertex corresponding to the smallest error bound, we can guarantee that the reduced-order model will have a small approximation error, but not necessarily the smallest. Note that such ordering procedure corresponds simply to applying a coordinate transformation Tx using a permutation matrix T.

In practice, when we apply our Kron reduction method to a CRN, we need to truncate not only one complex. From the a priori upper bound (22), we can extend this bound for the truncation of a set of complexes. By mainly utilizing triangle inequality, we have that for any input $u \in \mathcal{L}_2[0,\infty)$ and initial condition $x(0) = 0$ and $\hat{x}(0) = 0$, the outputs y and $\hat{y}_r$ satisfy the bound

$$\|y - \hat{y}_r\|_2 \leq 2\left(\sum_{i=r+1}^{n} M_{ii}\sqrt{\pi_i^c \pi_i^o}\right)\|u\|_2, \tag{25}$$

where y and $\hat{y}_r$ are the outputs of the original and the reduced-order model, respectively, π_i^cs and π_i^cs are the removed generalized controllability and observability Gramians, respectively, as in (20), and the scalar M_{ii} is the i-th diagonal element of the matrix $M = -A^{-1} = (L + R)^{-1}$.

4. CONCLUSIONS

We studied the usage of Kron Reduction in a balanced biochemical reaction network. Our study shows that the use of the Kron Reduction method is able to preserve the network structure and equilibrium point in the reduced network even with the presence of inflow and outflow in the network. Moreover, we also provide an a priori upper bound of the approximation error via generalized Gramian approach. The latter property has allowed us to guide systematically the selection of removed nodes/species via Kron reduction.

Abstract: Analytical approximations of the macroscopic behavior of agent-based models (e.g. via mean-field theory) often introduce a significant error, especially in the transient phase. For an example model called *continuous-time noisy voter model*, we use two data-driven approaches to learn the evolution of collective variables instead. The first approach utilizes the SINDy method to approximate the macroscopic dynamics without prior knowledge, but has proven itself to be not particularly robust. The second approach employs an informed learning strategy which includes knowledge about the agent-based model. Both approaches exhibit a considerably smaller error than the conventional analytical approximation.

Keywords: Opinion Dynamics (91D30), System Identification (93B30), Linear regression (62J07), Large Population Limit, Continuous-time Markov Chain.

1. INTRODUCTION

In the past years *agent-based modeling* has undoubtedly gained in importance. While its success in various applications is significant, agent-based models (ABMs) still have many limitations. Even for rather simple interaction rules between agents, the emerging macroscopic system behavior may be very complex and hard to predict analytically. Thus, a formal analysis is typically out of reach and computer simulations are used to examine the behavior of ABMs instead. As simulations of most ABMs scale at least linearly with the number of agents, they are often computationally infeasible for large populations of agents. Thus, we are interested in finding low-dimensional model reductions that scale sublinearly while preserving the macroscopic behavior of the underlying ABMs.

It is known that this macroscopic behavior can sometimes be expressed by a small number of *collective variables* (or *reaction coordinates*, to borrow a term from statistical physics and computational chemistry) that aggregate the most important dynamical information, see for example Helfmann et al. (2021). Furthermore, it is often observed that for a large number of agents the *effective dynamics* of the collective variables follows an almost deterministic and smooth evolution. Hence, the macroscopic dynamics may be approximated by a differential equation of the collective variables. We we will refer to this phenomenon as a *concentration (of measure) effect*. If we are only interested in the aggregated information provided by the collective variables, we can use the reduced system instead of the full agent-based model, which greatly lowers computational cost.

Finding suitable collective variables for a given system is a challenging task, see for instance Bittracher et al. (2017). However, we will assume from now on that a set of collective variables has been chosen and focus on the question of discovering their dynamics instead, i.e., finding a description of their evolution in the form of a differential equation.

In the next section we introduce an exemplary ABM called the *continuous-time noisy voter model* (CNVM), which models simple spreading processes on networks. The remaining sections of this extended abstract deal with analyzing this model for different examples of network topologies. In section 3 we present results about the CNVM on fully connected networks, where the appearance of concentration effects can be proven. In section 4 we discuss a ring-shaped network topology and derive approximate macroscopic dynamics analytically as well as via data-driven methods.

Although the network topologies that we discuss in sections 3 and 4 are rather simple, the methods we present lay the groundwork for analyzing more complex systems, which are more similar to real-world social networks and will be subject matter of future works.

2. THE CONTINUOUS-TIME NOISY VOTER MODEL

We define the continuous-time noisy voter model as a dynamical system on an undirected simple graph G with N nodes. Each node $i \in \{1, \dots, N\}$ in the graph represents an agent and has one of M opinions $\{1, \dots, M\}$. The state of the system at times $t \in \mathbb{R}_{\geq 0}$ is given by the stochastic process $\boldsymbol{x}(t) \in \mathcal{X}_N := \{1, \dots, M\}^N$, where $\boldsymbol{x}_i(t)$ is the opinion of node i at time t. We model the switching of the agents between opinions as Markov jump processes, i.e., $\boldsymbol{x}_i(t)$ is a continuous-time Markov chain on $\{1, \dots, M\}$ with transition rate matrix (generator matrix) $Q_i^G(\boldsymbol{x}) \in \mathbb{R}^{M,M}$. We define the rate at which agent i transitions from opinion m to a different opinion n as

$$(Q_i^G(\boldsymbol{x}))_{mn} = r_{mn}\frac{k_{i,n}^G(\boldsymbol{x})}{k_i^G} + \tilde{r}_{mn}, \tag{1}$$

where $r_{mn}, \tilde{r}_{mn} \in \mathbb{R}_{\geq 0}$ are constant parameters, k_i^G is the degree of the i-th node, and $k_{i,n}^G$ is the number of adjacent nodes (neighbors) of agent i that have opinion n. The first term of the rate (1) describes an influence on agent i by neighboring nodes of opinion n, while the second term controls transitions independently of the neighborhood of agent i, i.e., noise.

The CNVM as described above is a simple but quite general example of a spreading process on a network. The behavior of this model is heavily dependent on the underlying network G. Let us first examine the easiest case: the fully connected network.

3. FULLY CONNECTED NETWORK

Let us discuss the continuous-time noisy voter model in the case of a fully connected graph G_N on N nodes. Note that the cumulative rate of transitions from opinion m to opinion n happening is given by

$$\begin{aligned}\alpha_{mn}^{(N)}(\boldsymbol{x}) &:= \sum_{i:x_i=m} (Q_i^{G_N}(\boldsymbol{x}))_{mn} \\ &= \boldsymbol{y}_m\Big(r_{mn}\frac{\boldsymbol{y}_n}{N-1} + \tilde{r}_{mn}\Big),\end{aligned} \tag{2}$$

where the stochastic process $\boldsymbol{y}(t) \in \mathbb{N}_0^M$ is the collection of *opinion counts*, i.e.,

$$\boldsymbol{y}_m := \#\{i \in \{1,\dots,N\} \mid \boldsymbol{x}_i = m\}. \tag{3}$$

Due to their appearance in the *propensity function* $\alpha_{mn}^{(N)}$ in (2), the opinion counts $\boldsymbol{y}$ present themselves as a natural choice of collective variables. In fact, we are able to completely describe the ABM dynamics using $\boldsymbol{y}$, see Winkelmann and Schütte (2020).

Moreover, it is known that the evolution of *opinion shares* $\boldsymbol{c} := \frac{1}{N}\boldsymbol{y}$ shows a concentration effect, which is described in the following theorem.

Theorem 1. (Kurtz (1978)) Let $(N_\ell)_{\ell\in\mathbb{N}} \subset \mathbb{N}$ be strictly increasing and let $\boldsymbol{c}^{(\ell)}(t)$ denote the stochastic process of opinion shares on the fully connected graph on N_ℓ nodes. Assume it holds $\boldsymbol{c}^{(\ell)}(0) = c_0$ almost surely (a.s.) for all ℓ. Then

$$\boldsymbol{c}^{(\ell)}(t) \xrightarrow[\ell\to\infty]{a.s.} c(t) \quad \text{for all } t \in \mathbb{R}_{\geq 0},$$

where c(t) is the solution of the *reaction-rate equation* (RRE)

$$\dot{c}(t) = \sum_{\substack{m,n=1\\ m\neq n}}^{M} \tilde{\alpha}_{mn}(c(t))(e_n - e_m)\ , \quad c(0) = c_0,$$

e_n, e_m are standard unit vectors and

$$\tilde{\alpha}_{mn}(c) := c_m\Big(r_{mn}c_n + \tilde{r}_{mn}\Big).$$

An illustration on how the stochastic processes $\boldsymbol{c}^{(\ell)}(t)$ become more concentrated around the solution of the RRE as the number of agents increases can be found in Figure 1. In the next section we will examine a more challenging network topology.

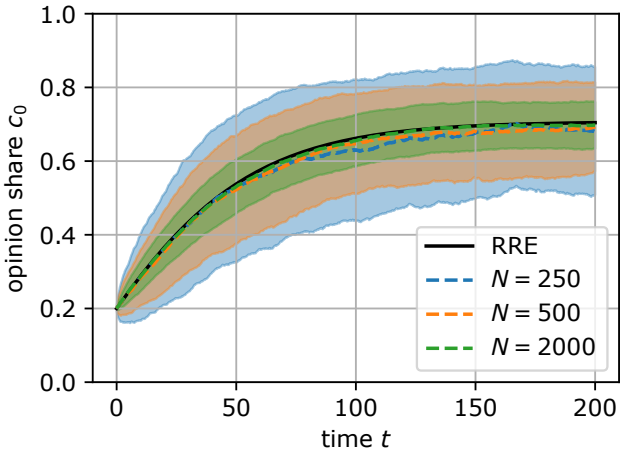

Fig. 1. Mean (dashed line) ± one standard deviation (shaded area) of 500 realizations of the CNVM on fully connected networks of sizes $N = 250, 500, 2000$. Black: solution of the reaction-rate equation.

4. RING-SHAPED NETWORK

While the ring-shaped network (cycle graph) still has a fairly simple structure, analytical results for concentration effects with respect to suitable collective variables are not available. We assume that there are only $M = 2$ opinions, 0 and 1, and set $m \in \{0, 1\}$ and $n = 1 - m$. Let us again inspect the propensity function for this network structure:

$$\begin{aligned}\alpha_{mn}^{(N)}(\boldsymbol{x}) &= \sum_{i:x_i=m} (Q_i^{G_N}(\boldsymbol{x}))_{mn} \\ &= \frac{r_{mn}}{2}(\boldsymbol{y}_m^1 + 2\boldsymbol{y}_m^2) + \boldsymbol{y}_m\tilde{r}_{mn},\end{aligned} \tag{4}$$

where $\boldsymbol{y}$ is defined as in (3), and

$$\boldsymbol{y}_m^\ell := \#\{i \in \{1,\dots,N\} \mid \boldsymbol{x}_i = m \text{ and } k_{i,n}^G(\boldsymbol{x}) = \ell\} \tag{5}$$

is the count of agents of opinion m with ℓ neighbors of opinion $n = 1 - m$. Thus, a natural choice of collective variables is given by

$$\boldsymbol{z} := (\boldsymbol{y}_0^0, \boldsymbol{y}_0^1, \boldsymbol{y}_0^2, \boldsymbol{y}_1^0, \boldsymbol{y}_1^1, \boldsymbol{y}_1^2). \tag{6}$$

Note that $\boldsymbol{z}$ includes $\boldsymbol{y}$ because $\boldsymbol{y}_m = \boldsymbol{y}_m^0 + \boldsymbol{y}_m^1 + \boldsymbol{y}_m^2$.

4.1 The analytical approach

In this section we will derive an ODE $\dot{z} = f(z)$ that approximates the evolution of the collective variables $\boldsymbol{z}$. For this purpose we need to characterize at which rate certain opinion transitions happen and how they impact $\boldsymbol{z}$.

Let us discuss the following example: $(x_{i-1}, x_i, x_{i+1}) = (m, m, m)$ and agent i transitions from opinion m to opinion n. This transition has a rate of $\tilde{r}_{mn}$ (cf. (1)), because agent i has no neighbor of different opinion, who could influence them. Due to the transition of agent i, y_m^0 decreases and y_n^2 increases by one. Additionally, for the agents $(i-1)$ and $(i+1)$ the number of neighbors with opinion n changes as well, but this depends on the opinions of agents $(i-2)$ and $(i+2)$. Assume we knew that $(x_{i-2}, x_{i+2}) = (m, m)$. Then the transition of agent i would further increase y_m^1 by two and decrease y_m^0 by two, leading to the total *state-change vector* $v = (-3, 2, 0, 0, 0, 1)$. The

three other cases $(x_{i-2}, x_{i+2}) = (m,n), (n,m), (n,n)$ yield three (potentially) different *reactions* with different state-change vectors. Unfortunately, only the combined rate $\tilde{r}_{mn}$ of all four reactions is known, not the single reaction rates. We distribute the total rate onto the four reactions by relative occurrence and assuming stochastic independence of x_{i-2} and x_{i+2}. For the above example $(x_{i-2}, x_{i-1}, x_i, x_{i+1}, x_{i+2}) = (m,m,m,m,m)$ this yields a share of

$$\Big(\frac{y^0_m}{y^0_m + 0.5y^1_m}\Big)^2$$

of the combined rate $\tilde{r}_{mn}$. Hence, we set the rate of the above reaction given by $v = (-3,2,0,0,0,1)$ happening somewhere in the system (propensity) to

$$\alpha(z) = y^0_m \tilde{r}_{mn} \Big(\frac{y^0_m}{y^0_m + 0.5y^1_m}\Big)^2. \tag{7}$$

Following this procedure for all possible scenarios, i.e., agent i being of opinion $m = 0,1$ and having $\ell = 0,1,2$ neighbors of opinion n, and agents $(i-2), (i+2)$ having opinions $(m,m), (m,n), (n,m), (n,n)$, yields a total of $2 \cdot 3 \cdot 4 = 24$ reactions with associated reaction rates $\alpha_j(z)$ and state-change vectors v_j, $j = 1, \dots, 24$. Thus, the evolution of z is given by

$$\dot{z} = \sum_{j=1,\dots,24} \alpha_j(z) v_j. \tag{8}$$

(The number of reactions can be reduced to 20 due to symmetry.)

Note that, in contrast to the fully connected networks (cf. theorem 1), we do not have any convergence guarantee for (8). In fact, in its derivation we made the assumption that certain agents are stochastically independent. While this is a common strategy in the construction of the macroscopic evolution, see for example *mean-field theory* (Porter and Gleeson (2014)), here it introduces an error, cf. Fig. 3. In the next sections, we will employ data-driven techniques to learn the macroscopic evolution and reduce the above mentioned error.

4.2 Learning collective variable dynamics using SINDy

A very popular technique to discover system dynamics from data is called *Sparse Identification of Nonlinear Dynamics* (SINDy) and was proposed by Brunton et al. (2016). It works as follows: Given a time-series of trajectory data $\{z^{(k)}\}$ and a library of basis functions $\{f_j\}$, we numerically approximate the derivatives at the trajectory points $\dot{z}^{(k)}$ (e.g., via finite differences) and solve for the optimal weights $\{\lambda_j\}$ such that $\sum_j \lambda_j f_j(z^{(k)}) \approx \dot{z}^{(k)}$ (linear regression). Additionally, we typically enforce a certain sparsity on the set of weights $\{\lambda_j\}$. Hence, there are many hyperparameters to be considered when applying SINDy: the method to generate derivatives, the library of basis functions, the optimizer and optimizer parameters (especially regarding the desired sparsity of coefficients), etc.

Our data set consist of 9 trajectories of z with different initial conditions, cf. Fig. 2. In order to find optimal hyperparameters, we employ grid search combined with leave-one-out cross-validation, i.e., for every choice of hyperparameters we train 9 models, so that model i trains on all except the i-th trajectory, and define the error as the deviation from the data in infinity norm on the validation trajectory i, averaged over the 9 models. This procedure showed that SINDy is rather sensitive to the choice of hyperparameters. For many choices the dynamics produced by SINDy is unstable, so that we had to artificially bound $z(t)$ to not produce an infinitely large error. The best choice of hyperparameters that we found was using central finite differences for calculating the derivatives, polynomials of degree less than 2 as basis functions, and the SSR optimizer (Boninsegna et al. (2018)). The dynamics produced by SINDy is visualized in Fig. 3 and its error is depicted in Fig. 4. Note that the average error is significantly lower than the error of the analytical model from section 4.1. However, there also exist trajectories where the dynamics learned by SINDy has a bigger error than the analytical model. As discovering the macroscopic dynamics using SINDy is not robust, we will explore an informed learning approach in the next section.

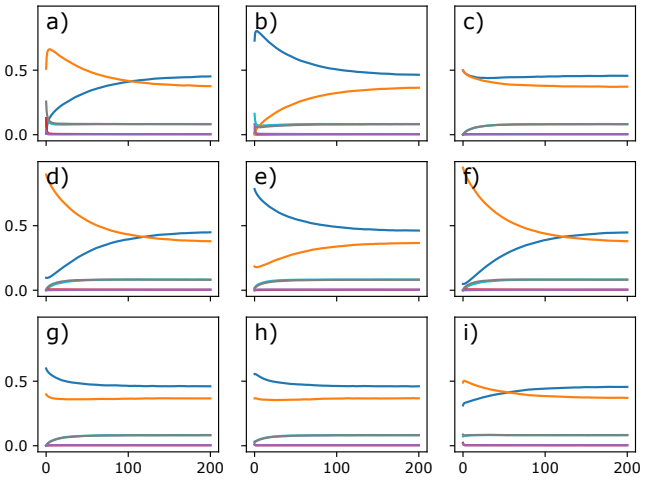

Fig. 2. The available trajectory data consists of 9 trajectories of $\frac{1}{N}\boldsymbol{z}(t)$ (cf. (6)) for $t \in [0, 200]$ and $N = 2000$, starting from different initial conditions and averaged over an ensemble of 500 simulations each. We will refer to the different trajectories by their label, e.g. "trajectory a)".

4.3 Learning the closure

In the analytical derivation of the collective variable equations in section 4.1 we introduced an error by distributing a cumulative rate onto four associated reactions (cf. (7)) under assumptions that may not be correct. Hence, we will employ a data-driven method in order to learn better ways of distributing the shares of the cumulative rate. In contrast to the SINDy technique from the previous section, we do not need to learn the complete dynamics without prior knowledge, but we apply the data-driven method precisely to the unknown part in the analytical equations, thus learning the *closure* of the equations.

To obtain the training data, we iterate through every snapshot of our training trajectories (cf. Fig. 2) and count the occurrences of all possible 5-tuples $(x_{i-2}, \dots, x_{i+2}) \in \{0,1\}^5$, which enables us to calculate the above mentioned shares of the cumulative rates. Then we employ linear

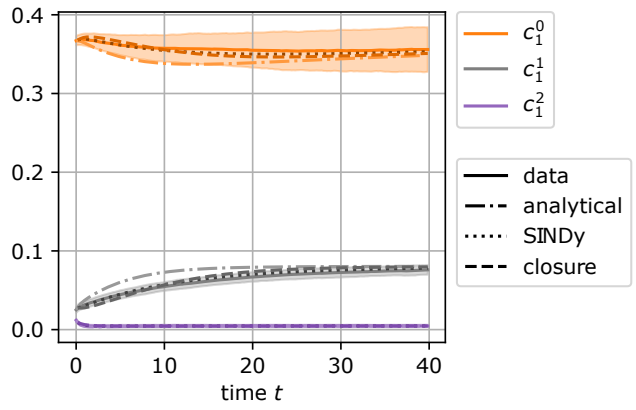

Fig. 3. Trajectory h) data and approximate solutions: "analytical" (cf. section 4.1), "SINDy" (cf. section 4.2), "closure" (cf. section 4.3). $c_m^\ell := y_m^\ell / N$.

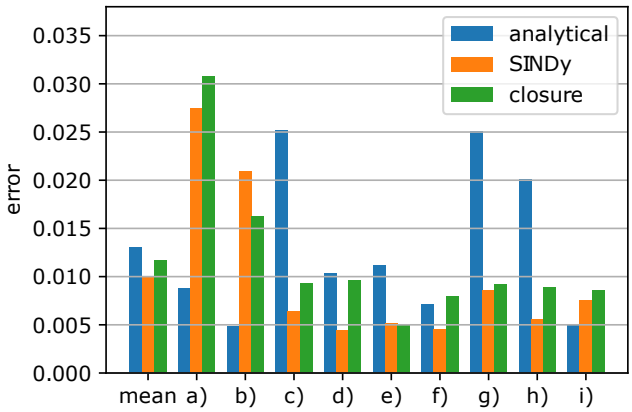

Fig. 4. Error of approximate dynamics for $\boldsymbol{z}$ (cf. (6)) for the 9 test trajectories (cf. Fig. 2): "analytical" (cf. section 4.1), "SINDy" (cf. section 4.2), "closure" (cf. section 4.3). The error is measured as deviation from mean of data w.r.t. infinity norm.

regression with an ℓ_1 regularization, see *LASSO* by Tibshirani (1996), to find an optimal approximation of the empirical share functions within the space of polynomials. We again employ grid search combined with leave-one-out cross-validation (cf. section 4.2) to find the best optimizer parameters and optimal degree of polynomials. As discussed in section 4.1, there are 20 share functions that need to be learned.

We found that this approach of learning the closure is significantly more robust than SINDy (cf. section 4.2) for our example as it rarely produces unstable dynamics, see table 1. However, the error of this method seems to be slightly larger than the error of SINDy, but still lower than the error of the analytical model, cf. Fig. 3 and Fig 4. Note also, that this approach is not inferior to SINDy on all 9 trajectories, e.g., it is superior to SINDy on trajectory b).

Further tests also showed that this approach of learning the closure requires significantly less data than SINDy to produce good results, i.e., we could beat the analytical model using only 5 of the 9 training trajectories while SINDy needed at least 7.

5. OUTLOOK

In this extended abstract we showed how one can employ data-driven methods in order to improve the accuracy of conventional macroscopic dynamics approximations. These methods, which we demonstrated for simple network topologies, will be extended to more complex systems in future works. Further tasks are to find the collective variables in a case where we can simulate the system (or some trajectories of it are given), and to derive stochastic models for mesoscopic populations where the deterministic limit of Theorem 1 is not a good approximation.

Linear quadratic optimal control of switched differential algebraic equations

Paul Wijnbergen * **Stephan Trenn** *

* *Bernoulli Institute for Maths, CS and AI, University of Groningen, 9747 AG, Groningen, The Netherlands (e-mail: p.wijnbergen@rug.nl, s.trenn@rug.nl).*

Abstract: In this abstract the finite horizon linear quadratic optimal control problem with constraints on the terminal state for switched differential algebraic equations is considered. Furthermore, we seek for an optimal solution that is impulse-free. In order to solve the problem, a non standard finite horizon problem for non-switched DAEs is considered. Necessary and sufficient conditions on the initial value x_0 for solvability of this non standard problem are stated. Based on these results a sequence of subspaces can be defined which lead to necessary and sufficient conditions for solvability of the finite horizon optimal control problem for switched DAEs.

Keywords: Switched systems, Differential Algebraic Equations, Optimal control, Linear systems.

1. INTRODUCTION

In this abstract we consider the following switched differential algebraic system

$$\begin{aligned} E_\sigma \dot{x} &= A_\sigma x + B_\sigma u \\ y &= C_\sigma x + D_\sigma u. \end{aligned} \tag{1}$$

where $\sigma : \mathbb{R} \to \mathbb{N}$ is the switching signal and $E_p, A_p \in \mathbb{R}^{n\times n}$ and (E_p, A_p) is regular, $B_p \in \mathbb{R}^{n\times m}$, $C_p \in \mathbb{R}^{q\times n}$ and $D_p \in \mathbb{R}^{p\times m}$ for $p, q, n, m \in \mathbb{N}$. We aim to find an impulse-free solution (x, u) on $[t_0, t_f)$ satisfying $x(t_0^-) = x_0$ and $x(t_f^-) \in \mathcal{V}^{\text{end}}$ that minimizes

$$J(x_0, u, t_f) = \int_{t_0}^{t_f} y(t)^\top y(t)\, \mathrm{d}t + x(t_f^-)^\top P x(t_f^-) \tag{2}$$

for some positive semi definite $P = P^\top \in \mathbb{R}^{n\times n}$ and y is the output resulting from the solution (x, u) of (1) satisfying $x(t_0^-) = x_0$. In general, trajectories of switched DAEs exhibit jumps (or even impulses), which may exclude classical solutions from existence. Therefore, we adopt the *piecewise-smooth distributional solution framework* introduced in Trenn (2009).

Differential algebraic equations (DAEs) arise naturally when modeling physical systems with certain algebraic constraints on the state variables. Examples of applications of DAEs in electrical circuits can be found e.g. in Tolsa and Salichs (1993); Riaza (2008); Reis (2010) and gas networks, where the algebraic constraints are induced by the network topology. *e.g.* in Grundel et al. (2014). The algebraic constraints are often eliminated such that the system is described by ordinary differential equations (ODEs). However, in the case of switched systems, the elimination process of the constraints is in general different for each individual mode. Therefore, in general, there does not exist a description as a switched ODE with a common state variable for every mode. This problem can be overcome by studying switched DAEs directly.

The literature on optimal control of non-switched DAEs is quite mature, (besides the already mentioned literature) see for the finite horizon e.g. Kunkel and Mehrmann (2008, 1997); Ilchmann et al. (2019, 2021); Wijnbergen and Trenn (2021b) on a finite horizon and for the infinite time horizon see e.g. Cobb (1983); Mehrmann (1989); Reis et al. (2015); Reis and Voigt (2019); Bankmann and Voigt (2019). Furthermore, several structural properties of switched DAEs have been investigated recently (Wijnbergen and Trenn, 2021a, 2020). However, to the best of the authors knowledge, optimal control of switched DAEs has not been studied yet.

The finite horizon problem is motivated by the study of optimal control on an infinite horizon, *i.e.,* the minimization of

$$J(x_0, u) = \int_{t_0}^{\infty} y(t)^\top y(t)\, \mathrm{d}t. \tag{3}$$

on the interval $[t_0, \infty)$ while using a dynamic programming approach. It can be shown that if there exists an input that minimizes (3), the optimal cost resulting from the interval $[t_f, \infty)$ is quadratic in $x(t_f^-)$, *i.e.,* $x(t_f^-)^\top P x(t_f^-)$ for some matrix $P \in \mathbb{R}^{n\times n}$. This result allows for a dynamic programming approach. Assuming that the matrix P and the optimal input u restricted to $[t_f, \infty)$ are known, it follows that the minimization of (3) is equivalent to finding the input u restricted to $[t_0, t_f)$ such that

$$\begin{aligned} J(x_0, u) &= \int_{t_0}^{t_f} y(t)^\top y(t)\, \mathrm{d}t + \int_{t_f}^{\infty} y(t)^\top y(t)\, \mathrm{d}t \\ &= \int_{t_0}^{t_f} y(t)^\top y(t)\, \mathrm{d}t + x(t_f^-)^\top P x(t_f^-). \end{aligned}$$

is minimal.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

For many real word applications Dirac impulses in the state are to be avoided as they can cause damage to components of the system or create hazardous situations. Therefore, we aim to find an optimal *impulse-free* solution (x, u). However, there generally only exists an optimal (impulse-free) solution on $[t_f, \infty)$ if the state at t_f is contained in some subspace, *i.e.,* $x(t_f^-) \in \mathcal{V}^{\text{end}}$ for some subspace $\mathcal{V}^{\text{end}} \subseteq \mathbb{R}^n$.

In order to solve the problem for switched systems with a switching signal that induces an arbitrary yet finitely many modes on the interval $[t_0, t_f)$ we will first consider the case that only two modes are induced on $[t_0, \infty)$ and the switch occurs at t_f. Within this context we aim to minimize (2) with respect to a non-switched DAE. Once conditions for the single switched case are obtained, conditions for the general case will follow straightforwardly. Hence first we will focus on finding an optimal solution to

$$E\dot{x} = Ax + Bu, \tag{4}$$
$$y = Cx + Du \tag{5}$$

that minimizes (2) under the constraint $x_0 \in \mathbb{R}^n$ and $x(t_f^-) \in \mathcal{V}^{\text{end}}$.

As the terminal cost matrix P represents the cost resulting from the interval $[t_f, \infty)$ and the mode active on this interval is not necessarily structurally related to the dynamics (4), we can only assume that $P \in \mathbb{R}^{n\times n}$ is some positive semi-definite matrix. This is in contrast to the assumption commonly made in the literature for optimal control of non switched DAEs that the terminal cost matrix is of the form $P = E^\top \tilde{P} E$ for some positive semi-definite $\tilde{P} \in \mathbb{R}^{n\times n}$ (Lewis, 1985; Bender and Laub, 1985; Katayama and Minamino, 1992). Also note that whereas commonly a closed interval is of interest, in this paper a half open interval is considered. Consequently, the terminal cost can penalizes algebraic states and as a result $x(t_f^-)$ is not necessarily equal to $x(t_f)$ or even well defined such that an optimal solution might fail to exist.

The remainder of this paper is structured as follows. The mathematical preliminaries and the main results are given in Section 2 and 3, respectively. Conclusions and a discussion on future work are given in Section 4.

2. MATHEMATICAL PRELIMINARIES

In the following, we consider *regular* matrix pairs (E, A), i.e. for which the polynomial $\det(sE - A)$ is not the zero polynomial. Recall the following result on the *quasi-Weierstrass form (QWF)* (Berger et al., 2012).

Proposition 1. A matrix pair $(E, A) \in \mathbb{R}^{n\times n} \times \mathbb{R}^{n\times n}$ is regular if, and only if, there exists invertible matrices $S, T \in \mathbb{R}^{n\times n}$ such that

$$(SET, SAT) = \left(\begin{bmatrix} I & 0 \\ 0 & N \end{bmatrix}, \begin{bmatrix} J & 0 \\ 0 & I \end{bmatrix} \right), \tag{6}$$

where $J \in \mathbb{R}^{n_1\times n_1}$, $0 \leqslant n_1 \leqslant n$, is some matrix and $N \in \mathbb{R}^{n_2\times n_2}$, $n_2 := n - n_1$, is a nilpotent matrix.

The matrices S and T can be calculated by using the so-called *Wong sequences* (Berger et al., 2012; Wong, 1974): Based on the Wong sequences we define the following projectors and selectors.

Definition 2. Consider the regular matrix pair (E, A) with corresponding quasi-Weierstrass form (6). The *consistency projector* of (E, A) is given by

$$\Pi := T \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} T^{-1},$$

the *differential selector* and the *impulse selector* are given by

$$\Pi^{\text{diff}} := T \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} S, \quad \Pi^{\text{imp}} := T \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix} S.$$

respectively

In all three cases the block structure corresponds to the block structure of the QWF. Furthermore we define

$$A^{\text{diff}} := \Pi^{\text{diff}} A, \qquad E^{\text{imp}} := \Pi^{\text{imp}} E,$$
$$B^{\text{diff}} := \Pi^{\text{diff}} B, \qquad B^{\text{imp}} := \Pi^{\text{imp}} B.$$

Note that all the above defined matrices do not depend on the specifically chosen transformation matrices S and T; they are uniquely determined by the original regular matrix pair (E, A). An important feature for DAEs is the so called consistency space, defined as follows for the DAE given in (4).

Definition 3. Consider the DAE (4), then the *consistency space* is defined as

$$\mathcal{V}_{(E,A)} := \left\{ x_0 \in \mathbb{R}^n \;\middle|\; \begin{array}{l} \exists \text{ smooth solution } x \text{ of (4)} \\ \text{with } u = 0 \text{ and } x(0) = x_0 \end{array} \right\},$$

and the *augmented consistency space* is defined as

$$\mathcal{V}_{(E,A,B)} := \left\{ x_0 \in \mathbb{R}^n \;\middle|\; \begin{array}{l} \exists \text{ smooth solutions } (x, u) \text{ of (4)} \\ \text{with } x(0) = x_0 \end{array} \right\}.$$

For studying impulsive solutions of (4), we consider the space of *piecewise-smooth distributions* $\mathbb{D}_{\text{pw}\mathcal{C}^\infty}$ from Trenn (2009) as the solution space. That is, we seek a solution $(x, u) \in (\mathbb{D}_{\text{pw}\mathcal{C}^\infty})^{n+m}$ to the following initial-trajectory problem (ITP) associated with (4):

$$x_{(-\infty,0)} = x^0_{(-\infty,0)}, \tag{7a}$$
$$(E\dot{x})_{[0,\infty)} = (Ax)_{[0,\infty)} + (Bu)_{[0,\infty)}, \tag{7b}$$

where $x^0 \in (\mathbb{D}_{\text{pw}\mathcal{C}^\infty})^n$ is some initial trajectory, and $f_{\mathcal{I}}$ denotes the restriction of a piecewise-smooth distribution f to an interval $\mathcal{I}$. In Trenn (2009) it is shown that the ITP (7) has a unique solution for any initial trajectory if, and only if, the matrix pair (E, A) is regular. As a direct consequence, the switched DAE considered in (1) with regular matrix pairs is also uniquely solvable (with piecewise-smooth distributional solutions) for any switching signal with locally finitely many switches.

The space of initial values for which there exists an impulse-free solution (x, u) of (4) is defined as follows.

Definition 4. Consider the DAE (4), then the *impulse controllable space* is defined as

$$\mathcal{C}^{\text{imp}} := \left\{ x_0 \in \mathbb{R}^n \;\middle|\; \begin{array}{l} \exists \text{ solution of (7) satisfying} \\ x(0^-) = x_0 \text{ and } (x, u)[0] = 0 \end{array} \right\},$$

The DAE is called impulse controllable if $\mathcal{C}^{\text{imp}} = \mathbb{R}^n$.

Lemma 5. (Cobb (1981)). The DAE (4) is impulse controllable if and only if there exist a feedback input $u = Lx + v$ such that in terms of the selectors Π^{diff} and Π^{imp} resulting from the Wong sequences based on $(E, A + BL)$, the solution x is given by $x = x^{\text{diff}} - B^{\text{imp}} v$ where x^{diff} solves

$$\dot{x}^{\mathrm{diff}} = (A + BL)^{\mathrm{diff}} x^{\mathrm{diff}} + B^{\mathrm{diff}} v \tag{8}$$

Given a matrix pair (E, A) and a matrix B we can always generate an impulse-controllable DAE with the same solution behavior for initial values $x_0 \in \mathcal{C}^{\mathrm{imp}}$.

Lemma 6. Consider the DAE (4). A solution (x, u) satisfying $x(0^-) = x_0 \in \mathcal{C}^{\mathrm{imp}}$ solves (4) if and only if (x, u) solves

$$EW\dot{x} = Ax + Bu \tag{9}$$

where W is an orthogonal projector onto $\mathcal{C}^{\mathrm{imp}}$. In addition, (9) is impulse controllable.

3. MAIN RESULTS

The concepts introduced in the previous section are now utilized to study the minimization of (2) subject to the non-switched DAE (4). We aim to minimize (2) over all (x, u) that are impulse-free and satisfy $x(t_0^-) = x_0$ and $x(t_f^-) \in \mathcal{V}^{\mathrm{end}}$.

As we aim to find an impulse-free solution (x, u) that minimizes (2), it is necessary that $x(t_0) = x_0 \in \mathcal{C}^{\mathrm{imp}}$. Consequently, it follows from Lemma 6 that we can assume without loss of generality that (4) is impulse controllable. Moreover, we can assume that an index-reducing feedback in the sense of Lemma 5 has been applied and that the system is of index-1.

In the case (4) is of index-1, we observe, by making use of the decomposition $x = x^{\mathrm{diff}} - B^{\mathrm{imp}}u$, that (x, u, y) solves (4) if, and only if, $(x^{\mathrm{diff}}, u, y)$ with $x^{\mathrm{diff}}(t_0^-) = \Pi x_0$ solves

$$\begin{aligned} \dot{x}^{\mathrm{diff}} &= A^{\mathrm{diff}} x^{\mathrm{diff}} + B^{\mathrm{diff}} u \\ \bar{y} &= C x^{\mathrm{diff}} + (D - CB^{\mathrm{imp}})u \end{aligned} \tag{10}$$

which shows that the minmization of (2) subject to (4) is equivalent to the minimization of

$$\bar{J}(x^{\mathrm{diff}}, u) = \int_{t_0}^{t_f} \bar{y}(t)^\top \bar{y}(t)\, \mathrm{d}t + \bar{x}(t_f^-)^\top P \bar{x}(t_f). \tag{11}$$

where $\bar{x} := x^{\mathrm{diff}} - B^{\mathrm{imp}}u$, subject to (10). This shows that the optimal control problem for non switched DAEs can be reduced to an equivalent problem for ordinary differential equations (ODEs). However, note that the latter problem is still not a standard finite horizon linear quadratic optimal control problem for ODEs as the terminal state of the input is penalized by the terminal cost and because of the subspace endpoint constraint $\bar{x}(t_f^-) = x(t_f^-) \in \mathcal{V}^{\mathrm{end}}$.

In order to ensure that the optimal input does not contain impulses, we assume that $\bar{D} := D - CB^{\mathrm{imp}}$ has full column rank, such that $\bar{D}^\top \bar{D}$ is positive definite. For ODE optimal control problems with a cost resulting from an output (10) this is standard. However, in the literature on optimal control on DAE it is often assumed that $D^\top D$ is positive definite, which we do not require here. Note that a sufficient condition for $\bar{D}$ to have full column rank is

$$\operatorname{rank} [CW \;\; D] = m$$

were W is some projector onto $\ker E$. This assumption is very similar to the assumption that the system (4) is impulse-observable.

3.1 Regarding the terminal cost

As the terminal cost in (11) penalizes the input, it follows that if there exists a solution that minimizes (11), the value of $u(t_f^-)$ must be well defined and satisfies given the optimal state $x^{\mathrm{diff}}(t_f^-)$

$$\begin{aligned} &((x^{\mathrm{diff}}(t_f^-) - B^{\mathrm{imp}}u(t_f^-))^\top P((x^{\mathrm{diff}}(t_f^-) - B^{\mathrm{imp}}u(t_f^-)) \\ &\quad \leqslant ((x^{\mathrm{diff}}(t_f^-) - B^{\mathrm{imp}}v)^\top P((x^{\mathrm{diff}}(t_f^-) - B^{\mathrm{imp}}v)) \end{aligned}$$

for all v satisfying $x^{\mathrm{diff}}(t_f^-) - B^{\mathrm{imp}}v \in \mathcal{V}^{\mathrm{end}}$. Using Lagrange multipliers and noting that the terminal cost is a convex function of $u(t_f^-)$ leads to the following result.

Lemma 7. Let (x^{diff}, u) be a solution satisfying $\bar{x}(t_0^-) = x_0$ and $\bar{x}(t_f^-) \in \mathcal{V}^{\mathrm{end}}$ that minimizes (11). Then the terminal cost satisfies

$$\bar{x}(t_f^-)^\top P \bar{x}(t_f^-) = x^{\mathrm{diff}}(t_f^-)^\top \Psi^\top P \Psi x^{\mathrm{diff}}(t_f^-). \tag{12}$$

where $\Psi = (I - B^{\mathrm{imp}}N)$ for some N satisfying

$$\begin{bmatrix} I & 0 & N \end{bmatrix} \ker \begin{bmatrix} B^{\mathrm{imp}\top} P B^{\mathrm{imp}} & B^{\mathrm{imp}\top} \Pi_{\mathcal{V}^\perp}^\top & -2B^{\mathrm{imp}\top} P \Pi \\ \Pi_{\mathcal{V}^\perp} B^{\mathrm{imp}} & 0 & -\Pi_{\mathcal{V}^\perp} \Pi \end{bmatrix} = 0.$$

where $\Pi_{\mathcal{V}^\perp}$ is an orthogonal projector onto the orthogonal complement of $\mathcal{V}^{\mathrm{end}}$.

It follows from Lemma 7 that instead of minimizing (11) directly, we can focus on finding an input that minimizes

$$\begin{aligned} \bar{J}_\Psi(x^{\mathrm{diff}}, u) = \int_{t_0}^{t_f} \bar{y}(t)\bar{y}(t)\, \mathrm{d}t \\ + x^{\mathrm{diff}}(t_f^-)^\top \Psi^\top P \Psi x^{\mathrm{diff}}(t_f^-) \end{aligned} \tag{13}$$

and verify whether the optimal input satisfies (12). However, the computation of the input that minimizes (13) is rather straightforward. After denoting

$$\bar{y}(t)^\top \bar{y}(t) = \begin{bmatrix} x^{\mathrm{diff}} \\ u \end{bmatrix}^\top \begin{bmatrix} Q & S^\top \\ S & R \end{bmatrix} \begin{bmatrix} x^{\mathrm{diff}} \\ u \end{bmatrix}$$

we can state the following result.

Lemma 8. The cost functional $\bar{J}_\Psi(x^{\mathrm{diff}}, u)$ satisfies

$$\begin{aligned} &\bar{J}_\Psi(x^{\mathrm{diff}}, u) - x^{\mathrm{diff}}(t_0^-)^\top X(t_0) x^{\mathrm{diff}}(t_0^-) \\ &\qquad = \int_{t_0}^{t_f} \left(\left\| u + R^{-1}(\bar{B}^{\mathrm{diff}\top} X + S^\top) \bar{x}^{\mathrm{diff}} \right\|_2^2 \right) \end{aligned}$$

where X solves

$$\begin{aligned} \dot{X} = A^{\mathrm{diff}\top} X + X^\top A^{\mathrm{diff}} + Q \\ - (S + X^\top B^{\mathrm{diff}}) R^{-1} (B^{\mathrm{diff}\top} X + S^\top). \end{aligned} \tag{14}$$

with terminal condition $X(t_f) = \Psi^\top P \Psi$.

Corollary 9. If an input u minimizes (13), then

$$u = -R^{-1}(B^{\mathrm{diff}\top} X + S^\top) x^{\mathrm{diff}} \tag{15}$$

where X is a solution to (14) with $X(t_f) = \Psi^\top P \Psi$.

The result of Corollary 9 shows that if there exists an optimal control, it needs to be of a particular form. However, a feedback of the form (15) does not necessarily controls an initial value Πx_0 to the desired subspace, *e.g.,* in the case $\mathcal{V}^{\mathrm{end}}$ is the zero subspace, and hence an optimal control might fail to exist. In order to determine which intial values are controlled to $\mathcal{V}^{\mathrm{end}}$ at t_f^- we define the following flow operator.

Definition 10. The backwards state transition matrix for the closed loop ODE

$$\dot{x}^{\text{diff}} = \left(A^{\text{diff}} - B^{\text{diff}} R^{-1} \left(B^{\text{diff}\top} X + S^\top\right)\right) x^{\text{diff}}$$

is given by $\Omega(t, t_f)$. Hence $x^{\text{diff}}(t) = \Omega(t, t_f) x^{\text{diff}}(t_f^-)$.

Recall that the state $x = x^{\text{diff}} - B^{\text{imp}} u$ and thus for the input (15) we have $x(t_f^-) = M x^{\text{diff}}(t_f^-)$ where

$$M := I - B^{\text{imp}} R^{-1} \left(B^{\text{diff}\top} \Psi^\top P \Psi + S^\top\right).$$

As $x^{\text{diff}}(t_f^-) = \Pi\xi$ for some $\xi \in \mathbb{R}^n$ it follows that $x(t_f^-) \in \mathcal{V}^{\text{end}}$ if and only if

$$x^{\text{diff}}(t_f^-) = \Pi\xi \in \ker \Pi_{\mathcal{V}^\perp} M$$

Next, observe that the input (15) satisfies (12) if and only if

$$\begin{aligned} x(t_f^-)^\top P x(t_f^-) &= x^{\text{diff}}(t_f^-)^\top M^\top P M \Pi x(t_f^-) \\ &= x^{\text{diff}}(t_f^-)^\top \Psi^\top P \Psi x^{\text{diff}}(t_f^-). \end{aligned}$$

This is the case if $M^\top P M x^{\text{diff}}(t_f^-) = \Psi^\top P \Psi x^{\text{diff}}(t_f^-)$. Given these observations, we can state the following result regarding the minimization of (11).

Theorem 11. There exists an impulse-free solution (x, u) satisfying $x(t_0^-) = x_0$ and $x(t_f^-) \in \mathcal{V}^{\text{end}}$ that minimizes (11) if and only if

$$x_0 \in \mathcal{V}^{\text{init}} := \Omega(t_0, t_f) \ker \begin{bmatrix} \Pi_{\mathcal{V}^\perp} M \\ M^\top P M - \Psi^\top P \Psi \end{bmatrix} \Pi.$$

3.2 Multiple switched case

Given the result of Theorem 11 we are now able to state conditions for the existence of a solution that minimizes (2) subject to (1). To do so, we define the following sequence

$$\begin{aligned} \mathcal{V}_{\mathtt{n}}^{\text{end}} &= \mathcal{V}^{\text{end}}, \\ \mathcal{V}_{i-1}^{\text{end}} &= \mathcal{V}_i^{\text{init}}, \end{aligned} \qquad i = \mathtt{n}, \mathtt{n}-1, ..., 0$$

where $\mathcal{V}_i^{\text{init}}$ is defined according to Theorem 11 on the interval $[t_i, t_{i+1})$ w.r.t. $\mathcal{V}_i^{\text{end}}$.

Theorem 12. There exists an impulse-free solution (x, u) that minizes (2) and satisfies $x(t_0^-) = x_0$ and $x(t_f^-) \in \mathcal{V}^{\text{end}}$ if and only if $x_0 \in \mathcal{V}_0^{\text{init}}$.

4. CONCLUSION

In this abstract we considered the finite horizon optimal control problem for switched DAEs. Based on sovability of `n` nonstandard optimal control problems for ODEs solvability of the optimal control problem for switched DAEs can be concluded. In this abstract impulse-freeness of the solution (x, u) was required. A natural direction of research is to investigate the existence of optimal impulsive solutions.

Abstract: We propose new mathematical connections between Hamilton-Jacobi (HJ) partial differential equations (PDEs) with initial data and neural network architectures. Specifically, we prove that some classes of neural networks correspond to representation formulas of HJ PDE solutions whose Hamiltonians and initial data are obtained from the parameters or the activation functions of the neural networks. These results do not require any learning stage. In addition these results do not rely on universal approximation properties of neural networks; rather, our results show that some classes of neural network architectures naturally encode the physics contained in some HJ PDEs. Our results naturally yield efficient neural network-based methods for evaluating solutions of some HJ PDEs in high dimension without using grids or numerical approximations.

Keywords: Optimal Control, Hamilton-Jacobi Partial Differential Equations, Neural Networks, Grid-Free Numerical Methods, High Dimensions

1. INTRODUCTION

Hamilton-Jacobi (HJ) partial differential equations (PDEs) are widely used in physics, optimal control, game theory, and imaging sciences. An HJ PDE is given as follows

$$\begin{cases} \dfrac{\partial S}{\partial t}(\boldsymbol{x},t) + H(t,\boldsymbol{x},\nabla_{\boldsymbol{x}} S(\boldsymbol{x},t)) = 0 & \text{in } \mathbb{R}^n \times (0,+\infty), \\ S(\boldsymbol{x},0) = J(\boldsymbol{x}) & \text{in } \mathbb{R}^n, \end{cases} \tag{1}$$

where $S\colon \mathbb{R}^n \times [0,+\infty) \to \mathbb{R} \cup \{+\infty\}$ denotes the solution to the PDE, $H\colon [0,+\infty) \times \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ is the Hamiltonian, and $J\colon \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ is the initial condition. The computational complexity of standard grid-based numerical algorithms for solving HJ PDEs scales exponentially with respect to the dimension n. This exponential scaling is often referred to as the "curse of dimensionality" (CoD) [Bellman (1961)]. Due to the CoD, these grid-based methods are infeasible for solving high-dimensional problems (e.g., dimensions greater than five) and thus are infeasible for many practical applications.

In the literature, several methods are proposed to overcome the curse of dimensionality when solving high dimensional HJ PDEs and optimal control problems. These methods include, but are not limited to, max-plus methods [Akian et al. (2008); Fleming and McEneaney (2000); McEneaney (2006)], optimization methods [Darbon and Osher (2016); Yegorov and Dower (2017)], tensor decomposition techniques [Dolgov et al. (2019); Horowitz et al. (2014); Todorov (2009)], sparse grids [Bokanowski et al. (2013); Kang and Wilcox (2017)], polynomial approximation [Kalise et al. (2019)], model order reduction [Alla et al. (2017); Kunisch et al. (2004)], dynamic programming and reinforcement learning [Alla et al. (2019); Bertsekas (2019)] and neural networks [Bachouch et al. (2018); Jiang et al. (2016); Nakamura-Zimmerer et al. (2019); Jin et al. (2020)].

Recently, we proposed several neural network architectures for solving different classes of high-dimensional HJ PDEs [Darbon et al. (2020); Darbon and Meng (2021); Darbon et al. (2021)]. These neural network architectures have solid theoretical guarantees from the theory of HJ PDEs, and they can leverage efficient hardware dedicated to neural networks and designed for future real-time applications. By using the theory of HJ PDEs, the parameters in these neural networks are assigned directly from the PDEs. Therefore, we do not need any training process. This is the main difference of our proposed neural network methods with traditional neural network methods.

In the following sections, we summarize our proposed three architectures. The first architecture is a shallow neural network proposed in Darbon et al. (2020) and is summarized in Section 2. The second is a neural network with two hidden layers proposed in Darbon and Meng (2021) and is summarized in Section 3. The last one is a deep neural network proposed in Darbon et al. (2021) and is summarized in Section 4.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

Throughout, we use $\mathbb{R}^{n\times l}$ to denote the set of matrices with n rows and l columns with entries in $\mathbb{R}$, and use S^n to denote the set of real-valued symmetric matrices in $\mathbb{R}^{n\times n}$. We use $C(0,T;X)$ to denote the set of continuous functions from $[0,T]$ to a space X.

2. A SHALLOW NEURAL NETWORK ARCHITECTURE

A shallow neural network architecture for solving a class of high-dimensional HJ PDEs is proposed in Darbon et al. (2020). The target PDE is a subclass of HJ PDEs (1) whose Hamiltonian H does not depend on $(\boldsymbol{x},t)$, and whose initial condition J is convex. We define the neural network function $f\colon \mathbb{R}^n\times[0,+\infty)\to\mathbb{R}$ by

$$f(\boldsymbol{x},t) \doteq \max_{i\in\{1,\dots,m\}} \{\langle \boldsymbol{p}_i,\boldsymbol{x}\rangle - t\theta_i - \gamma_i\}, \tag{2}$$

with parameters $\boldsymbol{p}_i\in\mathbb{R}^n$, $\theta_i\in\mathbb{R}$, and $\gamma_i\in\mathbb{R}$ for $i=1,\dots,m$ (where i is the index for the neuron, and m is the total number of neurons involved). The illustration for this neural network architecture is shown in Fig. 1.

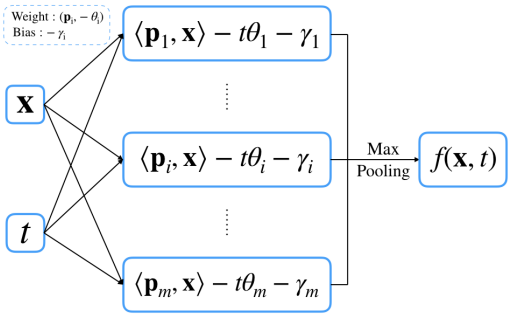

Fig. 1. Architecture of the neural network (2) that represents the viscosity solution to certain class of HJ PDEs, whose Hamiltonian does not depend on $(\boldsymbol{x},t)$, and whose initial condition is convex.

In Darbon et al. (2020), both theoretical guarantees and numerical experiments are provided for this architecture. Under certain assumptions, the neural network function f computes the viscosity solution to the HJ PDE (1) whose initial condition $J\colon\mathbb{R}^n\to\mathbb{R}$ and Hamiltonian $H\colon\mathbb{R}^n\to\mathbb{R}\cup\{+\infty\}$ are defined using the parameters $\{(\boldsymbol{p}_i,\theta_i,\gamma_i)\}_{i=1}^m$ as follows

$$J(\boldsymbol{x}) \doteq \max_{i\in\{1,\dots,m\}} \{\langle \boldsymbol{p}_i,\boldsymbol{x}\rangle - \gamma_i\}, \tag{3}$$

and

$$H(\boldsymbol{p}) \doteq \begin{cases} \inf\limits_{\boldsymbol{\alpha}\in\mathcal{A}(\boldsymbol{p})} \left\{\sum\limits_{i=1}^m \alpha_i\theta_i\right\}, & \text{if } \boldsymbol{p}\in \operatorname{dom} J^*,\\ +\infty, & \text{otherwise,}\end{cases} \tag{4}$$

where J^* denotes the Fenchel-Legendre transform of the function J (see Hiriart-Urruty and Lemaréchal (1993b)), and the set $\mathcal{A}(\boldsymbol{p})\subseteq\mathbb{R}^m$ is defined by

$$\mathcal{A}(\boldsymbol{p}) \doteq \operatorname*{arg\,min}_{\substack{(\alpha_1,\dots\alpha_m)\in\Lambda_m\\ \sum_{i=1}^m \alpha_i\boldsymbol{p}_i=\boldsymbol{p}}} \left\{\sum_{i=1}^m \alpha_i\gamma_i\right\}.$$

Here, we use Λ_m to denote the unit simplex in $\mathbb{R}^m$, i.e.,

$$\Lambda_m \doteq \left\{(\alpha_1,\dots,\alpha_m)\in[0,1]^m : \sum_{i=1}^m \alpha_i = 1\right\}.$$

We also proved that the function f with the same parameters $\{(\boldsymbol{p}_i,\theta_i,\gamma_i)\}_{i=1}^m$ may solve different HJ PDEs. The function H defined in (4) is a lower bound for all possible Hamiltonians in these HJ PDEs. In this way, we identified the smallest Hamiltonian H in (4) for the set of HJ PDEs whose viscosity solution is the function f with certain parameters $\{(\boldsymbol{p}_i,\theta_i,\gamma_i)\}_{i=1}^m$. We refer readers to Darbon et al. (2020) for detailed assumptions and characterization for this set of HJ PDEs. In Darbon et al. (2020), we also provided several numerical experiments showing the ability of our proposed architectures for overcoming the CoD.

3. A NEURAL NETWORK ARCHITECTURE WITH TWO HIDDEN LAYERS

A neural network architecture, with two hidden layers, for solving another class of high-dimensional HJ PDEs is proposed in Darbon and Meng (2021). This class assumes a convex Hamiltonian that is independent of (x,t). The neural network function $f\colon\mathbb{R}^n\times[0,+\infty)\to\mathbb{R}$ involved is defined by

$$f(\boldsymbol{x},t) \doteq \min_{i\in\{1,\dots,m\}} \left\{tL\left(\frac{\boldsymbol{x}-\boldsymbol{u}_i}{t}\right) + a_i\right\}, \tag{5}$$

with parameters $\boldsymbol{u}_i\in\mathbb{R}^n$ and $a_i\in\mathbb{R}$ for $i=1,\dots,m$. The activation function $L\colon\mathbb{R}^n\to\mathbb{R}$ corresponds to the Lagrangian function in the theory of HJ PDEs and optimal control problems. An illustration is shown in Fig. 2.

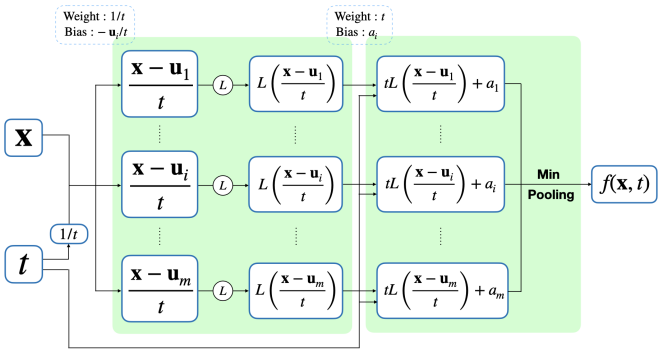

Fig. 2. Architecture of the neural network (5) that represents the viscosity solution to certain class of HJ PDEs whose Hamiltonian is convex and does not depend on $(\boldsymbol{x},t)$.

The initial data $J\colon\mathbb{R}^n\to\mathbb{R}$ is defined by

$$J(\boldsymbol{x}) \doteq \min_{i\in\{1,\dots,m\}} \{L'_\infty(\boldsymbol{x}-\boldsymbol{u}_i) + a_i\}, \tag{6}$$

where L'_∞ is the asymptotic function of L (see (Hiriart-Urruty and Lemaréchal, 1993a, Chap. IV.3.2)). Under certain assumptions, the function f defined in (5) is shown to compute the viscosity solution to the HJ PDE (1) with Hamiltonian $H=L^*$ (i.e., H equals the Fenchel-Legendre transform of the activation function L in the neural network, and H does not depend on $(\boldsymbol{x},t)$) and initial condition J defined in (6). Although the initial

condition J has a specific form in (6), this form can be used to approximate other meaningful initial conditions when m approaches infinity. In Darbon and Meng (2021), we also provided several numerical experiments in high dimensions. From the experimental results, we observe that our proposed architecture can overcome the CoD for certain HJ PDEs. Another neural network architecture with two hidden layers is proposed in the same paper. We refer readers to Darbon and Meng (2021) for more details about the theoretical guarantees and numerical results for these two architectures.

4. A DEEP NEURAL NETWORK ARCHITECTURE

A deep neural network architecture is proposed in our recent paper Darbon et al. (2021) for representing the viscosity solution to the backward HJ PDE

$$\begin{cases} -\dfrac{\partial V(\boldsymbol{x},t)}{\partial t} + H(t,\boldsymbol{x},\nabla_{\boldsymbol{x}} V(\boldsymbol{x},t)) = 0 & \boldsymbol{x}\in\mathbb{R}^n, t\in(0,T), \\ V(\boldsymbol{x},T) = J(\boldsymbol{x}) & \boldsymbol{x}\in\mathbb{R}^n, \end{cases} \tag{7}$$

with Hamiltonian $H\colon [0,T]\times\mathbb{R}^n\times\mathbb{R}^n\to\mathbb{R}$ of the form

$$H(t,\boldsymbol{x},\boldsymbol{p}) \doteq \frac{1}{2}\boldsymbol{p}^T C_{pp}(t)\boldsymbol{p} - \frac{1}{2}\boldsymbol{x}^T C_{xx}(t)\boldsymbol{x} - \boldsymbol{p}^T C_{xp}(t)\boldsymbol{x},$$

and terminal condition $J\colon\mathbb{R}^n\to\mathbb{R}$ of the form

$$J(\boldsymbol{x}) \doteq \min_{i\in\{1,\dots,m\}} \left\{ \frac{1}{2}\boldsymbol{x}^T G_i \boldsymbol{x} + \boldsymbol{a}_i^T \boldsymbol{x} + b_i \right\}.$$

The coefficients in H, i.e., $C_{pp}(t)$, $C_{xx}(t)$, and $C_{xp}(t)$, are functions depending on t and taking values in $\mathbb{R}^{n\times n}$. The parameters in J contain matrices $G_i\in S^n$, vectors $\boldsymbol{a}_i\in\mathbb{R}^n$, and scalars $b_i\in\mathbb{R}$, for $i=1,\dots,m$.

Under certain assumptions (see Darbon et al. (2021)), the viscosity solution to (7) can be represented by a function V_{NN} defined by

$$\begin{aligned} V_{NN}(\boldsymbol{x},t) &\doteq \min_{i\in\{1,\dots,m\}} V_i(\boldsymbol{x},t), \\ V_i(\boldsymbol{x},t) &\doteq \frac{1}{2}\boldsymbol{x}^T P_i(t)\boldsymbol{x} + \boldsymbol{q}_i(t)^T\boldsymbol{x} + r_i(t), \end{aligned} \tag{8}$$

where the function $P_i\in C(0,T;S^n)$ solves the following Riccati final value problem (FVP)

$$\begin{cases} \dot{P}_i(t) = P_i(t)^T C_{pp}(t) P_i(t) - P_i(t)^T C_{xp}(t) \\ \qquad\qquad -C_{xp}(t)^T P_i(t) - C_{xx}(t) \quad t\in(0,T), \\ P_i(T) = G_i, \end{cases} \tag{9}$$

the functions $\boldsymbol{q}_i\in C(0,T;\mathbb{R}^n)$ solves the following linear FVP

$$\begin{cases} \dot{\boldsymbol{q}}_i(t) = P_i(t)^T C_{pp}(t)\boldsymbol{q}_i(t) - C_{xp}(t)^T\boldsymbol{q}_i(t) \quad t\in(0,T), \\ \boldsymbol{q}_i(T) = \boldsymbol{a}_i, \end{cases} \tag{10}$$

and the function $r_i\in C(0,T;\mathbb{R})$ solves the following FVP

$$\begin{cases} \dot{r}_i(t) = \dfrac{1}{2}\boldsymbol{q}_i(t)^T C_{pp}(t)\boldsymbol{q}_i(t) \quad t\in(0,T), \\ r_i(T) = b_i. \end{cases} \tag{11}$$

In our implementations, we apply the Runge-Kutta method to solve (9), (10), and (11). The Runge-Kutta method can itself be expressed using a Resnet architecture, so that the implementation for the function V_{NN} defined in (8) can be expressed using the deep neural network illustrated in Fig. 3.

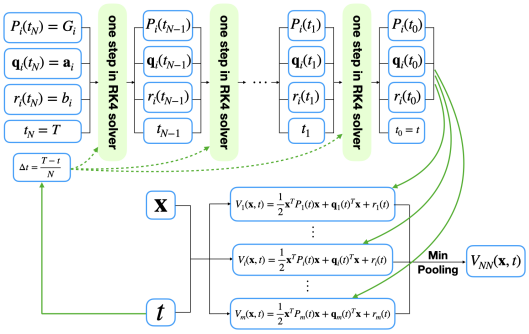

Fig. 3. A deep neural network architecture defined by (8) (where each function V_i is computed using the Runge-Kutta method) that represents the viscosity solution to the HJ PDE (7).

The bottom part of Fig. 3 is a one-layer abstract architecture with a min-pooling activation function. The i-th abstract neuron is given by the function $V_i(\boldsymbol{x},t)$ in (8). The value on the i-th abstract neuron is computed using the top part of Fig. 3, which represents the Runge-Kutta method for solving (9), (10), and (11). Note that the top part of Fig. 3 can be replaced by another numerical method for solving (9), (10), and (11), if the method can be expressed using a neural network architecture.

In Darbon et al. (2021), we provide both theoretical guarantees and numerical results for our proposed deep architecture. For the purpose of illustration here, we extract an example of solving a high-dimensional HJ PDE below. We refer readers to Darbon et al. (2021) for more results on solving HJ PDEs and the corresponding optimal control problems in high dimensions.

We consider the HJ PDE (7) with

$$H(t,\boldsymbol{x},\boldsymbol{p}) \doteq \frac{e^t}{4}\|\boldsymbol{p}\|^2 - \frac{e^{-t}}{4}\|\boldsymbol{x}\|^2 - \frac{1}{2}\langle\boldsymbol{p},\boldsymbol{x}\rangle, \tag{12}$$

and the terminal condition J is defined by

$$J(\boldsymbol{x}) \doteq \min\left\{\Psi_1(\boldsymbol{x}),\Psi_2(\boldsymbol{x}),\Psi_3(\boldsymbol{x}),\Psi_4(\boldsymbol{x})\right\}, \tag{13}$$

where $\Psi_1,\Psi_2,\Psi_3,\Psi_4\colon\mathbb{R}^n\to\mathbb{R}$ are defined by

$$\begin{aligned} \Psi_1(\boldsymbol{x}) &\doteq 0.5\|\boldsymbol{x}\|^2 + 0.9x_1 + 0.405, \\ \Psi_2(\boldsymbol{x}) &\doteq 0.5\|\boldsymbol{x}\|^2 - 0.9x_1 + 0.405, \\ \Psi_3(\boldsymbol{x}) &\doteq 0.25\|\boldsymbol{x}\|^2 + 0.9x_2 + 0.405, \\ \Psi_4(\boldsymbol{x}) &\doteq 0.25\|\boldsymbol{x}\|^2 - 0.9x_2 + 0.405, \end{aligned}$$

for each $\boldsymbol{x}=(x_1,\dots,x_n)\in\mathbb{R}^n$. We solve a 16-dimensional problem, i.e., we set $n=16$, and the numerical results at earlier times t are shown in Fig. 4. In each figure, we plot two-dimensional slices of the function $\boldsymbol{x}\mapsto V_{NN}(\boldsymbol{x},t)$ for illustration. We consider the points $\boldsymbol{x}=(x_1,x_2,\boldsymbol{0})\in\mathbb{R}^{16}$ where $(x_1,x_2)\in\mathbb{R}^2$ is any grid point in a two-dimensional rectangular domain and $\boldsymbol{0}$ denotes the zero vector in $\mathbb{R}^{14}$. From the numerical results, our proposed deep neural network overcomes the CoD in this example.

Keywords: Optimal control theory, control of quantum and Schroedinger systems, Sum-of-squares, convex optimization, industrial applications of optimal control

1. INTRODUCTION

Quantum optimal control has numerous applications, within quantum computing, laser control of chemical reactions, and nuclear magnetic resonance. In quantum computing, better quantum optimal control provides faster and more accurate two-qubit gates, and multi-level operations in general, eventually allowing for fault-tolerant quantum computation.

There are many excellent results, which establish conditions for controllability, as surveyed in D'Alessandro (2007) and Jurdjevic (2016), but constructive, algorithmic approaches still leave space for improvement. For the control of systems involving more than three levels, including the pulse-shaping for two-qubit gates, there are no deterministic, globally convergent solvers. There are two key challenges. First, most formulations seem to assume commutativity of the Hamiltonian at different times. Second, the corresponding quantum optimal control on an N-level system is non-convex for $N \geq 4$, but only heuristics based on first-order optimality conditions are employed.

We have recently addressed the issues of non-commutativity and non-convexity of the problem by employing Magnus expansion (Magnus, 1954; Blanes et al., 2009) and tools from non-commutative polynomial optimisation (Pironio et al., 2010; Burgdorf et al., 2016). In addressing the non-commutativity of the problem, this improves most directly upon the work of Schutjens et al. (2013) and Theis et al. (2016), who consider the lowest-order term of the Magnus expansion, also known as the average Hamiltonian, and derive conditions for all other terms being zero. In contrast to their approach, we consider an arbitrary number of terms in the Magnus expansion. Our work complements research on Magnus expansion in numerical integration of the Schrödinger equation (Blanes et al., 2009; Singh, 2018; Kopylov, 2019, e.g.), which however have not been developed in the context of quantum control so far. In addressing the non-convexity of the problem, we utilise a hierarchy of progressively stronger convexifications. This improves upon essentially all related work on quantum optimal control, which guarantees only monotonic convergence to first-order critical points or local minima of a non-convex optimisation problem based on Pontryagin's maximum principle.

2. THE PROBLEM

Let us consider a finite N-dimensional quantum system whose time-evolution is governed by a Schrödinger equation. Given an initial condition $\hat{U}(0) = \hat{I}$, where $\hat{I}$ is a unit matrix in $\mathbb{C}^{N\times N}$, a terminal time $T > 0$, and a target unitary $\hat{U}^* \in U(N) \subset \mathbb{C}^{N\times N}$, where $U(N)$ is the Lie group of $N \times N$ unitary operators or matrices, we aim to control a time-dependent Hamiltonian $\hat{H}(t)$ over time $t \in [0, T]$. That is, we seek a particular solution of the initial value problem for the Schrödinger equation:

$$\frac{\partial}{\partial t}\hat{U}(t) = \hat{A}(t)\hat{U}(t) \tag{1}$$

where $\hat{A}(t) = \hat{H}(t)/i\hbar$ can explicitly be written in terms of controls $u_j(t) : [0, T] \to \mathbb{R}$ as

$$\hat{A}(t) = \sum_j u_j(t)\ \hat{H}_j/i\hbar. \tag{2}$$

In particular, we seek a solution that is optimal with respect to a given functional J, while using controls $\{u_j(t)\}$ constrained to some set Υ. Formally, the quantum optimal control problem reads:

$$\min_{\hat{U}(t),\{u_j(t)\}\in\Upsilon} J\left(\hat{U}(t), \{u_j(t)\}\right) \tag{3}$$
$$\text{s.t. } \frac{\partial}{\partial t}\hat{U}(t) = \left[\sum_j u_j(t)\ \hat{H}_j/i\hbar\right]\hat{U}(t),$$
$$\hat{U}(0) = \hat{I}.$$

where J is the (objective) functional for the control problem, which is polynomially or semidefinite representable (Helton and Vinnikov, 2007), and Υ is a polynomially representable set.

3. OUR APPROACH

It is well known that initial value problem (1) has a solution in the form of the Magnus expansion (Magnus, 1954; Blanes et al., 2009):

$$\Omega(T) = \sum_{m=1}^{\infty} \Omega_m(T), \tag{4}$$

where the individual terms in the series require evaluations of increasingly more complex integrals involving nested commutators. When the series $\Omega_m(T)$ is absolutely convergent, then $\hat{U}(t)$ can be written in the form

$$\hat{U}(t) = \exp \Omega(t). \tag{5}$$

In a key insight of this paper, we show that the nested commutators between the Hamiltonian at different times are instrumental in extending the reachable set. This expansion is accomplished via two distinct mechanisms. First, the nested commutators generate new linearly independent elements of the Lie algebra $\mathfrak{su}(N)$ and hence increase the dimension of the reachable set. The operator controllability is accomplished when this dimension reaches $N^2 - 1$.

The second mechanism is related to the controls $\{u_j(t)\}$, which figure in coefficients of the Lie algebra elements that are generated by the k terms of the Magnus expansion. The controls are, in general, arbitrary functions of time which allows for an arbitrary linear combination of the Lie algebra elements. Hence the two mechanisms result in both expanding the dimension of the reachable set as a Lie algebra and also in its dense cover by control functions and their integrals. We denote the expanded reachable set obtained with the lowest m terms in the Magnus series by $\mathrm{ME}(R(\hat{U}(0)), m)$.

Specifically, in the case of a time-dependent Hamiltonian, one need not consider only generators of the Lie group as they appear in $\hat{H}(t)$, but one can also consider the commuting relations obtained by Magnus expansion: (i) A necessary condition for reachability of any $\hat{U}(T) \in SU(N)$ from $\hat{U}(0) = \hat{I}$ to $\hat{U}(T)$, considering Magnus expansion is that the dimension of the Lie algebra generated by Magnus expansion has dimension $N^2 - 1$. (ii) A necessary and sufficient condition for the existence of time T^* such that for all $T > T^*$ one has exact-time operator controllability is that the dimension of the Lie algebra generated by Magnus expansion has dimension $N^2 - 1$.

It is to be pointed out that the validity of our approach is limited by the convergence of the Magnus expansion. This has been studied extensively, with the most recent result provided by Moan and Niesen (2008).

4. THE MAIN RESULT

Our second insight is that this approach can be made constructive, considering that for any number m of terms in the Magnus expansion, one obtains a non-commutative polynomial optimisation problem (NCPOP), which can be solved by solving a sequence (Pironio et al., 2010, cf.) of natural linear matrix inequalities (Boyd et al., 1994) in the original variables and additional variables for non-linear monomials, based on the Sums of Squares theorem of Helton (2002) and McCullough (2001).

Hence, under mild assumptions, for any initial state $\hat{U}(0)$, for any lower bound $\underline{m}$ on the number of terms in the Magnus expansion, for any target state in the expanded reachable set $\mathrm{ME}(R(\hat{U}(0)), \underline{m})$, and any error $\epsilon > 0$, there is a number of terms $m(\epsilon) \geq \underline{m}$ such that ϵ-optimal control with respect to any polynomially-representable functional can be extracted from the solution of a certain convex optimisation problem in the model of Blum et al. (1989).

Notice that we use Magnus expansion in two ways here: First, $\underline{m}$ steps in the Magnus expansion guarantee we can reach any target in $\mathrm{ME}(R(\hat{U}(0))$. Second, we need $m(\epsilon) \geq \underline{m}$ number of steps to achieve the convergence within ϵ error introduced by the Magnus expansion. We also utilise recent results on the robustness of the GNS construction to small errors. Indeed, we can apply (Klep et al., 2018, Theorem 3.2) directly, if there are no constraints Υ.

Now notice that one could also consider an unconstrained problem, where $\sum_{m=1}^{\overline{m}} \Omega_m(T)$ is compared to $\log U^*$ directly, measuring a distance between the target element of the Lie algebra given by $\log U^*$ and the element of the Lie algebra emerging from the Magnus expansion $\tilde{\Omega} = \sum_{m=1}^{\overline{m}} \Omega_m(T)$ of the control problem. There, we can rewrite the expression for $\Omega_m(T)$ as $\sum_i \hat{O}_i \tilde{F}_i(\{\tilde{u}_j\}(t_1, \ldots, t_{m+1}))$. The operators $\hat{O}_i$ result from the commutators of the Magnus expansion which involve the Hamiltonians $\hat{H}_j$ at different times. The function $\tilde{F}_i(\tilde{u}_j\}(t_1, \ldots, t_{m+1}))$ is a polynomial of the time-dependent controls $u_j(t)$ at different times $t_1, \ldots, t_{m+1}$, originating from the same commutator, and after an appropriate discretization (sub-sampling) of time $\{u_j\} \to \{\tilde{u}_j\}$. The functions $\{\tilde{F}_i\}$ represent coefficients in the Lie algebra associated with the operator $\{O_i\}$ which, if the system is controllable, constitute the complete set of generators of the Lie algebra. In this formulation, the control problem reduces to optimization of these coefficients, and in particular minimization of the difference between these coefficients and those of $\log U^*$. Since $\log U^*$ is not unique, one needs to consider this comparison modulo 2π which in turn may weaken the guarantees of finding the global minimum. At the same time, however, the problem becomes a commutative polynomial optimization problem (POP).

5. CONCLUSIONS

We have presented an approach to quantum optimal control that exhibits global convergence, in theory, and relies on non-trivial but well-developed tools from non-commutative geometry and mathematical optimisation, in practice. In contrast to other quantum control approaches, the use of Magnus expansion provides the proper solution of the initial value problem of the Schrödinger equation involving time-dependent Hamiltonian. This has a significant impact on the controllability of quantum systems in that it expands the reachable set both in its dimension and volume. This opens new avenues for research and engineering in quantum control and its applications such as quantum computing.

Quantum optimal control can significantly enhance quantum computing in the context of Noisy Intermediate Scale Quantum (NISQ) computing devices. Immediately, one can improve fidelity of two-qubit gates. In principle, one can also replace the application of an entire quantum circuit with a control signal. This would make it possible to move beyond the quantum circuit model and the associated intricacy of approximate compiling and swap mapping to accommodate connectivity constraints present in many qubit technologies.

Abstract: In this article, we propose a novel system identification method for stable and sparse linear time-invariant systems. We adopt kernel-based regularization to take a priori information, such as the decay rate, of the target system into account. For promoting sparsity, we introduce the minimax concave penalty function, which is known to promote sparser results than the standard ℓ^1 penalty. The estimation problem is shown to be reduced to a convex optimization problem, which can be efficiently solved by the forward-backward algorithm. We show a numerical example of delayed FIR (finite impulse response) system identification to illustrate the effectiveness of the proposed method.

System identification, kernel method, sparse optimization, convex optimization, minimax concave penalty.

1. INTRODUCTION

The accuracy of system identification depends highly on how a priori information is utilized. The k

is one of the most effective methods to take such information into account, as discussed in Pillonetto et al. (2014). For example, in Pillonetto and De Nicolao (2010); Chen et al. (2012), it was shown that the kernel method can significantly improve the accuracy of system identification of a stable linear system by adopting the exponential convergence of impulse response. More recently, the method has been extended to a priori information on the DC gain (Fujimoto and Sugie, 2018), the frequency domain decay characteristics (Fujimoto, 2021b,a), and the relative degree (Fujimoto et al., 2017).

On the other hand, the notion of of vectors and functions also plays an important role in control systems design, e.g, maximum hands-off control (Nagahara et al., 2016; Nagahara, 2020, 2021), and sparse system identification (Chen et al., 2009; Fattahi and Sojoudi, 2018). In this article, we study identification of sparse impulse response that has only a few nonzero coefficients. For this, we introduce sparsity-promoting penalty function to the kernel regularization to take account of sparsity and other system properties at the same time. In particular, we propose to use the minimax concave penalty function discussed in Selesnick (2017) as a sparsity prior, instead of the standard ℓ^1 penalty used in Chen et al. (2009); Fattahi and Sojoudi (2018). Although the minimax concave penalty function is not convex, it promotes sparsity more than the ℓ^1 penalty. Moreover, by choosing appropriate hyper parameters, the cost function to be minimized becomes convex, and the minimization problem can be solved by an efficient algorithm. By a numerical example, we show the effectiveness of the proposed method in particular for an FIR (finite-impulse-response) system with a large delay.

Note that the approach is different from the work of Chen et al. (2014) that proposes to sparsify the hyper-parameter vector in multiple kernels by maximizing the marginal likelihood, which is not a convex optimization, and just a local optimal solution is obtained.

For vector $v = [v_1, \dots, v_m]^\top$, $\|v\|_1$ is the ℓ^1 norm defined by $\|v\|_1 \triangleq |v_1| + \cdots + |v_m|$, and $\|v\|_2$ is the ℓ^2 norm defined by $\triangleq \sqrt{v^\top v}$, where $\top$ denotes the transpose. A matrix A whose (i,j)-th element is A_{ij} is described as $A = [A_{ij}]$. For a square matrix A, $\|A\|$ denotes the maximum singular value of A. For symmetric matrix A, we write $A \geq 0$ when A is positive semi-definite.

2. PROBLEM FORMULATION

In this paper, we consider the FIR (finite impulse response) model described by

$$y_k = \sum_{i=0}^{m-1} g_i u_{k-i} + \epsilon_k, \quad k = 0, 1, 2, \dots, \tag{1}$$

where $\{u_k\}$ and $\{y_k\}$ are respectively the input and output sequences, $\{\epsilon_k\}$ is noise, and $\{g_i\}$ is the impulse response. The problem is to identify the impulse response $\{g_i : i =$

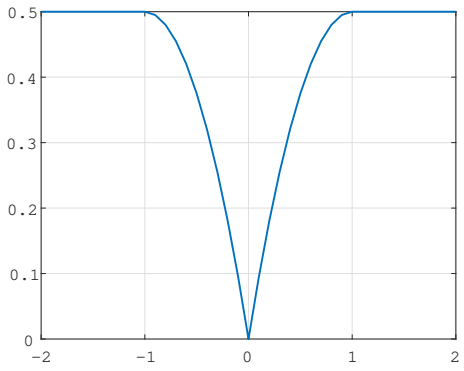

Fig. 1. Minimax concave penalty function ψ_B with $B = 1$.

$0, 1, \ldots, m-1\}$ from the input/output data $\{(u_k, y_k) : k = 0, 1, \ldots, N\}$. For this, we define the following vectors and matrix:

$$y \triangleq \begin{bmatrix} y_0 \\ \vdots \\ y_N \end{bmatrix}, \ \epsilon \triangleq \begin{bmatrix} \epsilon_0 \\ \vdots \\ \epsilon_N \end{bmatrix}, \ g \triangleq \begin{bmatrix} g_0 \\ \vdots \\ g_{m-1} \end{bmatrix},$$

$$U \triangleq \begin{bmatrix} u_0 & 0 & \ldots & 0 \\ u_1 & u_0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & 0 \\ u_{N-1} & u_{N-2} & \ldots & u_{N-m} \end{bmatrix}.$$

Then, we consider the squared ℓ^2 error $E(g)$ as

$$E(g) \triangleq \frac{1}{2}\|y - Ug\|_2^2. \tag{2}$$

The minimizer of $E(g)$ is the least-square solution, which is used when we have no prior information on g. However, it may cause overfitting (Bishop, 2006) in particular when the parameter size m is large. To avoid this, we adopt with the following regularization term:

$$\Omega(g) \triangleq \frac{\mu}{2} g^\top K^{-1} g + (1-\mu)\psi_B(g), \tag{3}$$

where $K = [K_{ij}]$ is a positive definite kernel matrix, and ψ_B is the (generalized) minimax concave penalty function (Selesnick, 2017) defined by

$$\psi_B(g) \triangleq \|g\|_1 - \min_h \left\{ \|h\|_1 + \frac{1}{2}\|B(g-h)\|_2^2 \right\}, \tag{4}$$

where B is a matrix, which is a hyper-parameter, such that $B^\top B$ is non-singular. Figure 2 shows the curve of the 1-dimensional minimax concave penalty function ψ_B with $B = 1$.

The kernel matrix is introduced to take a priori knowledge on the target system into account. For the simplicity of discussion, m is assumed to be even in the rest of this section. This paper uses the High-Frequency Decay (HFD) kernel (Fujimoto, 2021b) which is given by

$$K = F^\top \begin{bmatrix} K^{\mathrm{re}} & 0 \\ 0 & K^{\mathrm{im}} \end{bmatrix} F \in \mathbb{R}^{m \times m}, \tag{5}$$

where $K^{\mathrm{re}} = [K_{ij}^{\mathrm{re}}] \in \mathbb{R}^{\left(\frac{m}{2}+1\right)\times\left(\frac{m}{2}+1\right)}$ and $K^{\mathrm{im}} = [K_{ij}^{\mathrm{im}}] \in \mathbb{R}^{\left(\frac{m}{2}-1\right)\times\left(\frac{m}{2}-1\right)}$ are respectively given by

$$K_{ij}^{\mathrm{re}} = k_{\mathrm{HFD}}(\omega_{i-1}, \omega_{j-1}), \ K_{ij}^{\mathrm{im}} = k_{\mathrm{HFD}}(\omega_i, \omega_j), \tag{6}$$

$$k_{\mathrm{HFD}}(\omega_i, \omega_j) = \eta_1 \min\left\{ \frac{1}{\left(\omega_i^2 + \eta_2\right)^d}, \frac{1}{\left(\omega_j^2 + \eta_2\right)^d} \right\}, \tag{7}$$

$$\omega_i = \frac{2\pi}{N} i. \tag{8}$$

Also $F \in \mathbb{R}^{m\times m}$ is defined as

$$F = \begin{bmatrix} F^{\mathrm{re}} \\ F^{\mathrm{im}} \end{bmatrix}, \tag{9}$$

where $F^{\mathrm{re}} = [F_{ij}^{\mathrm{re}}] \in \mathbb{R}^{\left(\frac{m}{2}+1\right)\times m}$ and $F^{\mathrm{im}} = [F_{ij}^{\mathrm{im}}] \in \mathbb{R}^{\left(\frac{m}{2}-1\right)\times m}$ are given by

$$F_{ij}^{\mathrm{re}} = \cos\left(\frac{2\pi(i-1)(j-1)}{m}\right), F_{ij}^{\mathrm{im}} = -\sin\left(\frac{2\pi i(j-1)}{m}\right). \tag{10}$$

It is known that the estimated impulse response with the HFD kernel shows high-frequency decay property (Fujimoto, 2021b).

The minimax concave penalty function (4) promotes sparsity of the estimated impulse response. Although this is non-convex (see Figure 2), the cost function

$$J(g) \triangleq E(g) + \lambda\Omega(g), \tag{11}$$

with $\lambda > 0$ becomes convex if we appropriately choose B. In fact, we have the following proposition.

Assume

$$U^\top U + \lambda\left(\mu K^{-1} - (1-\mu)B^\top B\right) \geq 0. \tag{12}$$

Then $J(g)$ is convex over $\mathbb{R}^m$.

Proof: Define

$$\tilde{U} \triangleq \begin{bmatrix} U \\ V \end{bmatrix}, \quad \tilde{y} \triangleq \begin{bmatrix} y \\ 0 \end{bmatrix}, \quad \tilde{\lambda} \triangleq \lambda(1-\mu), \tag{13}$$

where V is a matrix satisfying $V^\top V = \lambda\mu K^{-1}$. Then it is easily shown that

$$J(g) = \frac{1}{2}\|\tilde{y} - \tilde{U}g\|_2^2 + \tilde{\lambda}\psi_B(g). \tag{14}$$

Then from Theorem 1 of Selesnick (2017), $J(g)$ is convex if $\tilde{\lambda}B^\top B \leq \tilde{U}^\top\tilde{U}$, which is equivalent to (12). □

By combining minmax concave penalty function and the HFD kernel, the estimated impulse response is expected to have sparsity in time domain, and high-frequency decay property in frequency domain.

3. OPTIMIZATION ALGORITHM

To satisfy (12), we choose B such that $\tilde{\lambda}B^\top B = \gamma\tilde{U}^\top\tilde{U}$ with $\gamma \in (0, 1)$. Then, minimizing $J(g)$ is equivalent to the following saddle point problem:

$$\min_g \max_h \frac{1}{2}\|\tilde{y} - \tilde{U}g\|_2^2 + \tilde{\lambda}\|g\|_1 - \tilde{\lambda}\|h\|_1 - \frac{\gamma}{2}\|\tilde{U}(g-h)\|_2^2. \tag{15}$$

This is efficiently solved by the forward-backward algorithm (see Selesnick (2017) and Bauschke and Combettes (2011) for details):

$$\begin{aligned} w[k] &= g[k] - c\tilde{U}^\top\left\{\tilde{U}\left(g[k] + \gamma(h[k] - g[k])\right) - \tilde{y}\right\}, \\ u[k] &= h[k] - c\gamma\tilde{U}^\top\tilde{U}(h[k] - g[k]), \\ g[k+1] &= S_{c\tilde{\lambda}}(w[k]), \\ h[k+1] &= S_{c\tilde{\lambda}}(u[k]), \quad k = 0, 1, 2, \ldots, \end{aligned} \tag{16}$$

where c is a step size of this iteration that satisfies $0 < c < \max\{1, \gamma/(1-\gamma)\}\|\tilde{U}^\top\tilde{U}\|$, and S_a is the soft-thresholding function with parameter $a > 0$ defined by

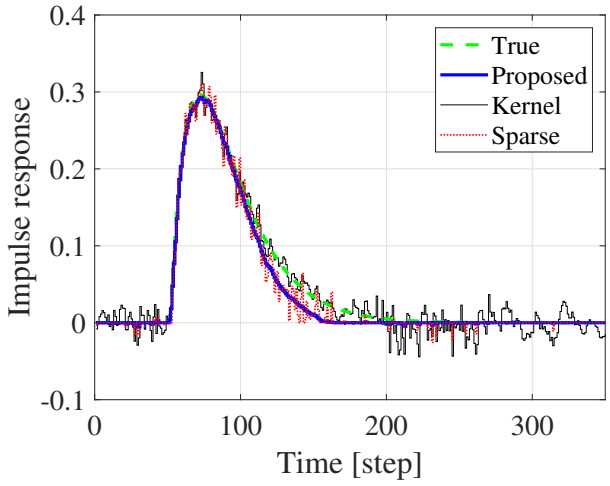

Fig. 2. Impulse response: true (broken line), estimated by the HFD kernel (thin-solid line), sparse regularization (dotted line), and by the proposed method (thick-solid line)

$[S_a(v)]_i \triangleq \mathrm{sign}(v)\max\{|v_i| - a, 0\}$, where $[S_a(v)]_i$ and v_i are respectively the i-th elements of $S_a(v)$ and v. We note that this function is the proximal operator of the ℓ^1 norm; see Nagahara (2020) for details.

4. NUMERICAL EXAMPLE

Let us consider the following continuous-time transfer function:

$$P(s) = \frac{100}{(s+3)(s+2)}e^{-s}. \tag{17}$$

Then, we discretize this by the zero-order hold discretization to obtain a discrete-time system $P_d(z)$. The goal is to estimate the impulse response of $P_d(z)$. We should note that the impulse response is exactly zero in $[0, 1]$ due to the delay e^{-s}. In this example, we assume we know the impulse response is delayed by some delay time, which is not known, and hence it can be assumed to be sparse in the time domain.

For this, we set the length of estimated impulse response to be $m = 350$. We set the input signal u_k in (1) taking ± 1 independently drawn from the Bernoulli distribution with equal probability 0.5. We also add noise ϵ_k in (1) independently drawn from the normal distribution with mean 0 and variance 0.1. The hyperparameters are tuned to $\eta_1 = 10, \eta_2 = 2, \lambda = 50$ and $\mu = 0.8$.

Figure 4 shows the results with the proposed, HFD kernel ($\mu = 1, \lambda = 50$), and sparse regularization($\mu = 0, \lambda = 10$). The proposed method estimate the delay well by using the sparsity of impulse response, and at the same time make the impulse response smooth by using the high-frequency decay property. On the other hand, the sparse regularization (dotted line) does not gives smooth impulse response, and the HFD kernel regularization (thin-solid line) can not estimate the delay of the system. This result indicates that using both the sparsity in time-domain and high-frequency decay in frequency domain can improve the identification accuracy for delayed systems in particular.

5. CONCLUSION

In this paper, we have proposed a novel method of sparse system identification with kernel regularization. We have adopted the minimax concave penalty function for sparsity promoting regularization. By numerical example, the proposed method has an advantage of estimating delayed systems.

Noncommutative Real Algebraic Geometry and Quantum Games

J. William Helton *

* *UC San Diego, La Jolla Ca 92093 USA , (e-mail: helton@math.ucsd.edu)*

Abstract: The last two decades produced a substantial noncommutative (in the free algebra) real and complex algebraic geometry. The aim of the subject is to develop a systematic theory of equations and inequalities for noncommutative polynomials in operator variables. A problem leading very directly to such equations and inequalities is finding good quantum strategies for games. The talk will focus on quantum games and present recent results done jointly with Adam Bene Watts, Igor Klep, Vern Paulsen Mousavi, Nezhadi, Russel, and Zehong Zhao.

Keywords: Quantum Games, Noncommutative Real Algebraic Geometry, Noncommutative optimization, SAT, Operator Theory Techniques

1. EXTENDED ABSTRACT

The talk will select topics from quantum games papers posted on arXiv in the last 2 years by the speaker as well as papers in progress.

A k-player game called kXOR can be played with a classical strategy or with a quantum strategy (if you have tons of equipment). 2XOR arose as a generalization of the famous Bell inequalities which proved quantum entanglement existed. The game is cooperative in that the k players are trying to improve their joint score and 1 is the max score any game can ever achieve; hence a game for which a score of 1 is possible is called a Cperfect or Qperfect game depending on whether the perfect strategy is Quantum or Classical. 2XOR was well understood by Tsielrson in the 1980's. Work with Watts focuses on 3XOR: we give a polynomial time algorithm for either producing a Qperfect strategy or alerting that none exists. Such existence was previously not known to be decidable.

Another line of work with Klep and Bene Watts shows how to associate (about) any quantum game with a left *-ideal in the algebra $\mathcal{P}$ of all noncommutative polynomials in the appropriate number of variables. Earlier Vern Paulsen with a variety of collaborators showed that any synchronous game G can be associated to a C^* algebra A, which amounts to associating G to a 2 sided ideal I with A being the quotient of $\mathcal{P}$ by I. This is extended to general games by our association of a left ideal to any game.

Given a game, each strategy employed has a score and the main problem is to maximize this score. A quantum strategy consists of operators (matrices) on a Hilbert space (typically n dimensional). So typically we fix n and compute a local optium $\hat{X}$, of course we wish we knew if this was a global optimium, but an even more primative question is: does a higher max exist at some dimension $\tilde{n} > n$? Helton, Paulsen Mousavi, Nezhadi, Russel, give a necessary condition for the answer to be no.

Abstract: The Second Law of thermodynamics implies that no thermodynamic system with a single heat source at constant temperature can convert heat into mechanical work in a repeatable manner. First, we note that this is equivalent to cyclo-passivity at the mechanical port of the thermodynamic system which is constrained by constant temperature at the thermal port. Second, we address the general system-theoretic question which physical systems with two power ports share this property, called one-port cyclo-passivity. Recently, sufficient conditions for one-port cyclo-passivity have been obtained, based on the structure of the interconnection matrix in the port-Hamiltonian formulation. We elaborate on these conditions and provide some extensions. Next we focus on control strategies which go beyond the classical Carnot cycle in order to convert energy in case of one-port cyclo-passivity, and apply this to a number of multiphysics systems.

Keywords: Energy control, passivity, thermodynamics, multiphysics systems
AMS Subject Classification: 93A10, 80A10

1. INTRODUCTION

Energy conversion is a common phenomenon in many multiphysics systems: electro-mechanical, electro-chemical, electro-kinetic, thermal-mechanical, thermal-chemical, thermal diffusion, etc. (see e.g. Kondepudi, Prigogine (2015)). On the other hand, the Second Law of thermodynamics states that *heat* cannot be freely converted into *mechanical work*. Thus energy at the thermal port can*not* be freely converted into energy at the mechanical port. Recently it has been shown in Van der Schaft, Jeltsema (2022, 2021) that this same phenomenon also occurs in quite a few other multiphysics systems. Furthermore, it has been shown that the presence of this phenomenon is closely related to the structure of the interconnection matrix in the port-Hamiltonian formulation of the system.

In fact, consider a (multi-)physical system with two power ports (u_1, y_1) and (u_2, y_2), as schematically depicted in Figure 1.

Fig. 1. Two-port physical system.

We assume throughout that the system is *cyclo-passive*; i.e., there is no internal energy creation and thus

$$\oint \left(y_1^\top(t)u_1(t) + y_2^\top(t)u_2(t)\right) dt \geq 0 \tag{1}$$

for all trajectories bringing the state back to its original value; see e.g. Willems (1972); Van der Schaft (2017, 2020). Now suppose that the state vector x in the port-Hamiltonian formulation of the system, see e.g. Van der Schaft, Jeltsema (2014); Van der Schaft (2017), can be split as

$$x = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

in such a way that the port-Hamiltonian equations take the form

$$\begin{aligned} \dot{x}_1 &= J_1(x_1, x_2)e_1 - \mathcal{R}_1(x_1, x_2, e_1) + u_1, \\ \dot{x}_2 &= J_2(x_1, x_2)e_2 - \mathcal{R}_2(x_1, x_2, e_1) + G_2(x_1, x_2)u_2, \end{aligned} \tag{2}$$

together with the corresponding output equations

$$\begin{aligned} y_1 &= e_1, \quad e_1 = \frac{\partial H}{\partial x_1}(x_1, x_2), \\ y_2 &= G_2^\top(x_1, x_2)e_2, \quad e_2 = \frac{\partial H}{\partial x_2}(x_1, x_2). \end{aligned} \tag{3}$$

Here H is the Hamiltonian (total stored energy) of the system, $J_1(x_1, x_2)$ and $J_2(x_1, x_2)$ are skew-symmetric matrices, and the mappings $\mathcal{R}_1(x_1, x_2, e_1), \mathcal{R}_2(x_1, x_2, e_1)$, modeling energy dissipation, are such that

$$e_1^\top \mathcal{R}_1(x_1, x_2, e_1) \geq 0, \quad e_2^\top \mathcal{R}_2(x_1, x_2, e_1) \geq 0 \tag{4}$$

Cyclo-passivity is confirmed by the computation of the following *differential dissipation inequality*

$$\begin{aligned} \frac{d}{dt}H &= y_1^\top u_1 + y_2^\top u_2 \\ &\quad - e_1^\top \mathcal{R}_1(x_1, x_2, e_1) - e_2^\top \mathcal{R}_2(x_1, x_2, e_1) \\ &\leq y_1^\top u_1 + y_2^\top u_2 \end{aligned} \tag{5}$$

Indeed, time-integration of the differential inequality and substitution of equality of initial and final state implies (1). Furthermore we note that if H is bounded from below then in fact the system is *passive*.

The assumptions reflected in the special structure of the port-Hamiltonian system (2) mean that the interaction between the x_1 part and the x_2 part of the system takes place only through the Hamiltonian $H(x_1, x_2)$, and *not* via a network coupling (the off-diagonal blocks of the J-matrix are zero).

Clearly, the assumed form of the equations implies that for any initial condition and any input function u_2 there exists an input function u_1 that keeps x_1 equal to a constant value $\bar{x}_1$. It follows, cf. Van der Schaft, Jeltsema (2021), that for any such input functions the system is cyclo-passive at port 2 with storage function $H(\bar{x}_1, x_2)$, and cyclo-passive at port 1 as well, with zero storage function.

Furthermore, instead of keeping x_1 constant, u_1 may be also chosen such as to keep $y_1 = e_1$ equal to some constant value $\bar{y}_1$. In this case it follows, cf. Van der Schaft, Jeltsema (2022, 2021), that the system for any such input function is again cyclo-passive at port 1 and port 2. In fact, the storage function for cyclo-passivity at port 1 is given as $\bar{y}_1^\top x_1$, and at port 2 by minus the partial Legendre transform of H with respect to y_1, that is

$$H_1^*(\bar{y}_1, x_2) = H(x_1, x_2) - \bar{y}_1^\top x_1, \quad y_1 = \frac{\partial H}{\partial x_1}(x_1, x_2), \quad (6)$$

where it is assumed that x_1 can be solved from the second equation as a function of y_1, x_2. (The * notation refers to the Legendre transform, while the subscript $_1$ is used because the *partial* Legendre transform with respect to x_1 is taken.) Indeed, in view of the assumptions on the structure of the system, we obtain

$$\frac{d}{dt} H_1^*(\bar{y}_1, x_2) \leq y_2^\top u_2 \quad (7)$$

This latter property was called *one-port cyclo-passivity* in Van der Schaft, Jeltsema (2022). Clearly, both cyclo-passivity properties imply restrictions on the possibilities for converting energy at port 1 to port 2: this is *not* possible in a recurrent manner while keeping either x_1 or y_1 constant. In general, such restrictions are not present in multiphysics systems whose port-Hamiltonian formulation exhibit non-zero off-diagonal terms in the J-matrix; see the analysis in Van der Schaft, Jeltsema (2022, 2021).

Note that the property of one-port cyclo-passivity in the thermodynamic case is exactly the same as the classical observation by Carnot that no thermal energy can be converted into mechanical energy ('work') while keeping the temperature of the heat source constant. Said otherwise, thermodynamic systems are one-port cyclo-passive (with first port being the thermal port and second port the mechanical port), but there are many other systems that share this property; see Van der Schaft, Jeltsema (2022, 2021) for a number of applications in various physical domains.

In this talk we will further elaborate on both notions of cyclo-passivity at one of the ports separately. First, we show that in some cases one-port cyclo-passivity can be *enforced* by adding extra state variables. In particular this shows that one-port cyclo-passivity is strictly speaking *not* an input-output property. This will be illustrated by the example of a linear DC-motor. In this case, the off-diagonal elements of the interconnection structure J between the mechanical and electrical port are non-zero (and in fact given by the gyration constant of the DC-motor). However, by adding the *angle* of the rotor as an extra state variable, a state space transformation can be defined that *eliminates* the coupling given by the gyration constant in the extended (non-minimal) state space formulation. The ramifications of this surprising observation will be investigated, as well connections with related phenomena such as the Blondel-Park transformation of the synchronous generator model. Second, we focus on extensions to the Carnot cycle for one-port cyclo-passive port-Hamiltonian systems. In particular, while the classical Carnot cycle switches between isothermals (y_1 constant), and adiabatics (x_1 constant), one may also consider other cyclic trajectories (involving multiple values of y_1) as well. Furthermore, the Carnot efficiency is defined as the delivered mechanical work divided by the supplied thermal energy during the isothermal at high temperature. This means that the thermal energy (Heat) released during the isothermal at low temperature is sought to be minimized. We will investigate how to define alternative notions of efficiency.

Third, we return to the original statement of the Second Law of thermodynamics. The formulation given by Lord Kelvin states that (see Fermi (1936)):

A transformation of a thermodynamic system whose only final result is to transform into work heat extracted from a source which is at the same temperature throughout is impossible.

Note that this allows for interactions with heat sources at more than one temperature; however such that the net heat that is taken from the sources at different temperatures during the cyclic process is zero; see Fermi (1936); Van der Schaft (2021). In fact, such interactions with multiple heat sources are indispensable in the derivation of Clausius' inequality leading to the definition of entropy. We will take a closer look at the consequences of this for general cyclo-passive port-Hamiltonian systems of the form described in (2).

Online parameter tracking in human reaching adaptation and control ⋆

Frédéric Crevecoeur *

* *Institute of Information and Communication Technologies, Electronics and Applied Mathematics, and Institute of Neuroscience, UCLouvain (e-mail: frederic.crevecoeur@uclouvain.be).*

Abstract: Recent experiments have suggested that the nervous system adapted feedback control strategies during an ongoing, perturbed movement. These findings raised the possibility that a function of motor adaptation could be to complement feedback control online, but this idea had not been tested with biologically realistic properties of the human motor system, considering in particular the non-linear limb dynamics and the presence of transmission delays in the neural feedback loop. This study addresses this question by showing that online adaptive control is indeed feasible in a simplified nonlinear model of the human arm, featuring a delay of 60ms as observed in experiments. It is shown that online adaptation can reduce the impact of non-linear effects arising due to limb dynamics within a single movement. Strikingly, the directions that most benefited from online adaptation correlated with known directional biases characterising the distribution of reaching representations in the primate's brain. Further, it is demonstrated that, for some movement directions, it is possible to learn to produce relatively straight hand paths with end-point errors comparable with human performance within tens of trials. These simulation results provide support to the hypothesis that a function of adaptation in the human sensorimotor system is to compensate online for unmodelled disturbances arising in novel or non-linear environments.

Keywords: Model-based control; Adaptive neural control; Human reaching; Control in neuroscience.

1. INTRODUCTION

A paradigmatic example of adaptation in biological control is the ability of primates to learn to compensate for force fields applied during reaching movements. Although it is often assumed that adaptation improves or preserves motor performances across movements (Shadmehr et al. (2010)), it has been recently suggested that adaptation of human reaching control was fast enough to influence an ongoing movement (Mathew and Crevecoeur (2021)).

These previous findings were modelled in the framework of adaptative optimal control (Bitmead et al. (1990)): a real-time identification procedure adapting the model parameters of a Linear Quadratic Gaussian regulator (LQG) online. This approach was applied to a simplified, linear, and fully observable model of limb control. It remained unknown whether this interpretation was amenable to more realistic models of reaching movements, including non-linear mechanical effects, noise, and sensorimotor delays.

The present study addresses this question by showing that it is possible based on linear approximations to control a human-inspired, non-linear two jointed arm with noise and temporal delays consistent with the sensorimotor system of humans (∼60ms, Scott (2016)). Moreover, it is shown that the benefits of the adaptive control mostly impacted reaching trajectories in directions that broadly corresponded to known directional biases in the distribution of movement representations in monkey's primary motor cortex. In all, the simulation results supported the hypothesis that the human nervous system adapts closed-loop control of reaching movements online.

2. ADAPTIVE CONTROL MODEL

2.1 Mechanical Model

The biomechanical system is described by the following differential equation: let $\theta = [\theta_s, \theta_e]^T$ denote the vector of shoulder and elbow angles (θ_s and θ_e, respectively), $\tau = [\tau_s, \tau_e]$ the vector of shoulder and elbow torques (Fig. 1), the second order differential equation governing the movement in the horizontal plane is (Li and Todorov (2007)):

$$\ddot{\theta} = M^{-1}(\theta)\left(\tau - C(\theta, \dot{\theta}) - D\dot{\theta}\right), \tag{1}$$

where $M(\theta) \in \mathbf{R}^{2\times 2}$ is the matrix of moments of inertia that depends on the cosine of θ_e, $C(\theta, \dot{\theta}) \in \mathbf{R}^2$ is a vector of nonlinear effects dependent on the factors $\sin(\theta_2)$, $\dot{\theta}_s\dot{\theta}_e$, $\dot{\theta}_s^2$, and $\dot{\theta}_e^2$, and $D \in \mathbf{R}^{2\times 2}$ captures linear viscous forces opposing to velocity (see Appendix).

The mechanical system is coupled with a linear model of muscles dynamics corresponding to a first-order, low-pass filter with time constant $\delta = 60ms$. A stochastic

disturbance is added to this model to include additive noise impacting motor commands (Jones et al. (2002)):

$$d\tau = \frac{1}{\delta}\left(u - \tau\right)dt + \alpha dW, \tag{2}$$

with $u \in \mathbf{R}^2$ representing the command vector, α is a scaling parameter and dW captures instantaneous changes of a standard Brownian motion.

2.2 Controller Definition

The design of an LQG controller for human reaching control follows previous work (Todorov and Jordan (2002)). The linearised model of (1) used in the controller is derived around an equilibrium point corresponding to the starting location of a movement θ_0, and by setting angular velocities to zero:

$$\ddot{\theta} \simeq M^{-1}(\theta_0)\left(\tau - D\dot{\theta}\right). \tag{3}$$

The system is discretised and coupled with (2) with explicit Euler integration (time step of $\Delta t = 10ms$). A static goal target (θ^*, with $\dot{\theta}^* = 0$) is added to the state vector, and the difference equation becomes:

$$x_{k+1} = Ax_k + Bu_k + \xi_k, \tag{4}$$

with $x = [\theta_s, \theta_e, \dot{\theta}_s, \dot{\theta}_e, \tau_s, \tau_e, \theta_s^*, \theta_e^*]^T$, and ξ_k being zero-mean, multivariate Gaussian disturbance with known covariance matrix Ω_ξ, coming from i.i.d. increments of αdW over one time step. The discrete time difference equation is coupled with an output measurement signal that included the delay in the feedback loop:

$$y_k = Hx_{k-h} + \omega_k, \tag{5}$$

with ω_k being zero-mean, Gaussian noise with known covariance matrix Ω_ω, and h representing the delay in number of sample times. This measurement signal represents the sensory data that is available to the brain, it is assumed that joint angles, velocities and actuator forces are encoded in limb afferent feedback. The delay is handled with system augmentation. We defined $z_k^T := [x_k^T, x_{k-1}^T, \ldots, x_{k-h}^T]$ and we used $h = 6$, compatible with the physiological long-latency delay of 60ms (Scott (2016)). The augmented state-space model matrices denoted by $\bar{A}$, $\bar{B}$ and $\bar{H}$ are defined in the Appendix. The state estimator is based on a predictive Kalman filter following standard definition:

$$\hat{z}_{k+1} = \bar{A}\hat{z}_k + \bar{B}u_k + K_k\left(y_k - \bar{H}\hat{z}_k\right). \tag{6}$$

Regarding movement simulations, we used finite horizon formulation with $N = 60$ time steps ($600ms$). The cost-function is a standard quadratic form defined as follows:

$$J(z,u) = z_N^T Q_N z_N + \sum_{k=1}^{N-1} z_k^T Q_k z_k + u_k^T R u_k. \tag{7}$$

We used a kinematic constraint defined on the change in joint angles during the first 10 time steps to penalise deviations from a straight line. Such kinematic constraint has been suggested in previous models of human reaching movements and simply captures the fact that humans spontaneously tend to reach straight (Mistry et al. (2013)). The other matrices for the running costs ($Q_k, 10 < k < N$) were set to zero. The terminal constraint was defined such that:

$$z_N^T Q_N z_N = w_1\|\theta_N - \theta^*\|^2 + w_2\|\dot{\theta}_N\|^2, \tag{8}$$

with θ^* the target joint coordinate and w_1 and w_2 are parameters. Their values were set manually to $w_1 = 500$, and $w_2 = 10$, and $R = 10^{-5}\mathbf{I}_{2\times 2}$. Based on these definitions, a standard LQG including an optimal linear state-feedback controller and optimal Kalman gains could be derived (Astrom (1970)). The next section presents how this controller was updated through time based on system identification.

2.3 Adaptive State-Feedback Control

The previous section set up a linear state-feedback controller for a non-linear system, resulting in model errors induced by non-linear effects. The adaptive optimal control model was based on the idea that the parameters of the linear model could be updated over time to compensate locally for non-linear effects. Schematically, the LQG controller featured a Kalman filter (Fig. 1, K) and a linear state-feedback controller that mapped the estimated state into motor commands (Fig. 1, C). In parallel, the error between the expected and measured feedback could be used to update the system model (Fig. 1, ID). This paper used recursive least square identification (Bitmead et al. (1990)). Calling Θ_{k-1} the estimated set of parameters at time $k-1$, the prediction error obtained at time k is:

$$\epsilon_k(\Theta_{k-1}) = y_k - \bar{H}\hat{z}_k \tag{9}$$

$$= y_k - H\hat{x}_{k-h}. \tag{10}$$

Observe that the second term of the right-hand side of (9) is the expected system output. Since it depends on the parameters through the use of the system matrices A and B in the predictive Kalman filter, we introduce the notation: $\hat{y}_k(\Theta_{k-1}) := \bar{H}\hat{z}_k$. The parameter update is:

$$\Theta_k = \Theta_{k-1} + \gamma\frac{\partial\hat{y}_k(\Theta_{k-1})}{\partial\Theta}\epsilon_k, \tag{11}$$

where γ is the online learning rate. In all the controller could be summarised as follows:

- A linear state-feedback controller dependent on estimated parameters $u_k := L(\Theta_k)\hat{x}_k$,
- An update of the estimated parameters Θ_k, followed by a re-computation of optimal control and Kalman gains with the novel parameter estimate.

In practice the set of parameters that updated was constrained by observing that the non-linearities impacted the relationship between torques and joint accelerations, in other words only the entries of the matrix A that approximated $M^{-1}(\theta)$ and $C(\theta,\dot{\theta})$ were allowed to change over time.

2.4 Heuristic Rules

Our first results below show the effect of the combined control and identification to compensate for non-linear effects online. Then, we explored in simulations whether

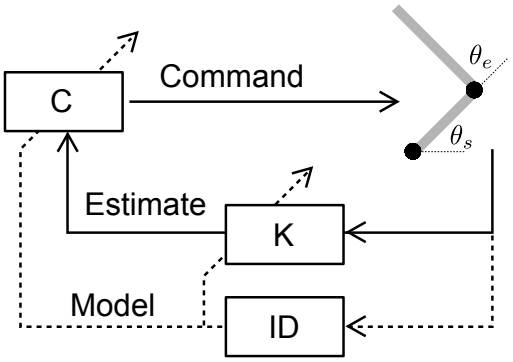

Fig. 1. Schematic depiction of the adaptive optimal feedback controller: (C) controller, (K) Kalman filter, (ID) system identification procedure, which updates the model parameters used in the state estimator and in the controller (dashed arrows). Solid arrows are the state feedback controller corresponding to the long-latency feedback loop.

it was possible to learn a representation of limb dynamics following repeated practice of the same movement. We used the following update rules defined heuristically but compatible with human behaviour:

(1) Gradual adaptation requires that the model updates carried over to the next trial. To limit the impact of noise, we computed for each trial an initial set of parameters corresponding to the average of the previous movement. We denote the time-varying parameters of trial i by $\Theta_{k,i}$ and the time average over a trial by $\bar{\Theta}_{.,i}$.
(2) We defined a composite cost in Cartesian coordinates to capture humans' spontaneous tendency to reach straight and to reduce end-point errors. This cost was the sum of the square end-point error ($d_e^2(i)$) and the square maximum perpendicular displacement relative to a straight line ($d_o^2(i)$), for the i^{th} movement. Let $c(i) := d_e^2(i) + d_o^2(i)$, we set $\Theta_{1,i+1}$ to $\bar{\Theta}_{.,i}$ if the condition $c(i) \leq \varepsilon c(i-1)$ was true with $\varepsilon = 1.05$. In other words, if the identification disrupted the trajectory such that the composite cost increased by more than 5%, due to noise or to an inadequate value of γ, the corresponding changes in estimated parameters were not retained.
(3) The online learning rate was adjusted from trial-to-trial: it was either divided in half if $c(i) > \varepsilon c(i-1)$, or multiplied by two (with the initial rate as upper limit).

3. RESULTS

Two standard tasks were simulated. The first task was a centre-out reaching task towards targets placed along a circle of radius $10cm$ around the start position corresponding to $45deg$ and $90deg$ of shoulder and elbow angles (Fig. 2a). Because the linearisation was computed around the starting point with zero velocity, it is expected that the trajectories are perturbed by non-linear effects away from this equilibrium, that is for movements of large amplitude or with high velocity. In particular, movements including the shoulder angle produce non-linear effects due to the function $C(\theta, \dot{\theta})$. It can be observed that these movements, mostly located in the second and fourth quadrant of the

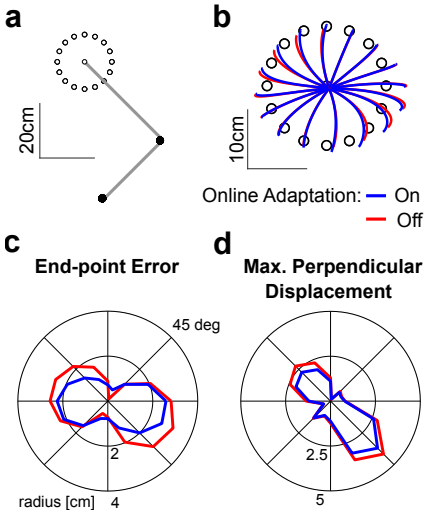

Fig. 2. Centre-out reaching task: (a) joint configuration with the start target at $\theta_s = 45$deg and $\theta_e = 90$deg plus all peripheral targets distants by 10cm; (b) end-point trajectories with (blue) or without (red) online learning; (c) polar representation of the norm of the end-point error aligned with the corresponding target angle; (d) same as (c) with the maximum perpendicular displacement.

workspace (Fig. 2b), were those that mostly benefited from the adaptive estimation of Θ_k. Indeed, with online identification (Fig. 2, blue), it was possible within a single trial to reduce the end-point error as well as the maximum perpendicular displacement (Fig. 2c and d). The simulations of Fig. 2 were obtained without process noise ($\Omega_\xi = \Omega_\omega = 0$), and an online learning rate of $\gamma = 0.005$.

The simulations in Fig. 2 show that it was possible to improve a linear control applied to a nonlinear system within a single reaching movement simply based o the observation that the movements with online adaptation tended to be straighter. Next, it was hypothesised that the controller could further improve if changes in Θ were kept in memory for the next movement using the heuristic learning rules defined above. It was found for the selected movement direction and amplitude (which includes a large change in shoulder angle, Fig. 3a) that iteratively updating the linear model across trials yielded movement paths that were relatively straight and accurate, with end-point error and maximum perpendicular displacements in the range of those observed in experiments ($\leq$ 2cm, Fig. 3b and c). These simulations included noise and an initial learning rate set manually to $\gamma = 7 \times 10^{-5}$. The performance of the control and estimation algorithm plateaued after ~ 30 trials, when the online learning rate γ was very close to 0, suggesting it was close to a local minimum for this particular movement, linearization, and parameter set.

4. DISCUSSION

The simulations showed that online identification of the parameters of a linear model of reaching control could at least partially compensate for non-linear effects in the presence of noise and delays compatible with the sensorimotor system of humans. The improvements could be observed within a single movement, as well as across few

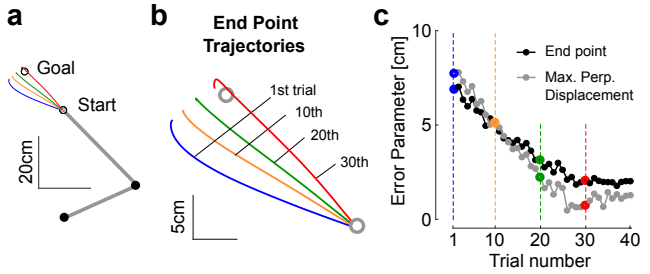

Fig. 3. (a) Joint configuration, start, and goal targets; (b) Selected movement traces at different stages of the learning process; (c) End-point error and maximum perpendicular displacement.

tens of trials when consecutive estimates were averaged and reused iteratively. The foregoing results thus provided support to the hypothesis that a function of sensorimotor adaptation is not only to adapt movement control over medium or long timescales, but also to complement feedback control online.

Strikingly, because the largest impact of the model non-linearities arose in directions that included larger amount of shoulder motion, the benefits of the adaptive controller were mostly visible in the second and fourth quadrant of the workspace, which reproduced known biases in reach representation observed in the primate's brain (Lillicrap and Scott (2013)). This previous paper showed that the directional biases emerged from limb biomechanics, since they were reproduced in an artificial system featuring the details of limb and muscles dynamical properties. The present results propose an complementary view on the reason why whole limb flexion and extension movements may be over-represented in primary motor cortex: it is conceivable that an adaptive neural feedback controller needs more resources in the directions where non-linearities of the limb have a larger impact.

As concluding remarks, two important aspects must be emphasised. First, the combination of adaptation and control, and the iterative improvement across consecutive movements, were obtained without using any feedforward pathway. Thus, the results warrant further investigation to study if or when an often assumed feedforward controller in the brain is actually required. Second, the model can only improve: the online learning rate was not optimised, the identification procedure was not tuned to filter out the noise, the linear representation was low-dimensional (and derived from first principles), and the heuristic adaptation rules were simplistic. Optimising each component is expected to make the adaptive state-feedback controller a powerful candidate model of human reaching control.

ACKNOWLEDGEMENTS

The author want to thank J. Hendrickx for critical comments on an earlier version of the abstract.

Appendix A. DEFINITION OF MODEL PARAMETERS

The definitions and numerical values followed Li and Todorov (2007) and Crevecoeur and Scott (2014):

$$M(\theta) = \begin{pmatrix} a_1 + 2a_2\cos(\theta_e) & a_3 + a_2\cos(\theta_e) \\ a_3 + a_2\cos(\theta_e) & a_3 \end{pmatrix}, \quad \text{(A.1)}$$

$$C(\theta, \dot{\theta}) = \begin{pmatrix} -\dot{\theta}_e(2\dot{\theta}_s + \dot{\theta}_e) \\ \dot{\theta}_s^2 \end{pmatrix} a_2 \sin(\theta_e), \quad \text{(A.2)}$$

$$D = \begin{pmatrix} 0.14 & 0.014 \\ 0.014 & 0.14 \end{pmatrix}, \quad \text{(A.3)}$$

and the a_i were parameters linked to the segment masses and inertias. The numerical values were: $a_1 = 0.28$, $a_2 = 0.048$, and $a_3 = 0.1kgm^2$. The matrix H was the identity. The augmented matrices to include de delay were defined as follows:

$$\bar{A} = \begin{pmatrix} A & 0 & \dots & 0 \\ I & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \dots & I & 0 \end{pmatrix}, \bar{B} = \begin{pmatrix} B \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \quad \text{(A.4)}$$

$$\bar{H} = \begin{pmatrix} 0 & \dots & 0 & H \end{pmatrix}. \quad \text{(A.5)}$$

The noise covariance matrices were $\Omega_\xi = 0.01\bar{B}\bar{B}^T$ such that the noise only affected the control signal, and $\Omega_\omega = 0.01I_{8\times 8}$. The latter definition considered the possibility that all sensory signals were corrupted by additive noise.

Abstract: The concept of dissipativity is a cornerstone of systems and control theory. Typically, dissipativity properties are verified by resorting to a mathematical model of the system under consideration. In this extended abstract, we aim at assessing dissipativity by computing storage functions for linear systems directly from measured data. As our main contributions, we provide conditions under which dissipativity can be ascertained from a finite collection of noisy data samples. Different noise models will be considered that can capture a variety of situations, including the cases that the data samples are noise-free, the energy of the noise is bounded, or the individual noise samples are bounded. All of our conditions are phrased in terms of data-based linear matrix inequalities, which can be readily solved using existing software packages.

Keywords: System identification, dissipativity, linear systems.

1. INTRODUCTION

As is generally acknowledged, the concept of dissipativity (Willems, 1972a), (Willems, 1972b) has formed the foundation for large parts of systems and control theory as developed in the past fifty years. Indeed, the above papers together with Willems' work on linear quadratic problems and the associated algebraic Riccati equation (Willems, 1971) are generally considered to provide the main concepts and analysis tools in many areas of linear and nonlinear systems and control, ranging from stability theory, linear quadratic optimal control and stochastic realization theory, to network synthesis, differential games and robust control.

In the present work, we study dissipativity of linear finite-dimensional input-state-output systems from a data-driven perspective. It is well-known that for a given input-state-output system with given supply rate, one can test dissipativity by checking the feasibility of a linear matrix inequality involving the system matrices. In this extended abstract, we assume that the system dynamics are not known a priori. In this situation, the question arises whether we can verify dissipativity using measured system trajectories, instead of a system model.

Recently, the problem of inferring dissipativity properties from data has received considerable attention. The most relevant references for this extended abstract are (Maupong et al., 2017; Romer et al., 2019; Koch et al., 2020a; Steentjes et al., 2021). In (Maupong et al., 2017), the notion of (finite-horizon) L-dissipativity was introduced and also studied in (Romer et al., 2019). A discrete-time system is L-dissipative if the average of the supply rate over the interval $[0, L]$ is nonnegative for all system trajectories. In both these contributions, a crucial assumption is that the input trajectory is persistently exciting of a sufficiently high order (see (Willems et al., 2005) and (van Waarde et al., 2020a)). This property of the input sequence can be shown to imply that the data-generating system is uniquely identifiable from the data.

In this extended abstract we adopt the more classical notion of dissipativity for linear systems, rather than L-dissipativity, similar to the setup of (Koch et al., 2020a), see also (Steentjes et al., 2021) for dissipativity analysis and controller synthesis of interconnected networks. Our aim is to provide necessary and sufficient conditions for dissipativity based on data, for noiseless and noisy measurements.

Our approach involves bounding the noise by a quadratic matrix inequality, which implies that also the unknown system parameters satisfy a quadratic matrix inequality. Our goal is to ascertain dissipativity of *all* systems satisfying this inequality. The method thus fits in the robust control literature, where quadratic uncertainty descriptions have been studied in detail. We mention contributions to integral quadratic constraints (Megretski and Rantzer, 1997), the quadratic separator (Iwasaki and Hara, 1998), and the full block S-procedure (Scherer, 1997, 2001). We will apply a matrix S-lemma (van Waarde et al., 2022) that is a recent extension to matrix variables of the famous S-lemma (Yakubovich, 1977).

The outline of the extended abstract is as follows. In Section 2 we give a short recap of the concept of dissipativity of linear input-state-output systems. Then, in Section 3 we state the problem of data-driven dissipativity. Section 4 contains our results. First, we show that dissipativity of

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

an unknown linear system can only be ascertained on the basis of the given data if a matrix constructed from measured states and inputs has full rank. In the noiseless data case, this implies that one can only verify dissipativity from data if the data-generating system is the only one that explains the data, in other words, if the true system is identifiable from the data. In this case, dissipativity of the unknown system can be ascertained by checking the feasibility of a given data-based linear matrix inequality. In the noisy data case, it turns out that one does not need identifiability. In order to check dissipativity in this case, we combine the matrix S-lemma with a basic dualization lemma to provide a data-driven test for dissipativity. Finally, Section 5 contains our conclusions.

Notation

The *inertia* of a symmetric matrix S is denoted by $\mathrm{In}(S) = (\rho_-, \rho_0, \rho_+)$ where ρ_-, ρ_0, and ρ_+ respectively denote the number of negative, zero, and positive eigenvalues of S.

2. DISSIPATIVITY OF LINEAR SYSTEMS

Consider a linear discrete-time input-state-output system

$$\boldsymbol{x}(t+1) = A\boldsymbol{x}(t) + B\boldsymbol{u}(t) \tag{1a}$$
$$\boldsymbol{y}(t) = C\boldsymbol{x}(t) + D\boldsymbol{u}(t) \tag{1b}$$

where $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$, $C \in \mathbb{R}^{p\times n}$, and $D \in \mathbb{R}^{p\times m}$.

Let $S = S^\top \in \mathbb{R}^{(m+p)\times(m+p)}$. The system (1) is said to be *dissipative* with respect to the *supply rate*

$$s(u,y) = \begin{bmatrix} u \\ y \end{bmatrix}^\top S \begin{bmatrix} u \\ y \end{bmatrix} \tag{2}$$

if there exists $P \in \mathbb{R}^{n\times n}$ with $P = P^\top \geqslant 0$ such that the *dissipation inequality*

$$\boldsymbol{x}(t)^\top P \boldsymbol{x}(t) + s\big(\boldsymbol{u}(t), \boldsymbol{y}(t)\big) \geqslant \boldsymbol{x}(t+1)^\top P \boldsymbol{x}(t+1) \tag{3}$$

holds for all $t \geqslant 0$ and for all trajectories $(\boldsymbol{u}, \boldsymbol{x}, \boldsymbol{y}) : \mathbb{N} \to \mathbb{R}^{m+n+p}$ of (1).

It follows from (3) that dissipativity with respect to the supply rate (2) is equivalent to the feasibility of the linear matrix inequalities $P = P^\top \geqslant 0$ and

$$\begin{bmatrix} I & 0 \\ A & B \end{bmatrix}^\top \begin{bmatrix} P & 0 \\ 0 & -P \end{bmatrix} \begin{bmatrix} I & 0 \\ A & B \end{bmatrix} + \begin{bmatrix} 0 & I \\ C & D \end{bmatrix}^\top S \begin{bmatrix} 0 & I \\ C & D \end{bmatrix} \geqslant 0. \tag{4}$$

3. PROBLEM FORMULATION

Consider the linear discrete-time input-state-output system

$$\boldsymbol{x}(t+1) = A_s\boldsymbol{x}(t) + B_s\boldsymbol{u}(t) + \boldsymbol{w}(t) \tag{5a}$$
$$\boldsymbol{y}(t) = C_s\boldsymbol{x}(t) + D_s\boldsymbol{u}(t) + \boldsymbol{z}(t) \tag{5b}$$

where $(\boldsymbol{u}, \boldsymbol{x}, \boldsymbol{y}) \in \mathbb{R}^{m+n+p}$ are the input, state and output, and $(\boldsymbol{w}, \boldsymbol{z}) \in \mathbb{R}^{n+p}$ are noise terms. Throughout the extended abstract, we assume that the "true" system matrices (A_s, B_s, C_s, D_s) and the noise $(\boldsymbol{w}, \boldsymbol{z})$ are *unknown*. What is known instead are a finite number of input-state-output measurements of (5), which we collect in the matrices

$$U_- := [u(0)\ u(1)\ \cdots\ u(T-1)]$$
$$X := [x(0)\ x(1)\ \cdots\ x(T)]$$
$$Y_- := [y(0)\ y(1)\ \cdots\ y(T-1)].$$

We will also make use of the auxiliary matrices

$$X_- := [x(0)\ x(1)\ \cdots\ x(T-1)]$$
$$X_+ := [x(1)\ x(2)\ \cdots\ x(T)].$$

The goal of this extended abstract is to infer dissipativity properties of the true system from the data (U_-, X, Y_-).

We define

$$\Sigma^{\mathcal{N}} = \left\{ (A,B,C,D) \mid \begin{bmatrix} X_+ \\ Y_- \end{bmatrix} - \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} X_- \\ U_- \end{bmatrix} \in \mathcal{N} \right\},$$

where $\mathcal{N} \subseteq \mathbb{R}^{(n+p)\times T}$ is a set defining a *noise model* to be specified below. We assume that

$$(A_s, B_s, C_s, D_s) \in \Sigma^{\mathcal{N}}. \tag{7}$$

In the sequel, we will consider two types of noise models. The first one will capture noise-free situations in which the measurements (U_-, X, Y_-) are exact:

$$\mathcal{N}_0 := \{0\}. \tag{8}$$

The second noise model is defined by

$$\mathcal{N}_1 := \left\{ V \in \mathbb{R}^{(n+p)\times T} \mid \begin{bmatrix} I \\ V^\top \end{bmatrix}^\top \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{12}^\top & \Phi_{22} \end{bmatrix} \begin{bmatrix} I \\ V^\top \end{bmatrix} \geqslant 0 \right\}, \tag{9}$$

where $\Phi_{11} = \Phi_{11}^\top \in \mathbb{R}^{(n+p)\times(n+p)}$, $\Phi_{12} \in \mathbb{R}^{(n+p)\times T}$, and $\Phi_{22} = \Phi_{22}^\top \in \mathbb{R}^{T\times T}$ are known matrices. This noise model was studied before (van Waarde et al., 2022) in the context of data-driven quadratic stabilization and H_2 and H_∞ control. In order to be able to discuss some special cases of the noise model (9), we label the columns of V as $[v(0)\ v(1)\ \cdots\ v(T-1)]$. In the special case $\Phi_{12} = 0$ and $\Phi_{22} = -I$, the bound in (9) reduces to

$$VV^\top = \sum_{t=0}^{T-1} v(t)v(t)^\top \leqslant \Phi_{11}. \tag{10}$$

This inequality can be interpreted as an energy bound on the noise. In addition, norm bounds on the individual noise samples $v(t)$ also give rise to bounds of the form (10), although this generally leads to some conservatism. Indeed, note that $\|v(t)\|^2 \leqslant \epsilon$ implies that $v(t)v(t)^\top \leqslant \epsilon I$ for all t. As such, the bound (10) is satisfied for $\Phi_{11} = T\epsilon I$. We also note that $\mathcal{N}_1$ can be interpreted as the dual model to the one studied in (Berberich et al., 2020), and both models are equivalent under mild conditions (van Waarde et al., 2021).

We now define the property of *informativity for dissipativity*, which is the main concept studied in this extended abstract. This definition is inspired by (van Waarde et al., 2020b), and we refer to that paper for a general treatment.

Definition 1. Let a noise model $\mathcal{N}$ be given. The data (U_-, X, Y_-) are *informative for dissipativity* with respect to the supply rate (2) if there exists a $P = P^\top \geqslant 0$ such that (4) holds for every system $(A, B, C, D) \in \Sigma^{\mathcal{N}}$.

The rationale behind Definition 1 is as follows: on the basis of the given data we are unable to distinguish between the systems in $\Sigma^{\mathcal{N}}$ in the sense that any of these systems could have generated the data. Nonetheless, if *all* of these systems are dissipative, then we can also conclude that the *true* data-generating system is dissipative. Note that we restrict our attention to the situation in which the systems in $\Sigma^{\mathcal{N}}$ are dissipative with a *common* storage function.

The following assumptions will be valid throughout:

(A1) The matrix S has inertia $\mathrm{In}(S) = (p, 0, m)$.
(A2) The set $\mathcal{N}_1$ is bounded and has nonempty interior.

It is a well-known fact that a necessary condition for dissipativity of any system of the form (1) is that $m \leqslant \rho_+$, i.e., the input dimension does not exceed the positive signature of S. Assumption (A1) requires that the input dimension is equal to this positive signature, and in addition that the matrix S is nonsingular. This assumption is satisfied, for example, for the positive-real and bounded-real case (Scherer and Weiland, 1999). Indeed, in the positive-real case we have that $m = p$ and

$$S = \begin{bmatrix} 0 & I_m \\ I_m & 0 \end{bmatrix},$$

so that $\mathrm{In}(S) = (m, 0, m)$. In the bounded-real case we have

$$S = \begin{bmatrix} \gamma^2 I_m & 0 \\ 0 & -I_p \end{bmatrix}$$

for $\gamma > 0$, which implies that $\mathrm{In}(S) = (p, 0, m)$. Assumption (A2) can be verified straightforwardly by assessing certain definiteness properties of the matrix Φ (van Waarde et al., 2021).

The main contribution of this extended abstract is to provide necessary and sufficient conditions for data informativity for the noise models $\mathcal{N}_0$ and $\mathcal{N}_1$.

4. MAIN RESULTS

In this section we state our main results. We will not provide proofs here, but instead refer the interested reader to the extended manuscript (van Waarde et al., 2021).

4.1 A necessary condition for informativity

We begin with a necessary condition for informativity, that applies to both noise models $\mathcal{N}_0$ and $\mathcal{N}_1$.

Theorem 1. Let a noise model $\mathcal{N}$ be given. If the data (U_-, X, Y_-) are informative for dissipativity with respect to the supply rate (2), then

$$\mathrm{rank} \begin{bmatrix} X_- \\ U_- \end{bmatrix} = n + m. \tag{11}$$

Essentially, Theorem 1 and the rank condition (11) formalize the intuition that dissipativity can only be assessed from data that are sufficiently rich. In the noise-free setting (involving model $\mathcal{N}_0$), the rank condition (11) implies that the system matrices A_s, B_s, C_s and D_s can be uniquely identified from the (U_-, X, Y_-)-data. In this setting, the interpretation of Theorem 1 is that dissipativity can *only* be verified from data that are rich enough to uniquely identify the underlying data-generating system.

4.2 Informativity and noiseless data

We now give a characterization of informativity for dissipativity for the noiseless case.

Theorem 2. Consider the noise model $\mathcal{N}_0$. The data (U_-, X, Y_-) are informative for dissipativity with respect to the supply rate (2) if and only if

$$\mathrm{rank} \begin{bmatrix} X_- \\ U_- \end{bmatrix} = n + m \tag{12}$$

and there exists $P = P^\top \geqslant 0$ such that

$$\begin{bmatrix} X_- \\ X_+ \end{bmatrix}^\top \begin{bmatrix} P & 0 \\ 0 & -P \end{bmatrix} \begin{bmatrix} X_- \\ X_+ \end{bmatrix} + \begin{bmatrix} U_- \\ Y_- \end{bmatrix}^\top S \begin{bmatrix} U_- \\ Y_- \end{bmatrix} \geqslant 0. \tag{13}$$

Theorem 2 provides a data-based condition for dissipativity in terms of a linear matrix inequality. Linear matrix inequalities can be solved using standard software packages. We note, however, that such solvers are known to be unreliable for LMI's which define feasible sets without interior points. As such, from a numerical point of view it is desirable that there exists a positive definite P such that left-hand side of (13) is positive definite.

We note that the condition of Theorem 2 has appeared in a similar setting in (Koch et al., 2020b, Thm. 4) and (Koch et al., 2020a, Thm. 3), where an "if"-statement was proven. Our contribution is to prove that these conditions are necessary and sufficient by leveraging Theorem 1.

4.3 Informativity and noisy data

We now consider the noise model $\mathcal{N}_1$ defined in (9). Define

$$N_1 := \left[\begin{array}{c|c} I & \begin{matrix} X_+ \\ Y_- \end{matrix} \\ \hline 0 & \begin{matrix} -X_- \\ -U_- \end{matrix} \end{array}\right] \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{12}^\top & \Phi_{22} \end{bmatrix} \left[\begin{array}{c|c} I & \begin{matrix} X_+ \\ Y_- \end{matrix} \\ \hline 0 & \begin{matrix} -X_- \\ -U_- \end{matrix} \end{array}\right]^\top. \tag{14}$$

We now arrive at the following characterization of informativity for dissipativity, given the noise model $\mathcal{N}_1$.

Theorem 3. Suppose that there exists $V \in \mathbb{R}^{(n+m)\times(n+p)}$ such that

$$\begin{bmatrix} I \\ V \end{bmatrix}^\top N_1 \begin{bmatrix} I \\ V \end{bmatrix} > 0. \tag{15}$$

Partition

$$\begin{bmatrix} \hat{F} & \hat{G} \\ \hat{G}^\top & \hat{H} \end{bmatrix} := -S^{-1},$$

where $\hat{F} = \hat{F}^\top \in \mathbb{R}^{m\times m}$, $\hat{G} \in \mathbb{R}^{m\times p}$, and $\hat{H} = \hat{H}^\top \in \mathbb{R}^{p\times p}$. Given the noise model $\mathcal{N}_1$, the data (U_-, X, Y_-) are informative for dissipativity with respect to the supply rate (2) if and only if there exist a real $n\times n$ matrix $Q = Q^\top > 0$ and a scalar $\alpha \geqslant 0$ such that

$$\begin{bmatrix} Q & 0 & 0 & 0 \\ 0 & \hat{H} & 0 & -\hat{G}^\top \\ 0 & 0 & -Q & 0 \\ 0 & -\hat{G} & 0 & \hat{F} \end{bmatrix} - \alpha N_1 \geqslant 0. \tag{LMI}$$

Theorem 3 provides a tractable method for verifying informativity for dissipativity, given the noise model $\mathcal{N}_1$. The procedure involves solving the linear matrix inequality (LMI) for Q and α. Given Q, a common storage function P for all systems in $\Sigma^{\mathcal{N}_1}$ is readily computable as $P = Q^{-1}$.

The condition (15) implies that the interior of the set of explaining systems $\Sigma^{\mathcal{N}_1}$ is nonempty. The proof of Theorem 3 uses two building blocks. The first one is the so-called matrix S-lemma (van Waarde et al., 2022). This is a generalization to matrix variables of the classical S-lemma, developed in the seventies of the previous century by (Yakubovich, 1977). The second building block is a dualization result that essentially states that the quadruple (A, B, C, D) is dissipative with respect to the supply rate S, with storage function P if and only if the dual

system $(A^\top, C^\top, B^\top, D^\top)$ is dissipative with respect to a related supply rate $\hat{S}$, with storage function P^{-1}, see (van Waarde et al., 2021). A behavioral analogue of this result was obtained in (Willems and Trentelman, 2002, Prop. 12).

We note that a sufficient condition for data-driven dissipativity with a common storage function was given in (Koch et al., 2020a, Thm. 4). The attractive feature of Theorem 3 is that it provides a necessary and sufficient condition, by making use of the matrix S-lemma.

Assuming that the assumptions of Theorem 3 are satisfied, an interesting byproduct on the result is the following: if all systems in $\Sigma^{\mathcal{N}_1}$ are dissipative with common storage function $P = P^\top \geqslant 0$, then P is necessarily *positive definite*. We note that conditions under which all storage functions are positive definite have been studied before in (Hill and Moylan, 1976, Lem. 1), even for nonlinear systems. In that paper, certain minimality conditions were imposed as well as a signature condition on the supply rate. Here, we do not assume minimality but we conclude that all storage functions are positive definite by using Assumption (A1) and an argument related to the noise model.

5. CONCLUSIONS

In this extended abstract we have provided methods to verify dissipativity properties of linear systems directly from measured data. We have considered both the case of exact data and the case that the data are corrupted by noise. In the case of exact data, we have shown that one can only ascertain dissipativity of a system from given data if the system can be uniquely identified from the data. If this is the case, dissipativity can be verified by means of a data-based linear matrix inequality. In the case of noisy data, we have combined the matrix S-lemma (van Waarde et al., 2022) with a dualization property relating dissipativity properties of the original system with those of its dual to characterize data informativity for dissipativity. As in the noiseless case, also in this setting, dissipativity properties of the data-generating system can be ascertained if a data-based LMI is solvable.

Abstract: The existing proofs of the fundamental lemma use arguments by contradiction and do not give insight into the assumptions of controllability and persistency of excitation of the input. We present an alternative constructive proof that reduces the required persistency of excitation and characterizes the nongeneric cases in which the extra persistency of excitation beyond the time horizon is needed.

Keywords: behavioral approach; exact identification; persistency of excitation; data-driven control.

1. INTRODUCTION

The fundamental lemma of Willems et al. (2005) addresses the following question: Given a finite trajectory $w_\mathrm{d} \in (\mathbb{R}^q)^T$ of a linear time-invariant (LTI) system $\mathscr{B}$ and a natural number L, $1 \leq L \leq T$, under what conditions the windows of length L

$$\begin{bmatrix} w_\mathrm{d}(1) \\ \vdots \\ w_\mathrm{d}(L) \end{bmatrix}, \begin{bmatrix} w_\mathrm{d}(2) \\ \vdots \\ w_\mathrm{d}(L+1) \end{bmatrix}, \ldots, \begin{bmatrix} w_\mathrm{d}(T-L+1) \\ \vdots \\ w_\mathrm{d}(T) \end{bmatrix},$$

constructed from the length-T trajectory w_d span the space $\mathscr{B}|_L$ of all length-L trajectories of the system?

Using the Hankel matrix

$$\mathscr{H}_L(w_\mathrm{d}) := \begin{bmatrix} w_\mathrm{d}(1) & w_\mathrm{d}(2) & \cdots & w_\mathrm{d}(T-L+1) \\ \vdots & \vdots & & \vdots \\ w_\mathrm{d}(L) & w_\mathrm{d}(L+1) & \cdots & w_\mathrm{d}(T) \end{bmatrix},$$

the question is rephrased as: Given $w_\mathrm{d} \in \mathscr{B}|_T$, where $\mathscr{B}$ is LTI, under what conditions

$$\mathscr{B}|_L = \text{image } \mathscr{H}_L(w_\mathrm{d})? \tag{1}$$

We call (1) a *data-driven representation* of the restricted behavior $\mathscr{B}|_L$. It is used in data-driven analysis, signal processing, and control, see the overview (Markovsky and Dörfler, 2021).

Let m, ℓ, and n be the number of inputs, lag (observability index), and order of $\mathscr{B}$. A necessary and sufficient condition for (1) with $L \geq \ell$ is

$$\text{rank } \mathscr{H}_L(w_\mathrm{d}) = mL + n. \tag{2}$$

This condition is refered to as *generalized persistency of excitation* (Markovsky and Dörfler, 2020). It is verifiable from the data w_d and the prior knowledge of m, ℓ, and n.

Contrary to (2), the solution given in (Willems et al., 2005) assumes a given input/output partitioning $w = \left[\begin{smallmatrix} u \\ y \end{smallmatrix}\right]$ of the variables. Moreover, the fundamental lemma provides sufficient conditions only: (1) holds under the following conditions

A1: $\mathscr{B}$ is controllable and
A2: u_d is persistently exciting of order $L+n$.

The order of persistency of excitation of u_d, denoted $\mathrm{PE}(u_\mathrm{d})$, is the maximal L for which $\mathscr{H}_L(u_\mathrm{d})$ is full row rank. The controllability assumption is not verifiable from the data and is restrictive. In particular, it excludes autonomous systems.

The crux of the fundamental lemma is the need of an extra persistency of excitation of order n in Assumption A2. (Willems et al., 2005) as well as subsequent publications (van Waarde et al., 2020; De Persis and Tesi, 2020; van Waarde et al., 2020; van Waarde, 2021) do not explain why the extra persistency of excitation is needed nor when it is needed. Presently it is not known how conservative assumptions A1 and A2 are.

Initial conditions can be specified by a sufficiently long "past" trajectory $w_\mathrm{d,ini} \in \mathscr{B}|_{T_\mathrm{ini}}$. As shown in (Markovsky and Rapisarda, 2008, Lemma 1), "sufficiently long" is $T_\mathrm{ini} \geq \ell$. Then, the concatenation $w_\mathrm{d,ini} \wedge w_\mathrm{d}$ of $w_\mathrm{d,ini}$ and w_d sets the initial conditions for w_d. Our goal (refered to as "(GOAL)") is to find for given $L \geq \ell$ conditions on u_d and $\mathscr{B}$, under which for any initial condition $w_\mathrm{d,ini}$, a trajectory $w_\mathrm{d,ini} \wedge w_\mathrm{d} \in \mathscr{B}|_{T_\mathrm{ini}+T}$ satisfies (2). Section 2 certify (GOAL) by showing that there is no initial condition for which (2) fails. Assumptions A1 and

A2': $\mathrm{PE}(u_\mathrm{d}) = L$

generically guarantee (GOAL). The question occurs: What are the nongeneric cases of A1 and A2' in which (GOAL) fails? The answered is given in Section 3.

2. RELAXATION OF THE FUNDAMENTAL LEMMA

Consider a controllable LTI systems $\mathscr{B}$ with an input/output partitioning of the variables $w = \left[\begin{smallmatrix} u \\ y \end{smallmatrix}\right]$. In view of A2', $\mathrm{PE}(u_\mathrm{d}) = L + k$. Next, we show that the minimal k, for which (GOAL) holds, is the controllability index ℓ_ctr of $\mathscr{B}$. Let $h(0), h(1), \ldots$ be the Markov parameters of $\mathscr{B}$ and σ, $(\sigma w)(t) := w(t+1)$ be the unit shift operator.

Lemma 1. For $w_\mathrm{d} \in \mathscr{B}|_T$ and natural numbers L, k such that $L + k \leq T$ and $k \geq \ell_\mathrm{ctr}$,

$$\begin{bmatrix} \mathscr{H}_L(\sigma^k u_\mathrm{d}) \\ \mathscr{H}_L(\sigma^k y_\mathrm{d}) \end{bmatrix} = \underbrace{\begin{bmatrix} 0_{mL \times mk} & I_{mL} \\ \mathscr{T}_\mathrm{ini} & \mathscr{T} \end{bmatrix}}_{M} \underbrace{\begin{bmatrix} \mathscr{H}_k(u_\mathrm{d}) \\ \mathscr{H}_L(\sigma^k u_\mathrm{d}) \end{bmatrix}}_{\mathscr{H}_{k+L}(u_\mathrm{d})}, \tag{3}$$

where

$$\mathscr{T}_\mathrm{ini} := \begin{bmatrix} h(k) & h(k-1) & \cdots & h(1) \\ h(k+1) & h(k) & \cdots & h(2) \\ \vdots & \vdots & & \vdots \\ h(k+L-1) & h(k+L-2) & \cdots & h(L) \end{bmatrix} \in \mathbb{R}^{pL \times mk}$$

and

$$\mathscr{T} := \begin{bmatrix} h(0) & & & \\ h(1) & h(0) & & \\ \vdots & \ddots & \ddots & \\ h(L-1) & \cdots & h(1) & h(0) \end{bmatrix} \in \mathbb{R}^{pL \times mL}.$$

In (3), the first $k \geq \ell_\mathrm{ctrb}$ input samples $\big(u(1), \ldots, u(k)\big)$ play the role of the initial condition $x(k)$ for $\sigma^k w_\mathrm{d}$. Due to controllability any $x(k) \in \mathbb{R}^n$ can be reached by the an input $\big(u(1), \ldots, u(k)\big)$.

Theorem 1. With $L \geq \ell$, assumptions A1 and

A2": $\mathrm{PE}(u_\mathrm{d}) = L + \ell_\mathrm{ctrb}$

are necessary and sufficient for (GOAL).

3. CHARACTERIZATION OF THE NONGENERIC CASES

Lemma 2. The following are equivalent:

(1) $u_\mathrm{d} \in (\mathbb{R}^m)^T$ is persistently exciting of order $\mathrm{PE}(u_\mathrm{d}) = \ell_u$,
(2) u_d is a response of an autonomous system LTI system $\mathscr{B}_u$ with $T \geq (m+1)\ell_u - 1$ samples, *i.e.*, $u_\mathrm{d} \in \mathscr{B}_u|_T$, and for a minimal state-space representation

$$\mathscr{B}_\mathrm{ss}(A_u, C_u) := \{\, u \mid \text{there is } x_u \in (\mathbb{R}^n)^\mathbb{N}, \text{ such that } \sigma x_u = A_u x_u,\ u = C_u x_u \,\}.$$

of $\mathscr{B}_u$ with initial condition $x_{u,\mathrm{ini}} = x_u(1)$ that generates u_d, the pair $\big(A_u, x_{u,\mathrm{ini}}\big)$ is controllable.

By Lemma 2 a system $\mathscr{B}$ with m inputs, lag ℓ, and order n, which input u is persistently exciting of order ℓ_u, can be augmented with a model $\mathscr{B}_u$ of the input, resulting in an extended autonomous system $\mathscr{B}_\mathrm{ext}$ for $w = \left[\begin{smallmatrix} u \\ y \end{smallmatrix}\right]$. Let $\mathscr{B}_\mathrm{ss}(A_u, C_u)$ be a minimal state-space representation of the input model $\mathscr{B}_u$ and $\mathscr{B}_\mathrm{ss}(A, B, C, D)$ be a minimal input/state/output representation of $\mathscr{B}$. The extended system $\mathscr{B}_\mathrm{ext}$ is given by $\mathscr{B}_\mathrm{ext} = \mathscr{B}_\mathrm{ss}(A_\mathrm{ext}, C_\mathrm{ext})$, where

$$A_\mathrm{ext} = \begin{bmatrix} A_u & 0 \\ BC_u & A \end{bmatrix} \text{ and } C_\mathrm{ext} = \begin{bmatrix} C_u & 0 \\ DC_u & C \end{bmatrix}.$$

The extended state is $x_\mathrm{ext} = \left[\begin{smallmatrix} x_u \\ x \end{smallmatrix}\right]$, where x_u is the state of $\mathscr{B}_\mathrm{ss}(A_u, C_u)$ and x is the state of $\mathscr{B}_\mathrm{ss}(A, B, C, D)$. By using the input model $\mathscr{B}_u$, we transform the original problem about $\mathscr{B}$ into an equivalent problem about $\mathscr{B}_\mathrm{ext}$.

The following proposition derives a state transformation that block-diagonalizes A_ext. The block-diagonalization leads to a representation of $\mathscr{B}_\mathrm{ext}$ with decoupled states of $\mathscr{B}_u$ and $\mathscr{B}$. The decoupling simplifies the subsequent analysis.

Proposition 1. Assume that A and A_u have no common eigenvalues and let $V \in \mathbb{R}^{n \times n_u}$ be the solution to the equation

$$AV - VA_u = BC_u.$$

Then, $\mathscr{B}_\mathrm{ext} = \mathscr{B}_\mathrm{ss}\,(A'_\mathrm{ext}, C'_\mathrm{ext})$, where

$$A'_\mathrm{ext} = \begin{bmatrix} A_u & 0 \\ 0 & A \end{bmatrix} \text{ and } C'_\mathrm{ext} = \begin{bmatrix} C_u & 0 \\ C' & C \end{bmatrix}, \text{ with } C' := DC_u - CV.$$

The state of $\mathscr{B}_\mathrm{ss}\,(A'_\mathrm{ext}, C'_\mathrm{ext})$ is $x'_\mathrm{ext} = \left[\begin{smallmatrix} x_u \\ Vx_u + x \end{smallmatrix}\right]$, where x_u is the state of $\mathscr{B}_\mathrm{ss}(A_u, C_u)$ and x is the state of $\mathscr{B}_\mathrm{ss}(A, B, C, D)$.

Proposition 1 shows that the nongeneric cases of A1 and A2', in which (GOAL) fails correspond to a special choice of the initial condition of $\mathscr{B}$:

$$x_\mathrm{ini} = -V x_{u,\mathrm{ini}}. \tag{4}$$

By choosing the initial condition (4), we have that

$$w_\mathrm{d} = \begin{bmatrix} C_u \\ C' \end{bmatrix} \exp_{A_u} x_{u,\mathrm{ini}},$$

where $\exp_\lambda$ is the exponential function $\exp_\lambda(t) := e^{\lambda t}$. Then, $\mathrm{rank}\, \mathscr{H}_L(w_\mathrm{d}) \leq n_u$. In a trajectory w_d corresponding to (4) the transient is removed, *i.e.*, y_d, has no terms $\exp_\lambda$ where λ is an eigenvalue of A.

The characterization of the persistently exciting inputs as an output of an autonomous LTI system together with Theorem 1 allow us to do experiment design under additional constraints, such as smoothness and bounds of the input. This direction for future work is particularly useful for data-driven control of power electronics systems and will be presented elsewhere.

Abstract: In this paper, we discuss hands-off feedback control of discrete-time linear time-invariant systems based on receding horizon control. Hands-off control, also known as sparse control, is a control that has a long time duration over which the control action is exactly zero whilst satisfying control objectives. To obtain the maximum hands-off control, the ℓ^1-norm optimization is adopted. For a model predictive control formulation, we need to numerically solve the ℓ^1 optimization with equality/inequality constraints. Although fast iterative algorithms are known to solve the optimization problem, they will often not be fast enough for control systems that need real-time computation. To obtain the control values in real time, we propose to stop the iteration for the ℓ^1 optimization after just one step. We prove that this strategy leads to practical stability of the closed-loop, provided the systems are open-loop stable. Simulation results show the effectiveness of the proposed method.

Keywords: Optimal control, sparse control, model predictive control, real-time computation, convex optimization, stability.

1. INTRODUCTION

Due to the public interest in climate change, it is crucial to consider the impact of industrial products on the environment, rather than pursuing maximum efficiency. *Maximum hands-off control* is a recently developed mathematical framework for achieving such a requirement in product design of control systems. More precisely, the control problem is to find a feasible control that has the minimum time duration in which the actuators are active. In other words, maximum hands-off control is the sparsest (or L^0-optimal) control, with which the actuators can be stopped over the inactive time duration; this results in decreased energy consumption, elimination of CO2 emissions, and reduction of noise and vibration. Accordingly, hands-off control is often called *green control*.

Maximum hands-off control has been proposed in (Nagahara et al., 2016a) for continuous-time systems, and (Nagahara et al., 2016b) for discrete-time systems. In both cases, maximum hands-off control is first designed over a finite horizon, and then implemented as self-triggered control in (Nagahara et al., 2016a), and model predictive control (MPC) in (Nagahara et al., 2016b) to realize feedback control. Stability theorems are obtained for these feedback control methods, assuming that the L^1 norm (as a surrogate of L^0 norm) or the ℓ^1 norm (as a surrogate of ℓ^0 norm) optimization can be computed immediately and exactly. For a simple plant as a double integrator, the L^1 optimal control, or minimum fuel control (Athans and Falb, 2007), is obtained in a closed form, and hence the control is almost ideally implemented.

However, if the plant is not that simple, then we need to numerically compute the optimal control by optimization algorithms, such as proximal gradient algorithm (Beck and Teboulle, 2010), or alternating direction method of multipliers (ADMM) (Boyd et al., 2011). These methods require infinitely many iterations to obtain the exact solution, and in practical applications, we need to stop the iteration in a small number to obtain a control in real time. Then, the stability should be taken into account under non-exact optimal control.

In (Parys and Pipeleers, 2018; Parys et al., 2019; Schulze Darup et al., 2019), a real-time implementation of the proximal gradient method and the ADMM in MPC has been proposed. They consider just one-step iteration for the optimization, and derive stability results under such non-exact control. This method however assumes a quadratic cost function, which is not suitable for our maximum hands-off control using the non-smooth ℓ^1 norm in the cost function. In this paper, we give stability results under one-step iteration in the algorithm for maximum hands-off feedback control using MPC, assuming that the plant is controlled stable. This assumption is not so re-

Bayreuth, Germany, 12-16 September 2022

strictive since stabilization is often achieved by a local controller.

Notation

We will use the following notation throughout this paper: $\mathbb{R}$ denotes the set of real numbers. For positive integers n and m, $\mathbb{R}^n$ and $\mathbb{R}^{m\times n}$ denote the sets of n-dimensional real vectors and $m \times n$ real matrices, respectively. We use boldface lowercase letters, e.g. $\boldsymbol{v}$, to represent vectors, and upper case letters, e.g. A for matrices. For a positive integer n, $\mathbf{0}_n$ denotes the n-dimensional zero vector, that is, $\mathbf{0}_n = [0,\dots,0]^\top \in \mathbb{R}^n$. If the dimension is clear, the zero vector is simply denoted by $\mathbf{0}$. The superscript $(\cdot)^\top$ means the transpose of a vector or a matrix. For a matrix Φ, $\ker(\Phi)$ denotes the kernel (or the null space) of Φ. For a vector $\boldsymbol{v} = [v_1, v_2, \dots, v_n]^\top \in \mathbb{R}^n$, we define the ℓ^1 and ℓ^2 norms respectively by

$$\|\boldsymbol{v}\|_1 \triangleq \sum_{k=1}^{n} |v_k| \quad \text{and} \quad \|\boldsymbol{v}\|_2 \triangleq \sqrt{\sum_{k=1}^{n} |v_k|^2}.$$

2. FINITE-HORIZON MAXIMUM HANDS-OFF CONTROL

Here we consider a discrete-time linear time-invariant system modeled by

$$\boldsymbol{x}[k+1] = A\boldsymbol{x}[k] + \boldsymbol{b}u[k],\ k = 0, 1, 2, \dots, \tag{1}$$

where $\boldsymbol{x}[k] \in \mathbb{R}^n$ is the state, $u[k] \in \mathbb{R}$ is the scalar control input, and $A \in \mathbb{R}^{n\times n}$, $\boldsymbol{b} \in \mathbb{R}^n$.

For this system, we consider the reachability problem. That is, we find a control sequence (or vector)

$$\boldsymbol{u} \triangleq [u[0]\ u[1]\ \dots\ u[N-1]]^\top \tag{2}$$

that drives the state $\boldsymbol{x}[k]$ from a given initial state $\boldsymbol{x}[0] = \boldsymbol{x}_0$ to the origin $\boldsymbol{x}[N] = \mathbf{0}$ in N steps.

Assumption 1. We assume the following:

(1) The pair $(A, \boldsymbol{b})$ is reachable.
(2) The horizon length N is greater than or equal to n.

Under Assumption 1, there is at least one solution to the reachability problem. Actually there are infinitely many solutions if $N > n$. We call the solutions *feasible controls*. The set of feasible controls is described by

$$\mathcal{U}_{\boldsymbol{x}_0} = \left\{\boldsymbol{u} \in \mathbb{R}^N : A^N\boldsymbol{x}_0 + \Phi\boldsymbol{u} = \mathbf{0}\right\}. \tag{3}$$

where

$$\Phi \triangleq \left[A^{N-1}\boldsymbol{b}\ A^{N-2}\boldsymbol{b}\ \dots\ A\boldsymbol{b}\ \boldsymbol{b}\right]. \tag{4}$$

Among the feasible controls in $\mathcal{U}_{\boldsymbol{x}_0}$, we seek the minimum ℓ^1-norm control:

$$\underset{\boldsymbol{u}\in\mathbb{R}^N}{\text{minimize}}\ \|\boldsymbol{u}\|_1 \text{ subject to } \boldsymbol{u} \in \mathcal{U}_{\boldsymbol{x}_0}. \tag{5}$$

The solution of this ℓ^1 optimization is called the *maximum hands-off control*.

The optimization problem in (5) is effectively solved by using the alternating direction method of multipliers (ADMM) (Boyd et al., 2011). The algorithm is described as follows (Nagahara et al., 2016b):

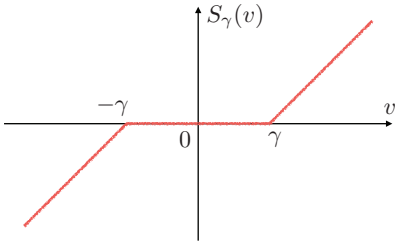

Fig. 1. Soft-thresholding operator $S_\gamma(v)$

$$\begin{aligned}\boldsymbol{v}[j+1] &:= \Pi_{\boldsymbol{x}_0}(\boldsymbol{u}[j] - \boldsymbol{w}[j]),\\ \boldsymbol{u}[j+1] &:= S_\gamma(\boldsymbol{v}[j+1] + \boldsymbol{w}[j]),\\ \boldsymbol{w}[j+1] &:= \boldsymbol{w}[j] + \boldsymbol{v}[j+1] - \boldsymbol{u}[j+1],\\ & j = 0, 1, 2, \dots,\end{aligned} \tag{6}$$

where $\gamma > 0$ is a step-size parameter, $\Pi_{\boldsymbol{x}_0}$ is the projection operator onto $\mathcal{U}_{\boldsymbol{x}_0}$, that is,

$$\Pi_{\boldsymbol{x}_0}(\boldsymbol{v}) = G\boldsymbol{v} + L\boldsymbol{x}_0, \tag{7}$$

with

$$G \triangleq I - \Phi^\top(\Phi\Phi^\top)^{-1}\Phi, \quad L \triangleq -\Phi^\top(\Phi\Phi^\top)^{-1}A^N, \tag{8}$$

and S_γ is the element-wise soft thresholding operator defined by

$$S_\gamma(v) \triangleq \begin{cases} v - \gamma, & \text{if } v > \gamma,\\ 0, & \text{if } |v| \le \gamma,\\ v + \gamma, & \text{if } v < -\gamma, \end{cases} \tag{9}$$

for scalar v. Figure 1 shows the soft-thresholding operator.

Intuitively speaking, the algorithm in (6) is a combination of the projection $\Pi_{\boldsymbol{x}_0}$ onto the feasible control set $\mathcal{U}_{\boldsymbol{x}_0}$ and the *sparsity-promoting* soft-thresholding function S_γ.

3. REAL-TIME FEEDBACK CONTROL BY MPC

Now we implement the finite-horizon control scheme in MPC to realize feedback control. We assume at the moment that the exact maximum hands-off control, the exact solution to (5) is obtained for a given state $\boldsymbol{x}_0$. By $\boldsymbol{C}_{\text{exact}}(\boldsymbol{x}_0)$ we denote the map from the state $\boldsymbol{x}_0 \in \mathbb{R}^n$ to the exact maximum hands-off control, that is,

$$\boldsymbol{C}_{\text{exact}}(\boldsymbol{x}_0) \triangleq \underset{\boldsymbol{u}\in\mathcal{U}_{\boldsymbol{x}_0}}{\arg\min} \|\boldsymbol{u}\|_1. \tag{10}$$

Then, the feedback control $u[k]$ for (1) by MPC is described by

$$u[k] = \Gamma\boldsymbol{C}_{\text{exact}}(\boldsymbol{x}[k]), \quad k = 0, 1, 2, \dots, \tag{11}$$

where $\Gamma \triangleq [1\ 0\ \dots\ 0] \in \mathbb{R}^{1\times N}$ is a matrix to extract the first element in $\boldsymbol{C}_{\text{exact}}(\boldsymbol{x}[k])$, see (Nagahara et al., 2016b) for details.

It is however difficult to obtain the exact $\boldsymbol{C}_{\text{exact}}(\boldsymbol{x}[k])$ in real time. The idea to obtain a real-time solution to the optimization is to stop the iteration in the ADMM algorithm (6) before convergence. In particular, we can simply use a *one-step iteration* for the control. We denote this process by $\boldsymbol{C}_1(\boldsymbol{x}_0; \boldsymbol{u}, \boldsymbol{v})$ with initial guesses $\boldsymbol{u}$ and $\boldsymbol{w}$, namely,

$$\begin{aligned} \boldsymbol{v}^+ &= \Pi_{\boldsymbol{x}_0}(\boldsymbol{u}-\boldsymbol{w}) \\ \boldsymbol{u}^+ &= S_\gamma(\boldsymbol{v}^+ + \boldsymbol{w}) \\ \boldsymbol{w}^+ &= \boldsymbol{w} + \boldsymbol{v}^+ - \boldsymbol{u}^+ \\ \boldsymbol{C}_1(\boldsymbol{x}_0;\boldsymbol{u},\boldsymbol{w}) &= \begin{bmatrix} \boldsymbol{v}^+ \\ \boldsymbol{u}^+ \\ \boldsymbol{w}^+ \end{bmatrix} \end{aligned} \tag{12}$$

Then the feedback control is obtained by

$$u[k] = \tilde{\Gamma}\boldsymbol{C}_1(\boldsymbol{x}[k];\boldsymbol{u}[k],\boldsymbol{w}[k]), \quad k=0,1,2,\dots \tag{13}$$

where $\tilde{\Gamma} \triangleq [\boldsymbol{0}_{1\times N}\ \Gamma\ \boldsymbol{0}_{1\times N}]$, and $\boldsymbol{u}[k]$ and $\boldsymbol{w}[k]$ are initial guesses for the one-step iteration at time k. For the initial guesses $\boldsymbol{u}[k]$ and $\boldsymbol{w}[k]$, we adopt the *warm-start* strategy that uses the previous ones, that is, they are updated by

$$\begin{aligned} \boldsymbol{u}[k+1] &= \begin{bmatrix} u_1^+[k]\ u_2^+[k]\ \dots\ u_{N-1}^+[k]\ 0 \end{bmatrix}^\top, \\ \boldsymbol{w}[k+1] &= \begin{bmatrix} w_1^+[k]\ w_2^+[k]\ \dots\ w_{N-1}^+[k]\ 0 \end{bmatrix}^\top, \end{aligned} \tag{14}$$

where $u_i^+[k]$ and $w_i^+[k]$ are respectively the $(i+1)$-th element $(i=0,1,\dots,N-1)$ of $\boldsymbol{u}^+[k]$ and $\boldsymbol{w}^+[k]$ obtained from $\boldsymbol{C}_1(\boldsymbol{x}[k];\boldsymbol{u}[k],\boldsymbol{w}[k])$.

In summary, the feedback control system is described as follows:

- one-step optimization

$$\begin{aligned} \boldsymbol{v}^+[k] &= \Pi_{\boldsymbol{x}[k]}(\boldsymbol{u}[k]-\boldsymbol{w}[k]) \\ \boldsymbol{u}^+[k] &= S_\gamma(\boldsymbol{v}^+[k]+\boldsymbol{w}[k]) \\ \boldsymbol{w}^+[k] &= \boldsymbol{w}[k] + \boldsymbol{v}^+[k] - \boldsymbol{u}^+[k] \end{aligned} \tag{15}$$

- control signal selection

$$u[k] = \Gamma\boldsymbol{u}^+[k] \tag{16}$$

- state update

$$\begin{aligned} \boldsymbol{x}[k+1] &= A\boldsymbol{x}[k] + \boldsymbol{b}u[k] \\ \boldsymbol{u}[k+1] &= D\boldsymbol{u}^+[k], \\ \boldsymbol{w}[k+1] &= D\boldsymbol{w}^+[k], \end{aligned} \tag{17}$$

  where D is the "one-step" shift matrix defined by

$$D \triangleq \begin{bmatrix} 0 & 1 & & 0 \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ 0 & & & 0 \end{bmatrix}. \tag{18}$$

4. STABILITY ANALYSIS

From (15)–(17), the state-space equation of the feedback system is given by

$$\boldsymbol{\xi}[k+1] = \mathcal{A}\boldsymbol{\xi}[k] + \mathcal{B}S_\gamma(K\boldsymbol{\xi}[k]), \qquad \boldsymbol{\xi}[0] = \boldsymbol{\xi}_0, \tag{19}$$

with the augmented state $\boldsymbol{\xi} \triangleq [\boldsymbol{x}^\top, \boldsymbol{u}^\top, \boldsymbol{\nu}^\top]^\top$ where $\boldsymbol{\nu}[k] \triangleq \gamma\boldsymbol{w}[k]$, and the augmented system matrices

$$\mathcal{A} \triangleq \begin{bmatrix} A & 0 & 0 \\ 0 & 0 & 0 \\ DL & DG & D(I-G) \end{bmatrix}, \quad \mathcal{B} \triangleq \begin{bmatrix} \boldsymbol{b}\Gamma \\ D \\ -D \end{bmatrix} \tag{20}$$

and the augmented "controller matrix"

$$K \triangleq [L,\ G,\ I-G], \tag{21}$$

where L and G are defined in (8).

Let us consider the set

$$\mathcal{N}_\gamma \triangleq \{\boldsymbol{\xi} \in \mathbb{R}^{n+2N} : \|K\boldsymbol{\xi}\|_\infty \le \gamma\}. \tag{22}$$

Note that it contains a neighborhood of the augmented origin $\boldsymbol{0} \in \mathbb{R}^{n+2N}$. We further note that $S_\gamma(K\boldsymbol{\xi}) = \boldsymbol{0}$ for every $\boldsymbol{\xi} \in \mathcal{N}_\gamma$. Hence, on $\mathcal{N}_\gamma$, the dynamics (19) simplifies to the linear dynamics $\boldsymbol{\xi}^+ = \mathcal{A}\boldsymbol{\xi}$. Clearly, the stability of the linear dynamics depends on the eigenvalues of the matrix $\mathcal{A}$.

Theorem 1. The matrix $\mathcal{A}$ is Schur stable, if and only if A is Schur stable.

Proof. Since $\mathcal{A}$ is a block-triangular matrix, its eigenvalues correspond to the union of the eigenvalues of the diagonal blocks A, $0 \in \mathbb{R}^{N\times N}$, and

$$D(I-G) = DX, \quad X \triangleq \Phi^\top(\Phi\Phi^\top)^{-1}\Phi. \tag{23}$$

Since $\mathcal{A}$ inherits all eigenvalues of A, we immediately see that $\mathcal{A}$ is not Schur stable whenever A is not Schur stable.

It remains to show that $\mathcal{A}$ is Schur stable whenever A is Schur stable. Clearly, this relation holds if the matrix (23) is Schur. To prove that all eigenvalues $\lambda \in \mathbb{C}$ of (23) satisfy $|\lambda| < 1$, we use a result from Wielandt (1972) on eigenvalue locations for products of two matrices. As a preparation, we rewrite the matrix X using a singular value decomposition of the form $\Phi = U\Sigma V^\top$, where $U \in \mathbb{R}^{n\times n}$ and $V \in \mathbb{R}^{N\times N}$ are unitary matrices and where

$$\Sigma \triangleq \begin{bmatrix} \sigma_1 & & 0 & 0 \dots 0 \\ & \ddots & & \vdots\ \ddots\ \vdots \\ 0 & & \sigma_n & 0 \dots 0 \end{bmatrix} \in \mathbb{R}^{n\times N} \tag{24}$$

contains the singular values $\sigma_1 \ge \dots \ge \sigma_n$. Note that we have $\sigma_n > 0$ due to $\operatorname{rank}(\Phi) = n$. Using this decomposition, we easily find

$$\begin{aligned} X &= V\Sigma^\top U^\top (U\Sigma V^\top V\Sigma^\top U^\top)^{-1} U\Sigma V^\top \\ &= V\Sigma^\top U^\top U^{-\top}(\Sigma\Sigma^\top)^{-1}U^{-1}U\Sigma V^\top \\ &= V\Sigma^\top \begin{bmatrix} \sigma_1^{-2} & & 0 \\ & \ddots & \\ 0 & & \sigma_n^{-2} \end{bmatrix} \Sigma V^\top = V \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} V^\top. \end{aligned} \tag{25}$$

Hence, X has n eigenvalues 1 and $N-n$ eigenvalues 0. The statements in Wielandt (1972) build on the field of values (or the numerical range)

$$\mathcal{F}(\Psi) \triangleq \{\boldsymbol{c}^\dagger\Psi\boldsymbol{c}, \quad \boldsymbol{c} \in \mathbb{C}^\ell : \boldsymbol{c}^\dagger\boldsymbol{c} = 1\} \tag{26}$$

of matrices $\Psi \in \mathbb{C}^{\ell\times\ell}$. In this context, the identified structure (25) has two important implications. First, we have

$$\mathcal{F}(X) = \operatorname{conv}\{0,1\} = [0,1] \tag{27}$$

according to (Wielandt, 1972, p. 61) since X is normal with eigenvalues 0 and 1. Second, we can apply (Wielandt, 1972, Thm. 3) since X is symmetric and positive definite. As a consequence, we have $\lambda \in \mathcal{F}(D)\,\mathcal{F}(X)$ for all eigenvalues λ of (23). Hence, taking (27) into account, $|\lambda| < 1$ is guaranteed if $\mathcal{F}(D)$ is contained in the interior of the unit disk. Since we indeed have [1]

$$\mathcal{F}(D) = \left\{ \lambda \in \mathbb{C} \;\middle|\; |\lambda| < \cos\left(\frac{\pi}{N+1}\right) \right\} \tag{28}$$

according to (Marcus and Shure, 1979, Thm. 1), the proof is complete.

[1] Using the notation in Marcus and Shure (1979), D as in (18) can be constructed based on an "injection" with no cycles and m open circuits of length N. Hence, we find $\kappa = 0$ and $\nu = N$ according to (Marcus and Shure, 1979, p. 112). Consequently, equation (8) in Marcus and Shure (1979) applies, which leads to (28).

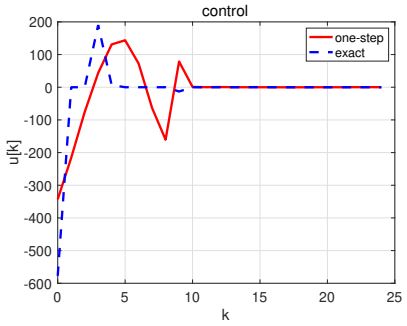

Fig. 2. Maximum hands-off control: exact control (dashed line) and control with one-step iteration (solid line).

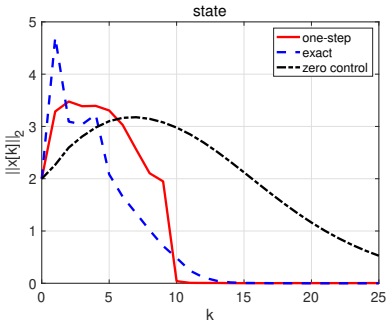

Fig. 3. 2-norm of the state $\|\boldsymbol{x}[k]\|_2$ by exact control (dashed line) and control with one-step iteration (solid line).

Remark 1. The stability result is for local dynamics around the origin. For the global dynamics, the stability is also analyzed in Schulze Darup et al. (2021).

5. NUMERICAL EXAMPLE

Let us consider a continuous-time plant

$$\dot{\boldsymbol{x}}_{\mathrm{c}}(t) = A_{\mathrm{c}}\boldsymbol{x}_{\mathrm{c}}(t) + \boldsymbol{b}_{\mathrm{c}}u_{\mathrm{c}}(t),$$

with

$$A_{\mathrm{c}} = \begin{bmatrix} -12 & -6.75 & -3.375 & -1.2656 \\ 8 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ 0 & 0 & 2 & 0 \end{bmatrix}, \quad \boldsymbol{b}_{\mathrm{c}} = \begin{bmatrix} 0.125 \\ 0 \\ 0 \\ 0 \end{bmatrix}.$$

Note that the above state-space realization is from the transfer function $1/(s+3)^4$. Then, we discretize this plant model with sampling period $h = 0.1$ to obtain a discrete-time model as in (1) by zero-order hold discretization (or step invariant transformation (Chen and Francis, 1995)). We set the initial state $\boldsymbol{x}[0] = [1, 1, 1, 1]^\top$ and the horizon length $N = 10$.

For the one-step ADMM algorithm in (15), we set the parameter $\gamma = 1$. We also compute the exact solution $\boldsymbol{C}_{\mathrm{exact}}(\boldsymbol{x}[k])$ for comparison. This is computed by CVX (Grant and Boyd, 2008, 2014) on MATLAB. Figure 2 shows the obtained control signals.

Since A is stable, the zero control $u \equiv 0$ is also a stabilizing control. That is, with this zero control, the state converges to the origin from any initial state. Although the zero control is obviously the sparsest control, the convergence rate achieved depends only on the time constant, or the largest absolute value of the eigenvalues of A. Figure 3 shows the 2-norm of the state $\boldsymbol{x}[k]$, $k = 0, 1, 2, \ldots, N$ by the proposed one-step control, the exact control, and the zero control. We can see that they all converge to zero. We can also see that the state by the zero-control converges much slower than the hands-off control. The latter converges to zero in finite time.

6. CONCLUSION

In this paper, we have considered discrete-time hands-off control within an MPC formulation. Having real-time applications in mind, we have proposed the one-step optimization with a warm-start and derived a stability result of the combined system when the controlled plant is stable. Future work includes the stability analysis for unstable plants.

Modeling the economic effects of the Covid-19 pandemic in a data-driven agent-based framework

Anton Pichler

Complexity Science Hub, 1090 Vienna, Austria
(e-mail: pichler@csh.ac.at)

Abstract: We introduce a dynamic disequilibrium agent-based model (ABM) that was used to forecast the economics of the Covid-19 pandemic. This model was designed to understand the upstream and downstream propagation of the industry-specific demand and supply shocks caused by Covid-19, which were exceptional in their severity, suddenness and heterogeneity across industries. We used this model to forecast sectoral and aggregate economic activity for the United Kingdom during the early phase of the pandemic. This work demonstrates that an out of equilibrium model calibrated against national accounting data can serve as a useful real time policy evaluation and forecasting tool.

We further extend this modeling framework to a large-scale, data-driven ABM of the New York metropolitan area that simulates both, epidemic and economic outcomes across industries, occupations, and income levels. This coupled epidemic-economic model is designed to address the potential tradeoff between economy and health which has been a key issue faced by policymakers. Our results show that lockdown policies affect different social groups very heterogeneously in terms of income and infections.

Keywords: production function, shock propagation, production network, synthetic population, distributional effects

1. INTRODUCTION

The social distancing measures imposed to combat the first wave of the Covid-19 pandemic created severe industry-specific disruptions to economic output. Some industries were shut down almost entirely by lack of demand, labor shortages restricted others, and many were initially largely unaffected. Feedback effects then amplified the initial shocks. The lack of demand for final goods such as restaurants or transportation propagated upstream, reducing demand for the intermediate goods that supply these industries. Supply constraints due to a lack of labor under social distancing propagated downstream, creating input scarcity that sometimes limited production even in cases where the availability of labor and demand would not have been an issue. The resulting supply and demand constraints interacted to create bottlenecks in production, which in turn led to unemployment, eventually decreasing consumption and causing additional amplification of shocks that further decreased final demand. The unprecedented scale and heterogeneity of the shocks caused a major disruption of the economy that presented a challenge for economic modelers.

Here, we summarize our recent (and still ongoing) work of modeling the economics of the Covid-19 pandemic which aims at addressing these challenges. This abstract is mainly based on a series of papers (del Rio-Chanona et al., 2020, Pichler et al., 2020, Pichler & Farmer, 2021, Pichler et al., 2022 and Pangallo et al., 2022) with a focus on (1) a dynamic disequilibrium model of the UK production network and (2) a disaggregated, large-scale coupled epidemic-economic model of the New York metropolitan area.

2. FORECASTING THE PROPAGATION OF PANDEMIC SHOCKS

We introduce a dynamic input-output model that addresses the unique features of the pandemic. The model, which is directly initialized from national accounts and other data sources where this is possible, has several new elements that affect production, consumption and changes in the labor force. We developed this model during March-April 2020, and used it to forecast the economic consequences of the relaxation of the lockdown in the UK in real-time, in a working paper we released in May 2020 (Pichler et al., 2020). Here we show that the model predicted aggregate economic effects very well and analyze why it succeeded. We first analyze how the model anticipated the impact of the Covid-19 pandemic on the UK economy, particularly at the sectoral level. We then show that our model accurately captures supply chain effects that explain the dynamics of related industries.

The Covid-19 episode was exceptional: (1) Pandemic shocks were highly heterogeneous across industries, making it necessary to model the economy at the sectoral level, taking sectoral inter-dependencies into account; (2) the shocks affected both supply and demand simultaneously, and led to both upstream and downstream propagation; (3) the shocks were so strong and were imposed and relaxed so quickly that the economy never had time to converge to a new steady state, making dynamic models better suited than static models.

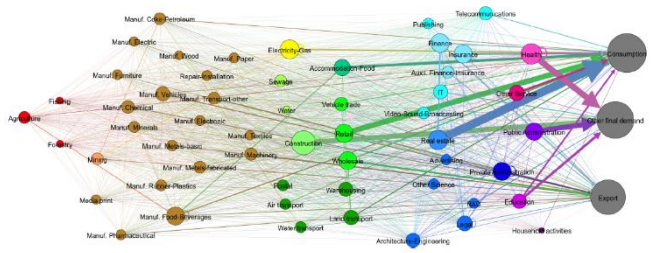

Fig. 1. The UK economy represented as a 55 sectors production network.

A key innovation in our economic model is the sector-specific treatment of the production function. We introduce a new production function that distinguishes between critical and non-critical inputs at the level of the 55 industries in the World Input-Output tables. The *partially binding Leontief* production function that we introduce here allows firms to keep producing as long as they have the inputs that are absolutely necessary. We show that a realistic specification of the production function is a key ingredient with strong effects on model accuracy.

Another key element of our modeling approach is a detailed representation of industry-specific input inventories. Inventories act as buffers in the presence of supply chain disruptions or demand shocks and thus can play an important role in shock propagation dynamics. We use a survey by the UK Office for National Statistics (ONS) on industry-level inventories to initialize our model. Our results are in line with previous work which has shown that inventory levels strongly affect the scale and dynamics of shock propagation.

We introduce a Covid-19-specific treatment of consumption. Most models do not incorporate the demand shocks that are caused by changes in consumer preferences in order to minimize risk of infection. We consider demand shocks to consumption due to "fear of infection" and consider the effect of the drop in current income due to unemployment and reduced expectations of permanent income due to pessimism about the end of the pandemic.

Finally, compared to other economic disaster models, our model explicitly considers labor. Industries adjust their labor force depending on supply constraints due to lockdown, lack of demand or lack of intermediate inputs. Adjustment is sluggish, so firms cannot instantly increase production if they lack workers, as hiring takes time.

We released our results for the UK economy online on May 21, 2020, not long after social distancing measures first began to take effect in March. Our central scenario considered a government policy for reopening that was very close to what the UK government decided. In that scenario, we predicted a 21.5% contraction of GDP in the UK economy in the second quarter of 2020 with respect to the last quarter of 2019. This forecast was remarkably close to the actual contraction of 22.1%.

In our recent work (Pichler et al. 2022) we show which of the modeling factors have been key for making good aggregate sectoral predictions, not just for GDP but also for other key economic variables.

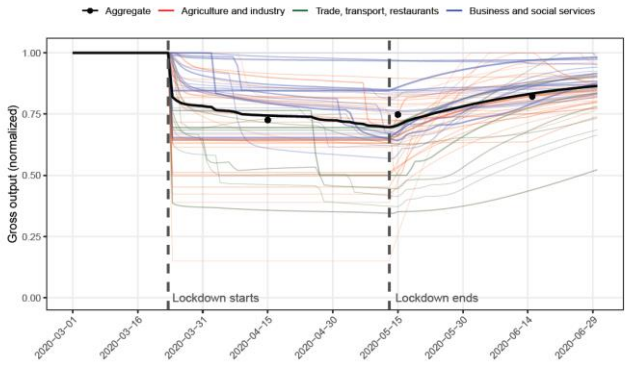

Fig. 2. Economic production as predicted by the model.

3. MODELING DISTRIBUTIONAL EFFECTS OF THE PANDEMIC

Since the outbreak of the Covid-19 pandemic, governments worldwide have successfully slowed down the transmission of the virus by enacting non-pharmaceutical interventions. These interventions include the shutdown of some customer-facing economic activities, e.g. entertainment and restaurants, and the imposition of work-from-home mandates. Such protective measures have distributional effects, i.e. heterogeneous outcomes across socio-economic groups. For instance, workers who can work from home become less likely to be infected after the imposition of these measures, while essential workers remain at risk. At the same time, these measures have different distributional economic effects depending on the industry and occupation of the workers. For example, low-income workers are more likely to work in customer-facing industries and perform in-person occupations, leading to higher risk of unemployment when these industries are closed.

Addressing the effectiveness of non-pharmaceutical interventions over behavioral change, both at the aggregate and distributional level, requires building theoretical, mechanistic models that jointly simulate epidemic and economic dynamics at a fine-grained level.

Here, we introduce an agent-based model (ABM) that simulates epidemic and economic outcomes of a large synthetic population in a metropolitan area. The socio-economic characteristics and the consumption and contact patterns are initialized from detailed census, survey, and mobility data, while the structure of the economy is initialized from input-output tables and national and regional accounts.

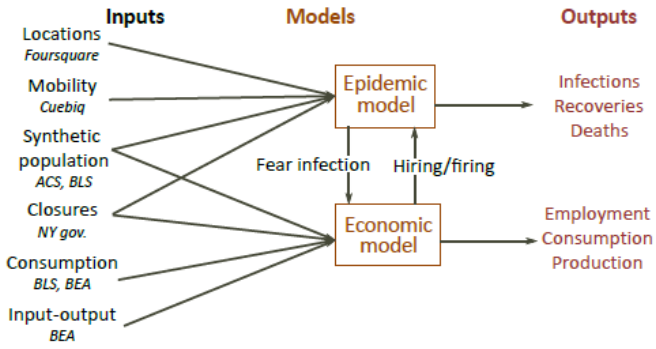

Fig. 3. Basic relationships between inputs and outputs in the epidemic-economic model.

Our joint epidemic-economic ABM merges and largely extends our former epidemic (Aleta et al. 2020) and economic (Pichler et al. 2020) models built to understand the effects of the Covid-19 pandemic and study the effectiveness of policy responses. We calibrate our model to the first wave of the pandemic in the New York metropolitan area and show that it quantitatively matches key epidemic and economic statistics, both in the aggregate and across income levels and industries. We then use our ABM to understand the interplay of behavior change and non-pharmaceutical interventions. Our key result is that strong behavior change, alike strict closure of economic activities, harms the economy but reduces infections and, thus, saves lives. This equivalence between behavior changes and closures also holds at the distributional level: We find that under strong behavior change and strict non-pharmaceutical interventions, low-income workers are more likely to become unemployed but less likely to become infected. The mechanisms behind these results suggest that a model like ours, initialized from various granular datasets, can be used to design policies that minimize health and economic damages to disadvantaged socio-economic groups, for instance by designing income support schemes that are specific to the industry and occupation of workers.

Abstract: In the transition to renewable energy sources, hydrogen will potentially play an important role for energy storage. The efficient transport of this gas is possible via pipelines. An understanding of the possibilities to control the gas flow in pipelines is one of the main building blocks towards the optimal use of gas.
For the operation of gas transport networks it is important to take into account the randomness of the consumers' demand, where often information on the probability distribution is available. Hence in an efficient optimal control model the corresponding probability should be included and the optimal control should be such that the state that is generated by the optimal control satisfies given state constraints with large probability. We comment on the modelling of gas pipeline flow and the problems of optimal nodal control with random demand, where the aim of the optimization is to determine controls that generate states that satisfy given pressure bounds with large probability. We include the H^2 norm of the control as control cost, since this avoids large pressure fluctuations which are harmful in the transport of hydrogen since they can cause embrittlement of the pipeline metal.

Keywords: gas pipeline flow, nodal control, boundary control, optimal control, hyperbolic differential equation, random demand, state constraints, pressure bound, classical solutions

1. INTRODUCTION

The isothermal Euler equations (see e.g. Banda et al. (2006), Gugat and Herty (2022))

$$\begin{cases} \rho_t + q_x = 0, \\ q_t + \left(p + \dfrac{q^2}{\rho}\right)_x = -\dfrac{1}{2}\theta \dfrac{q\,|q|}{\rho} \end{cases} \tag{1}$$

are a well-established model for gas pipeline flow, where ρ denotes the gas density, p the pressure, q the mass flow rate and $\theta \geq 0$ is a friction parameter. At the end $x = 0$ the flow rate that is desired by the consumers is given by a random variable, so we have $q(t,\, 0) = q_r(\omega)$ on a probability space $(\Omega,\, \mathcal{A},\, \mathbb{P})$. Here we assume that $q_r(\omega) \in C^1([0,\, T])$ for all $\omega \in \Omega$. Due to the influence of the random boundary term, also the pde solution becomes a random variable. At the end $x = L$ of the pipe, the pressure is controlled, $p(t,\, L) = u(t)$. We consider controls $u \in H^2([0,\, T])$. For the deterministic case, in Gugat and Sokolowski (2022), a similar optimal control problem for gas networks is considered and the existence of an optimal control is shown. See Göttlich and Schillinger (2021) for a related study for linear systems.

2. THE SYSTEM

Let a time horizon $T > 0$ be given. For the case of ideal gas where $p = a^2\rho$ with the sound speed $a > 0$, our system is governed by the initial boundary value problem

$$(\mathbf{S}^\omega) \begin{cases} q(0,x) = q_0(x), \;\; \rho(0,x) = \rho_0(x),\; x \in (0,\, L), \\ q(t,\, 0) = q_r(\omega), \;\; p(t,\, L) = u(t),\; t \in (0,\, T), \\ \begin{pmatrix} \rho \\ q \end{pmatrix}_t + \begin{pmatrix} 0 & 1 \\ a^2 - \dfrac{q^2}{\rho^2} & 2\,\dfrac{q}{\rho} \end{pmatrix} \begin{pmatrix} \rho \\ q \end{pmatrix}_x = \begin{pmatrix} 0 \\ -\dfrac{\theta}{2}\dfrac{q\,|q|}{\rho} \end{pmatrix}. \end{cases}$$

Let $R_0 > 0$ denote a constant reference density. Due to the theory of semi-global solutions (see Li (2010), Li et al. (2016)) for any given time horizon $T > 0$ there exist numbers $\varepsilon(T) > 0$ and $C_1(T) > 0$ such that for all $R \geq R_0$ and all initial states that satisfy

$$\max\{\|q_0\|_{C^1([0,\, L])},\; \|\rho_0 - R\|_{C^1([0,\, L])}\} \leq \varepsilon(T) \tag{2}$$

and all $q_r(\omega)$ with

$$\|q_r(\omega)\|_{C^1([0,\, T])} \leq \varepsilon(T) \tag{3}$$

and all controls with

$$\|u - a^2\, R\|_{C^1([0,\, T])} \leq \varepsilon(T) \tag{4}$$

that are C^1-compatible with the initial state $(q_0,\, \rho_0)$ there exists a classical solution $(q^\omega,\, \rho^\omega)$ of $(\mathbf{S}^\omega)$ on $[0,\, T]$ that satisfies the a priori estimate

$\max\{\|q^\omega\|_{C^1([0,\, T]\times[0,L])}, \|\rho^\omega - R\|_{C^1([0,\, T]\times[0,L])}\} \leq C_1(T)$
$\max\{\|q_0\|_{C^1([0,\, L])},\; \|\rho_0 - R\|_{C^1([0,\, L])}, \|q_r(\omega)\|_{C^1([0,\, T])},\; \|u -$

$a^2 R\|_{C^1([0,T])}\}$. Moreover, the state depends continuously in $(C^1([0,T]\times[0,L]))^2$ on the control $u \in C^1([0,T])$.

To guarantee that a regular solution exists, in the optimal control problem the control constraint (4) and the C^1-compatibility conditions with the initial state are prescribed.

3. THE OPTIMAL CONTROL PROBLEM

Let a lower pressure bound $p_{\min} > 0$ be given. For a control $u \in H^2(0,T)$ define the objective function

$$J(u,R) = \|u-R\|_{H^2(0,T)} \qquad (5)$$
$$-\ln\left(\mathbb{P}\left(\|(p_{\min}-p^\omega)_+\|_{C([0,T]\times[0,L])}=0\right)\right).$$

The optimal control problem $\mathbf{P_{dyn}}(T)$ is to minimize $J(u,R)$ subject to the constraints $R \geq R_0$, (4) and the C^1-compatibility conditions for u, where (p_ω, q_ω) solves $(\mathbf{S}^\omega)$.

The H^2-term in the objective function helps to avoid large pressure fluctuations in the pipe that can be harmful if the gas contains hydrogen due to the danger of embrittlement, see Guy et al. (2021). The optimal control of gas transportation systems is a classical topic in process engineering, see for example Osiadacz and Swierczewski (1994).

3.1 Existence of solutions

Theorem 1. Let $(q_0,\rho_0) \in \left(C^1([0,T])\right)^2$ be given such that $a^2\rho_0 > p_{\min}$ and (2) holds. Assume that (3) and the C^1-compatibility conditions of $q_r(\omega)$ and the initial data hold almost surely. Then an optimal control that solves $\mathbf{P_{dyn}}(T)$ does exist in $(0,\infty)\times H^2([0,T])$.

Proof. The set of admissible controls is non-empty, since for all $R > 0$ there exists a control $\hat{u} \in H^2(0,T)$ that is compatible with (q_0,ρ_0) and satisfies (4). The a priori estimate implies that if R is sufficiently large, we have almost surely $p^\omega = a^2R + a^2(\rho^\omega - R) \geq a^2R - a^2C_1(T)\,\varepsilon(T) \geq p_{\min}$. Hence if R is sufficiently large, there exists a control where the objective function attains a finite value. (Note that this does not require that $p^\omega \geq p_{\min}$ almost surely, but only that $p^\omega \geq p_{\min}$ has a nonzero probability.)

The H^2-norm is a weakly sequentially lower semi-continuous functional in $H^2(0,T)$. Results from Farshbaf-Shaker et al. (2018) imply that the probabilistic part of the objective function is also weakly sequentially lower semi-continuous in $H^2(0,T)$. This can be seen as follows. A sequence that converges weakly in $H^2(0,T)$ converges strongly in $C^1([0,T])$ to a limit point $u^* \in H^2(0,T)$. Due to the theory of semi-global solutions, (2), (3) and (4) imply that the controls generate classical solutions of $(\mathbf{S}^\omega)$ almost surely and the strong convergence in $C^1([0,T])$ of the controls implies that also the corresponding subsequence of generated states given by the classical solutions of $(\mathbf{S}^\omega)$ converges strongly in $\left(C^1([0,T]\times[0,L])\right)^2$ to the solution that is generated by the limit point u^*. Then Lemma 2 in Farshbaf-Shaker et al. (2018) implies that the probability is weakly sequentially upper semi-continuous in $H^2(0,T)$. This implies that the objective functional is a weakly sequentially lower semi-continuous functional in $(0,\infty)\times H^2(0,T)$.

We consider a minimizing sequence of feasible controls (R_k, u_k). Due to the H^2-term and (4), this sequence is bounded in $\mathbb{R}\times H^2(0,T)$. Hence it contains a subsequence that converges weakly in $\mathbb{R}\times H^2(0,T)$ and thus converges strongly in $\mathbb{R}\times C^1([0,T])$ to a limit point $(R^*, u^*) \in \mathbb{R}\times H^2(0,T)$. Moreover, this also implies that u^* satisfies (4) and that the values of the objective function $J(u^*)$ is minimal.

3.2 Numerical approaches

For the numerical solution, a kernel density estimator should be used to obtain a differentiable approximation of the objective function similar to the approach in Schuster et al. (2021). The controls are represented as Fourier series, $u(t) = \frac{a_0}{2} + \sum_{j=1}^{\infty} a_j \cos\left(j\frac{2\pi}{T}t\right) + b_j \sin\left(j\frac{2\pi}{T}t\right)$. Then we have $\frac{2}{T}\|u\|^2_{H^2(0,T)}$ $= \frac{a_0^2}{2} + \sum_{j=1}^{\infty}\left(1+\left(j\frac{2\pi}{T}\right)^2+\left(j\frac{2\pi}{T}\right)^4\right)\left(|a_j|^2+|b_j|^2\right)\Big)$. Truncation of the Fourier series after a finite number of modes leads to a semi-infinite optimization problem, for a survey see Stein (2012).

4. A NUMERICAL EXAMPLE

Gas network optimization has been of interest for decades, see e.g., Herty and Sachers (2007); Zlotnik et al. (2015) for a semilinear hyperbolic gas transport model and Mak et al. (2019) for a parabolic gas transport model. But gas network optimization with H^2 control and probabilistic terms in the objective function was not considered yet. We present a numerical example on a single edge for both, a probabilistic objective function with a L^2 control term and a probabilistic objective function with an H^2 control term.

We consider the isothermal Euler equations for ideal gases, i.e., for $(t,x) \in [0,T]\times[0,L]$ we have

$$p(t,x) = a^2\rho(t,x),$$

where a denotes the speed of sound in the gas. Due to the proportionality of pressure and density we consider density control at $x = L$ instead of pressure control. All values and constants are given in *Table 1.*

Letter	Value	Unit
T	12	h
L	30	km
a	343	m/s
θ	0.2	
R	46.3	kg/m^3
$\rho_{\min}$	40.4	kg/m^3

Table 1. Values for the numerical example.

At the end $x = 0$ we assume random gas outflow. Therefor we define a deterministic function

$$q_D(t) = -\frac{16}{\pi}\sin\left(\frac{\pi}{12\cdot 60^2}t\right)\cdot\frac{16}{\pi}\cos\left(\frac{\pi}{8\cdot 60^2}t\right) + 140.$$

Let

$$\xi \sim \mathcal{N}\left(1, \sqrt{0.1}\right),$$

be a Gaussian distributed random variable on an appropriate probability space $(\Omega, \mathcal{A}, \mathbb{P})$. Similar as in Schuster et al. (2021) we write $q_D(t)$ as Fourier series and multiply every Fourier term with a random number $\xi(\omega)$, $\omega \in \Omega$. For the implementation we cut the Fourier series after 10 terms. A sample of 20 random boundary functions $q_r(\omega)$ and the corresponding deterministic function $q_D(t)$ are shown in *Figure 1.* For the implementation we use the negative flow values since gas is transported from the end of the pipe $(x = L)$ to its beginning $(x = 0)$.

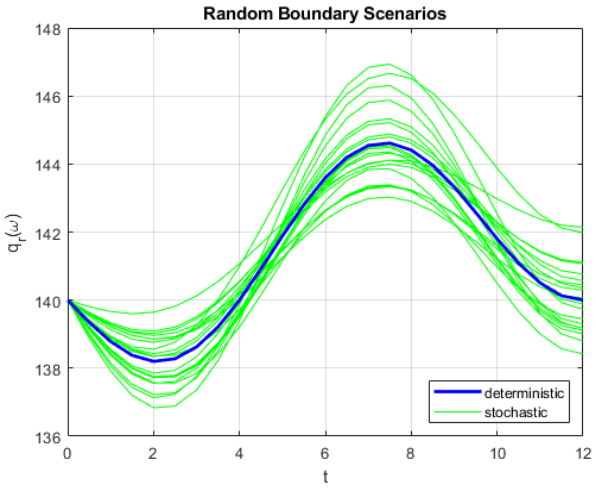

Fig. 1. Sample of 20 random boundary functions $q_r(\omega)$.

For the initial state we solve the stationary isothermal Euler equations

$$\begin{cases} q_x^\sigma = 0, \\ \left(a^2\rho^\sigma + \dfrac{(q^\sigma)^2}{\rho^\sigma}\right)_x = -\dfrac{1}{2}\theta\dfrac{q^\sigma\,|q^\sigma|}{\rho^\sigma}, \end{cases} \tag{6}$$

with the boundary conditions $q^\sigma(0) = q_D(0)$ and $\rho^\sigma(L) = 46.3\ kg/m^3$. The solution $(\rho^\sigma_{\text{init}}, q^\sigma_{\text{init}})$ of (6) serves as initial state for the dynamic problem.

The probabilistic term in the objective function is computed with a kernel density estimator approach (see Schuster et al. (2021)). Due to the friction along the pipe and due to the choice of initial states, for every time the density is minimal at $x = 0$. Thus we have $\rho^\omega(t,x) \geq \rho_{\min}$ iff $\rho^\omega(t,0) \geq \rho_{\min}$. We discretize the time interval using n_T+1 equidistant points $0 = t_0 < \cdots < t_{n_T} = T$ and we use a multivariate kernel density estimator approach with Gaussian product kernels to approximate the probabilistic term. For

$$\mathcal{P}_{\min} := \otimes_{i=1}^{n_T}[\rho_{\min}, \infty),$$

we have

$$\mathbb{P}\big(\ \rho^\omega(t,0) \geq \rho_{\min} \quad \forall t \in [0,T]\ \big) \approx$$
$$\int_{\mathcal{P}_{\min}} \frac{1}{N\sqrt{\det H}} \sum_{i=1}^{N}\prod_{j=1}^{n_T}\frac{1}{\sqrt{2\pi}} \exp\left(-\left(\frac{z_j - \rho_i(t_j)}{\sqrt{2\ H_{j,j}}}\right)^2\right)$$
$$= \frac{1}{N\ 2^{n_T}}\sum_{i=1}^{N}\prod_{j=1}^{n_T}\left[1 - \operatorname{erf}\left(\frac{\rho_{\min} - \rho_i(t_j)}{\sqrt{2H_{j,j}}}\right)\right].$$

Here N is the number of samples, $\rho_i(t_j)$ is the density for the i-th sample at $(t,x) = (t_j, 0)$ and H is a diagonal positive definite bandwidth matrix.

We define objective functions

$$J_{L^2}(u,R) = w_1\|u - R\|_{L^2(0,T)} - \ln\Big(\mathbb{P}\big(\ \rho^\omega(t,0) \geq \rho_{\min} \quad \forall t \in [0,T]\ \big)\Big),$$

and

$$J_{H^2}(u,R) = w_1\|u - R\|_{L^2(0,T)} + w_2\|u'\|_{L^2(0,T)} + w_3\|u''\|_{L^2(0,T)} - \ln\Big(\mathbb{P}\big(\ \rho^\omega(t,0) \geq \rho_{\min} \quad \forall t \in [0,T]\ \big)\Big),$$

with weights

$$w_1 = 2\cdot 10^{-3}, \quad w_2 = 1\cdot 10^{5}, \quad w_3 = 1\cdot 10^{12}.$$

The optimal controls for both objective functions ($N = 20$ and $n_T = 25$) are shown in *Figure 2.* The blue line shows the optimal density control for $J_{L^2}(u,R)$ and the red line in shows the optimal density control for $J_{H^2}(u,R)$. The results can be interpreted as follows: For an objective function without probabilistic term the optimal solution would obviously be $u \equiv R$. The density at $x = 0$ is only lower than $\rho_{\min}$ for the peak around 7 hours (cf. *Figure 1*). Thus the control only needs to be active in this time span. As it was expected the H^2 control is smoother than the L^2 control.

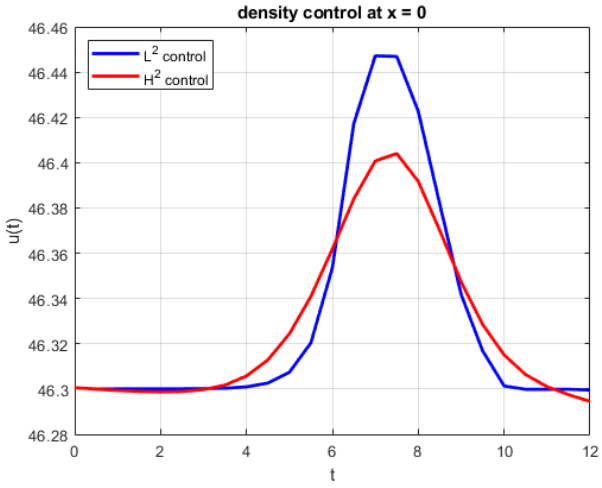

Fig. 2. Optimal control for $J_{L^2}(u,R)$ and $J_{H^2}(u,R)$.

We have

$$\mathbb{P}_{L^2}\big(\ \rho^\omega(t,0) \geq \rho_{\min} \quad \forall t \in [0,T]\ \big) \approx 74\%,$$

and

$$\mathbb{P}_{H^2}\big(\ \rho^\omega(t,0) \geq \rho_{\min} \quad \forall t \in [0,T]\ \big) \approx 66\%.$$

Thus a slight decrease of the probability leads to a smoother density control and less density fluctuations. This can also be seen in *Figure 3* and *Figure 4*. The peaks around 7 hours are smoother in *Figure 4* than in *Figure 3*. The blue line shows $\rho_{\min}$. The optimal density control and the corresponding densities at $x = 0$ would be even smoother if we would increase the weights w_2, w_3 for the L^2-Norm of the control derivatives.

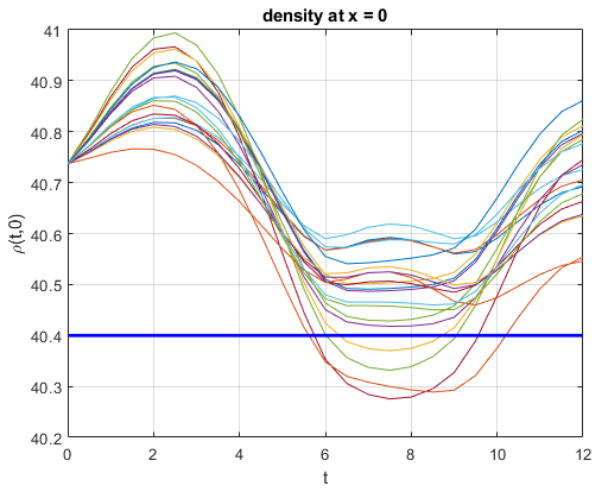

Fig. 3. Scenarios at $x = 0$ for the optimal density control of $J_{L^2}(u, R)$

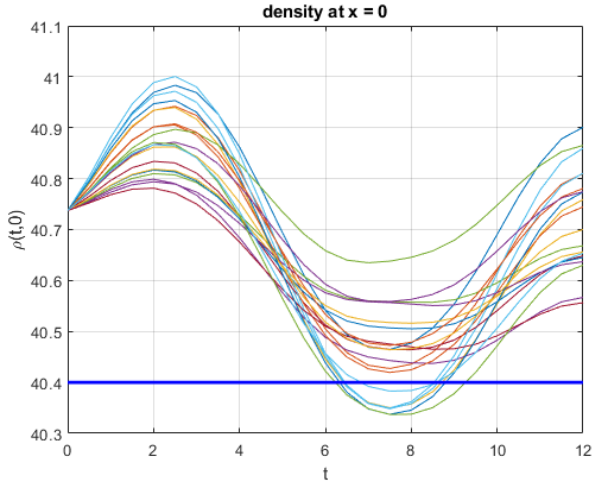

Fig. 4. Scenarios at $x = 0$ for the optimal density control of $J_{H^2}(u, R)$

5. CONCLUSION

In optimal control problems, it is important to take into account the uncertainty of the problem data in order to obtain controls that work sufficiently well in the set of data that is expected. Since in many applications information on the probability distribution of the data is available, this information should be used in an optimal control model. In our contribution we choose the probability that state constraints are satisfied as a part of the objective function. In this way, it is ensured that the optimization generates controls that are robust in the sense that the pressure bounds are satisfied with a high probability. We include an H^2 control cost in the objective functional, which is of particular interest in the context of hydrogen transport. It also serves as a Tychonov regularization term that is important for the proof of the existence of optimal controls.

Evasive subspaces and rank-metric codes

Giuseppe Marino *

* *University of Naples "Federico II"(e-mail: giuseppe.marino@unina.it).*

Abstract: We investigate the connections between rank-metric codes and evasive $\mathbb{F}_q$-subspaces of $\mathbb{F}_{q^m}^k$. We show how the parameters of a rank-metric code are related to special geometric properties of the associated evasive subspace and construct new MRD-codes.

Keywords: Evasive subspace, MRD code, linear cutting blocking set, scattered subspace, q-polynomial

1. INTRODUCTION

Rank-metric codes, in particular MRD codes, have been studied since the 1970s and have seen much interest in recent years due to a wide range of applications including storage systems (Roth (1991)), cryptosystems (Gabidulin (1995)), spacetime codes (Lusina et al (2003)) and random linear network coding (Koetter et al (2008)).

In finite geometry, there are several interesting structures, including quasifields, semifields, splitting dimensional dual hyperovals and maximum scattered subspaces, which can be equivalently described as special types of rank-metric codes; see Csajbók et al (2017), Dempwolff et al (2014), Dempwolff et al (2015), Sheekey (2016), Taniguchi et al (2014) and the references therein.

2. RANK-METRIC CODES

The *rank weight* $\mathrm{rk}(v)$ of a vector $v = (v_1, \dots, v_n) \in \mathbb{F}_{q^m}^n$ is the dimension of the $\mathbb{F}_q$-linear space generated by its entries, i.e.

$$\mathrm{wt}_{\mathrm{rk}}(v) = \dim_{\mathbb{F}_q}(\langle v_1, \dots, v_n \rangle_{\mathbb{F}_q})$$

and the *rank distance* between two vectors is defined as $\mathrm{d}_{\mathrm{rk}}(u, v) := \mathrm{wt}_{\mathrm{rk}}(u - v)$.

Definition 1. An $[n, k, d]_{q^m/q}$ *(rank-metric) code* $\mathcal{C}$ is a k-dimensional $\mathbb{F}_{q^m}$-subspace of $\mathbb{F}_{q^m}^n$ equipped with the rank distance. The parameter d is called the *minimum rank distance* and it is given by

$$\begin{aligned} d := \mathrm{d}_{\mathrm{rk}}(\mathcal{C}) &= \min\{\mathrm{d}_{\mathrm{rk}}(u, v) \colon u, v \in \mathcal{C}, u \neq v\} \\ &= \min\{\mathrm{wt}_{\mathrm{rk}}(v) \colon v \in \mathcal{C}, v \neq 0\}. \end{aligned}$$

A *generator matrix* for $\mathcal{C}$ is a matrix $G \in \mathbb{F}_{q^m}^{k \times n}$ such that

$$\mathcal{C} = \{vG \colon v \in \mathbb{F}_{q^m}^k\}.$$

When the minimum distance is not known or is irrelevant, we write $[n, k]_{q^m/q}$.

It is well-known that

$$\#\mathcal{C} \leq q^{\max\{m,n\}(\min\{m,n\}-d+1)},$$

which is a Singleton like bound for the rank metric; see Delsarte (1978).

When equality holds, we call $\mathcal{C}$ a *maximum rank-distance* (MRD for short) code. More properties of MRD codes can be found in Delsarte (1978), Gabidulin (1985), Gadouleau (2006), Morrison (2014) and Ravagnani (2016).

There are several slightly different definitions of equivalence of rank-distance codes. Here, we use the following notion of equivalence: two $[n, k]_{q^m/q}$ codes $\mathcal{C}_1$ and $\mathcal{C}_2$ are *equivalent* if and only if there exist $A \in \mathrm{GL}(n, q)$ such that

$$\mathcal{C}_1 = \mathcal{C}_2 \cdot A = \{vA \colon v \in \mathcal{C}_2\}.$$

Definition 2. An $[n, k]_{q^m/q}$ code is *nondegenerate* if the $\mathbb{F}_q$-span of the columns of its generator matrices has $\mathbb{F}_q$-dimension equal to n.

Generalized rank weights have been first introduced and studied by Kurihara-Matsumoto-Uyematsu (Kurihara et al (2012),Kurihara et al (2015)), Oggier-Sboui Oggier et al (2012) and Ducoat Ducoat et al (2015).

Let $\Lambda_q(n, m)$ be the set of Frobeniuos-closed subspaces of $\mathbb{F}_{q^m}^n$ i.e.

$$\Lambda_q(n, m) := \{U \leq \mathbb{F}_{q^m}^n : \theta(U) = U\}\},$$

where $\theta : x \in \mathbb{F}_{q^m} \mapsto x^q \in \mathbb{F}_{q^m}$.

Definition 3. Let $\mathcal{C}$ be an $[n, k, d]_{q^m/q}$ code, and let $1 \leq s \leq k$. The *s-th generalized rank weight* of $\mathcal{C}$ is the integer

$$\mathrm{d}_{\mathrm{rk},s}(\mathcal{C}) := \min\{\dim_{\mathbb{F}_{q^m}}(\mathcal{A}) : \mathcal{A} \in \Lambda_q(n, m), \dim(\mathcal{A} \cap \mathcal{C}) \geq s\}.$$

Proposition 4. (Bounds Martínez-Peñas (2016)). Let $\mathcal{C}$ be an $[n, k, d]_{q^m/q}$ code and let $1 \leq s \leq k$. Then

$$\mathrm{d}_{\mathrm{rk},s}(\mathcal{C}) \leq \min\left\{n - k + s, sm, \frac{m}{n}(n - k) + m(s - 1) + 1\right\}.$$

Definition 5. Let s be a positive integer. An $[n, k]_{q^m/q}$ code $\mathcal{C}$ is s-MRD if $d_{\mathrm{rk},s}(\mathcal{C}) = n - k + s$.

According to Proposition 4, an $[n, k]_{q^m/q}$ s-MRD code may exist only if

$$n - k + s \leq \min\left\{sm, \frac{m}{n}(n - k) + m(s - 1) + 1\right\}.$$

3. EVASIVE SUBSPACES

Let $V = V(k, q^m)$ be a k-dimensional vector space over the finite field $\mathbb{F}_{q^m}$. Note that V is also a km-dimensional vector space over $\mathbb{F}_q$.

Definition 6. An $\mathbb{F}_q$-subspace U of V will be called $(h, r)_q$-*evasive* if $\langle U \rangle_{\mathbb{F}_{q^m}}$ has dimension at least h over $\mathbb{F}_{q^m}$ and the h-dimensional $\mathbb{F}_{q^m}$-subspaces of V meet U in $\mathbb{F}_q$-subspaces of dimension at most r. When $h = r$, an $(h, h)_q$-evasive subspace of V is said to be *h-scattered*.

Note that in the definition above the condition on the dimension of $\langle U \rangle_{\mathbb{F}_q^m}$ is to exclude trivial examples for which some of

our results would not apply. So, take an $\mathbb{F}_q$-subspace U of V such that the condition $\dim_{q^m}\langle U\rangle_{q^m} \geq h$ holds. Then it is easy to find an h-dimensional $\mathbb{F}_{q^m}$-subspace meeting U in an $\mathbb{F}_q$-subspace of dimension at least h and hence for an $(h,r)_q$-evasive subspace $h \leq r$ must hold. Clearly, if $\dim_q U \leq r$ then U is an $(h,r)_q$-evasive subspace. The $(k,r)_q$-evasive subspaces are the $\mathbb{F}_q$-subspaces of dimension at most r which span V over $\mathbb{F}_{q^m}$.

4. SOME BOUNDS OF EVASIVE SYSTEMS

Recently, the concept of q-systems has been introduced in Randrianarisoa (2020). A *q-system* U over $\mathbb{F}_{q^m}$ with parameters $[n,k,d]$ is an n-dimensional $\mathbb{F}_q$-subspace generating over $\mathbb{F}_{q^m}$ a k-dimensional $\mathbb{F}_{q^m}$-vector space V, where

$$d = n - \max\{\dim(U \cap H) : H \text{ is a hyperplane of } V\}.$$

With our notation, it is equivalent to say that U is $(k-1, n-d)_q$-evasive in $V(k,q^m)$ and it is not $(k-1, n-d+1)_q$-evasive.

Two $[n,k,d]_{q^m/q}$ systems U_1 and U_2 are said to be *(linearly) equivalent* if there exists $M \in \mathrm{GL}(k,q^m)$ such that $U_1 = M \cdot U_2$.

Let $\mathfrak{U}(n,k,d)_{q^m/q}$ denote the set of equivalence classes of $[n,k,d]_{q^m/q}$ systems, and let $\mathfrak{C}(n,k,d)_{q^m/q}$ denote the set of equivalence classes of nondegenerate $[n,k,d]_{q^m/q}$ codes. Then, define the maps

$$\begin{aligned} \Phi : \quad \mathfrak{C}(n,k,d)_{q^m/q} &\longrightarrow \mathfrak{U}(n,k,d)_{q^m/q} \\ [\mathrm{rowsp}(u_1^\top \mid \ldots \mid u_n^\top)] &\longmapsto [\langle u_1, \ldots u_n\rangle_{\mathbb{F}_q}] \end{aligned}$$

$$\begin{aligned} \Psi : \mathfrak{U}(n,k,d)_{q^m/q} &\longrightarrow \quad \mathfrak{C}(n,k,d)_{q^m/q} \\ [\langle u_1, \ldots u_n\rangle_{\mathbb{F}_q}] &\longmapsto [\mathrm{rowsp}(u_1^\top \mid \ldots \mid u_n^\top)] \end{aligned}$$

The maps Φ and Ψ are well-defined and they are inverse to each other (cf. Randrianarisoa (2020)).

The geometric point of view allows to give a geometric characterization of the generalized rank weights of a rank-metric code via its associated q-system.

Theorem 7. (Randrianarisoa (2020)). Let $\mathcal{C}$ be a nondegenerate $[n,k]_{q^m/q}$ code and let $U \in \Phi([\mathcal{C}])$ be any of the $[n,k]_{q^m/q}$ systems associated. Then

$$\begin{aligned} \mathrm{d}_{\mathrm{rk},r}(\mathcal{C}) = n - \max\{ &\dim_{\mathbb{F}_q}(U \cap W) : W \subseteq V, \\ &\dim_{\mathbb{F}_{q^m}}(W) = k - r\}. \end{aligned}$$

The following result gives a precise description of the connections between evasive subspaces and rank-metric codes.

Theorem 8. ((Marino et al, 2022, Thm. 3.3)). Let $\mathcal{C}$ be a nondegenerate $[n,k]_{q^m/q}$ code, and let $U \in \Phi([\mathcal{C}])$. Then, U is $(h,r)_q$-evasive if and only if $\mathrm{d}_{\mathrm{rk},k-h}(\mathcal{C}) \geq n-r$. In particular, $\mathrm{d}_{\mathrm{rk},k-h}(\mathcal{C}) = n-r$ if and only if U is $(h,r)_q$-evasive but not $(h,r-1)_q$-evasive.

Corollary 9. Let $\mathcal{C}$ be a nondegenerate $[n,k]_{q^m/q}$ code and let $U \in \Phi([\mathcal{C}])$. Then U is an h-scattered $[n,k]_{q^m/q}$ system if and only if $\mathcal{C}$ is $(k-h)$-MRD.

In Csajbók et al (2021), the following upper bound on the dimension of an h-scattered system has been proved.

Theorem 10. Let U be an h-scattered $[n,k]_{q^m/q}$ system. Then

$$n \leq \frac{km}{h+1}.$$

An $[n,k]_{q^m/q}$ system is said to be *maximum h-scattered* if it is h-scattered and meets the bound of Theorem 10 with equality, i.e.,

$$n = \frac{km}{h+1}.$$

Theorem 11. Let k, m be positive integers and let q be a prime power. The following hold.

(1) There exist maximum $(k-1)$-scattered $[m, k, m-k+1]_{q^m/q}$ systems (see Delsarte (1978)).
(2) If km is even, then there exist maximum 1-scattered $[\frac{km}{2}, k,]_{q^m/q}$ systems (see Blokhius et al (2000); Bartoli et al (2018); Csajbók et al (2017)).

In Zini et al (2021) a connection between maximum h-scattered subspaces and MRD codes has been established.

Theorem 12. ((Zini et al, 2021, Theorem 3.2)). Suppose that $h+1$ divides km and let $n := \frac{km}{h+1}$. Let U be an $[n,k]_{q^m/q}$ system and let $\mathcal{C} \in \Psi([U])$ be any of its associated $[n,k]_{q^m/q}$ codes. Then, U is maximum h-scattered if and only if $\mathcal{C}$ is an MRD code.

About the existence of maximum h-scattered the following result holds true.

Theorem 13. If $h+1$ divides k and $m \geq h+1$, then there exist maximum h-scattered $[\frac{km}{h+1}, k]_{q^m/q}$ systems.

If $h+1$ does not divide k we have the following result.

Theorem 14. If $m \geq 4$ is even and $r \geq 3$ is odd, then there exist maximum $(m-3)$-scattered $[\frac{rm}{2}, \frac{r(m-2)}{2}]_{q^m/q}$ system.

The main open problem about h-scattered in $V(k,q^m)$ is their existence for every admissible values of k, m and h. In particular the first open case is the existence of 2-scattered $\mathbb{F}_q$-subspaces of $V(4,q^6)$ of dimension 8.

From Bartoli et al (2021) and Marino et al (2022) we have the following more general bounds on evasive subspaces.

Proposition 15. Let U be a $(k-1,r)_q$-evasive $[n,k]_{q^m/q}$ system. Then

$$km \leq n(m-n+r+1).$$

Proposition 16. Let U be an $(h,r)_q$-evasive $[n,k]_{q^m/q}$ system. The following hold.

(1) $r \geq \max\{h, h-1+\frac{h+1}{m-1}\}$.

(2) $n \leq km - hm + r$,

(3) If $r \leq \frac{m}{m-1}h$, then

$$n \leq \frac{km}{r+1-m(r-h)}.$$

5. SMALL LINEAR CUTTING BLOCKING SETS AND NEW MRD

Another family of q-systems has been recently introduced in Alfarano et al. (2021).

Definition 17. An $[n,k]_{q^m/q}$ system U is said to be t-cutting if for every $\mathbb{F}_{q^m}$-subspace H of $V(k,q^m)$ of codimension t we have $\langle H \cap U\rangle_{\mathbb{F}_{q^m}} = H$. When $t=1$, we simply say that U is *cutting* (or a *linear cutting blocking set*).

The study of these objects was due to their connection to minimal rank-metric codes. A codeword is said to be *m*inimal if its support does not contain the support of any other non-proportional nonzero codeword. A code for which every codeword is minimal is called *minimal*. The importance of minimal codes relies on their connection with cryptography and coding theory.

Theorem 18. (Alfarano et al. (2021)). Let $\mathcal{C}$ be an $[n,k]_{q^m/q}$ code, and let $U \in \Phi([\mathcal{C}])$ be any of the associated $[n,k]_{q^m/q}$ systems. Then, $\mathcal{C}$ is a minimal rank-metric code if and only if U is a linear cutting blocking set.

The following bound on the parameters of linear cutting blocking set was determined in Alfarano et al. (2021).

Proposition 19. Let U be a cutting $[n,k]_{q^m/q}$ system, with $k \geq 2$. Then $n \geq m + k - 1$.

Moreover, in Alfarano et al. (2021) it was observed that linear cutting blocking sets are related with scattered subspaces when $k = 3$. In this case, scattered susbapces were used to construct linear cutting blocking sets, as the following result shows.

Proposition 20. (Alfarano et al. (2021)). If U is a scattered $[n,3]_{q^m/q}$ system with $n \geq m + 2$, then U is cutting.

The previous result has been generalized in Bartoli et al (in press).

Theorem 21. Let U be an $[n,k]_{q^m/q}$ system. Then, U is $(k-2, n-m-1)_q$-evasive if and only if it is cutting.

Note that, in general, the lower bound in Proposition 19 is not tight.

Corollary 22. If $m < (k-1)^2$ then there are no linear cutting blocking set of dimension $m + k - 1$.

Furthermore, it is interesting to observe what happens in the extremal case $m = (k-1)^2$.

Corollary 23. Let U be a $[k(k-1), k]_{q^{(k-1)^2}/q}$ system and let $\mathcal{C}$ be a code associated to U. The following are equivalent.

(1) U is $(k-2)$-scattered.
(2) U is cutting.
(3) $\mathcal{C}$ is MRD.
(4) $\mathcal{C}$ is minimal.

In Bartoli et al (in press) the cases $(k,m) = (4,3)$ and $(k,m) = (4,4)$ have been investigated.

Denote by $c_q(k,m)$ the smallest dimension of a linear cutting blocking set in $V(k,q^m)$. Then Proposition 19 can be rewritten as

$$c_q(k,m) \geq k + m - 1,$$

and we have seen that this is not always an equality; see Corollary 22. In Bartoli et al (in press) has been shown that $c_q(4,3) = 8$ for every prime power q. Also in Bartoli et al (in press), it has been proved that $c_q(4,4) \geq 8$. In particular it has shown that $c_q(4,4) = 8$ when $q = 2^{2h+1}$, with $h \geq 0$, constructing a scattered $[8,4]_{q^4/q}$ system which is also $(2,3)_q$-evasive. If $\mathcal{C}$ is an $[8,4]_{q^4/q}$ MRD associated with U, its generalized rank weights are

$$\mathrm{d}_{\mathrm{rk},1}(\mathcal{C}) = 3,\ \mathrm{d}_{\mathrm{rk},2}(\mathcal{C}) = 5,\ \mathrm{d}_{\mathrm{rk},3}(\mathcal{C}) = 7,\ \mathrm{d}_{\mathrm{rk},4}(\mathcal{C}) = 8.$$

The importance of this result is multiple, and it is related to the theory of rank-metric codes. On the one hand it provides a construction of a minimal rank-metric code of dimension 4 with respect to the field extension $\mathbb{F}_{q^4}/\mathbb{F}_q$ of shortest length. On the other hand it provides the first example of a $[2n, 2(n-d+1), d]_{q^n/q}$ MRD code which is not the direct sum of two $[n, n-d+1, d]_{q^n/q}$ MRD codes.

Sampling formulae in reproducing kernel Hilbert spaces

Harry Dym *

* *Department of Mathematics, The Weizmann Institute of Science, Rehovot 76100, Israel (e-mail: harry.dym@weizmann.ac.il).*

Abstract: The classical sampling formula associated with the names of Shannon, Whittaker, Nyquist and Kotelnikov, will be exhibited as a special case of a general sampling formula in the setting of reproducing kernel Hilbert spaces of entire functions due to Louis de Branges. Other applications of these spaces and generalizations to spaces of vector valued entire functions will also be discussed briefly.

Keywords: Sampling formulas, reproducing kernel Hilbert spaces, de Branges spaces.

The classical sampling formula associated with the names of Shannon, Whittaker, Nyquist and Kotelnikov, may be formulated as follows:

If $f(\lambda) = \int_{-T}^{T} e^{i\mu s}\varphi(s)ds$ *for some function* φ *with the property* $\int_{-T}^{T} |\varphi(s)|^2 ds < \infty$, *then*

$$f(\lambda) = \sum_{n=-\infty}^{\infty} f(\mu_n)\frac{\sin(\lambda-\mu_n)T}{(\lambda-\mu_n)T} \quad \text{with } \mu_n = \frac{n\pi}{T}, \tag{1}$$

i.e., $f(\lambda)$ *can be recovered from its values at the points* μ_n.

This formula is usually derived by exploiting the interplay between the Fourier series expansion of φ and classical formulas for Fourier integrals.

I shall, however, discuss another approach that invokes the Paley-Wiener theorem to reinterpret this sampling formula as a special case of a family of such formulas that arise in a class of reproducing kernel Hilbert spaces of entire functions that was introduced and deeply investigated by Louis de Branges.

The de Branges theory begins with an entire function $E(\lambda)$ that is subject to the constraint

$$|E(\lambda)| > |E(\overline{\lambda})| \quad \text{for every point } \lambda \text{ in the open upper half-plane } \mathbb{C}_+. \tag{2}$$

To each such function $E(\lambda)$ there is an associated reproducing kernel Hilbert space $\mathcal{B}(E)$ of entire functions f (that may be characterized by some growth conditions on f) with reproducing kernel

$$K_\omega(\lambda) = \frac{E(\lambda)E(\omega)^* - E^{\#}(\lambda)E^{\#}(\omega)^*}{-2\pi i(\lambda-\overline{\omega})},$$

in which $h^{\#}(\lambda) = h(\overline{\lambda})^*$ for entire functions h, and inner product

$$\langle f, g\rangle_{\mathcal{B}(E)} = \int_{-\infty}^{\infty} (E^{-1}g)(\mu)^*(E^{-1}f)(\mu)d\mu.$$

This means that for each choice of $\omega \in \mathbb{C}$ and $f \in \mathcal{B}(E)$:

(i) $K_\omega \in \mathcal{B}(E)$.

(ii) $\langle f, K_\omega\rangle_{\mathcal{B}(E)} = f(\omega)$.

To proceed further, it is convenient to express the reproducing kernel in terms of the functions

$$A(\lambda) = \frac{E^{\#}(\lambda)+E(\lambda)}{2} = A^{\#}(\lambda)$$

and

$$B(\lambda) = \frac{E^{\#}(\lambda)-E(\lambda)}{2i} = B^{\#}(\lambda).$$

The constraint (2) forces the zeros of $B(\lambda)$, if any, to be real. Since

$$E(\lambda) = A(\lambda) - iB(\lambda) \quad \text{and} \quad E^{\#}(\lambda) = A(\lambda) + iB(\lambda),$$

it is readily checked that

$$K_\omega(\lambda) = \frac{A(\lambda)B(\overline{\omega}) - B(\lambda)A(\overline{\omega})}{\pi(\lambda-\overline{\omega})}$$

Moreover, if $\omega_1, \omega_2, \dots$ is a sequence of real zeros of $B(\lambda)$, then

$$\begin{aligned}\langle K_{\omega_j}, K_{\omega_k}\rangle_{\mathcal{B}(E)} &= K_{\omega_j}(\omega_k)\\ &= \frac{A(\omega_k)B(\omega_j) - B(\omega_k)A(\omega_j)}{\pi(\omega_k-\omega_j)}\\ &= 0 \quad \text{if } j \neq k.\end{aligned}$$

Under reasonable conditions on $E(\lambda)$, the set $\{K_{\omega_j}\}$ is an orthogonal basis for $\mathcal{B}(E)$ and hence every $f \in \mathcal{B}(E)$ can be expressed as

$$\begin{aligned}f(\lambda) &= \sum \langle f, K_{\omega_j}\rangle_{\mathcal{B}(E)} \|K_{\omega_j}\|^{-2}_{\mathcal{B}(E)} K_{\omega_j}(\lambda)\\ &= \sum f(\omega_j)\|K_{\omega_j}\|^{-2}_{\mathcal{B}(E)} K_{\omega_j}(\lambda).\end{aligned} \tag{3}$$

This is de Branges' sampling formula; see e.g., De Branges (1959), De Branges (1968); and, for an introduction to sampling theory Garcıa (2015).

Formula (1) is the special case of (3) that is obtained by choosing $E(\lambda) = e^{-i\lambda T}$, $T > 0$. For this choice of $E(\lambda)$, $A(\lambda) = \cos \lambda T$, $B(\lambda) = \sin \lambda T$ and

$$K_\omega(\lambda) = (\pi(\lambda-\overline{\omega}))^{-1}\sin(\lambda-\overline{\omega})T.$$

Formula (3) opens the door to many generalizations of (1).

The talk will be largely expository. However, if time permits, some highlights of a relatively recent paper, Dym

and Sarkar (2017) written jointly with S. Sarkar, that discusses sampling in de Branges spaces of vector valued entire functions, will be mentioned briefly; see also Arov and Dym (2018).

Multilayer crisscross error and erasure correction

Umberto Martínez-Peñas *

* *IMUVa-Mathematics Research Institute, University of Valladolid, Spain (e-mail: umberto.martinez@uva.es).*

Abstract: In this work, the multi-cover metric is introduced. It is defined as a Cartesian product of classical cover metrics. A Singleton bound is given and maximum multi-cover distance (MMCD) codes are defined. Puncturing and shortening of linear MMCD codes are studied. It is shown that the dual of a linear MMCD code is not necessarily MMCD, and those satisfying this duality condition are defined as dually MMCD codes. Finally, constructions of dually MMCD codes are given, which also include some new linear codes attaining the Singleton bound for the classical cover metric and classical crisscross error correction.

Keywords: Crisscross error correction, duality, extremal codes, sum-rank distance

1. INTRODUCTION

The cover metric was introduced in (Roth, 1991) to measure the number of crisscross errors in memory chip arrays, which affect entire rows and columns. Two types of codes attaining the Singleton bound for the cover metric were introduced in (Roth, 1991), one of them based on the rank metric and patented in (Ordentlich et al., 2015).

In this work, we extend the cover metric to a tuple of ℓ matrices, where ℓ is a fixed positive integer. We call the new metric the multi-cover metric. This metric is suitable to correct simultaneously a number of crisscross errors and erasures distributed over the ℓ matrices.

In Section 2, we provide a Singleton bound for the multi-cover metric, and we call codes attaining it maximum multi-cover distance (MMCD) codes. As it can easily be seen, concatenated codes and Cartesian products of codes for the classical cover metric yield codes that are not MMCD. As in the sum-rank metric, MRD codes yield MMCD codes but only work for very tall matrices and are decodable over large finite fields. In Section 3, we study the puncturing and shortening of MMCD codes, and we show that the dual of a linear MMCD code is not necessarily MMCD, in contrast with MDS or MRD codes. Those satisfying this duality condition will be called dually MMCD codes. Finally, in Section 4, we provide a general family of dually MMCD codes for square matrices that can be corrected efficiently for a variety of alphabet sizes.

2. DEFINITIONS AND BASIC PROPERTIES

We denote $\mathbb{N} = \{0, 1, 2, \ldots\}$. Fix q a prime power and let $\mathbb{F}_q$ be the finite field of size q. For positive integers m and n, we denote by $\mathbb{F}_q^{m\times n}$ the set of $m \times n$ matrices with entries in $\mathbb{F}_q$. Throughout this manuscript, we will fix positive integers ℓ, $n_1, n_2, \ldots, n_\ell$, $m_1, m_2, \ldots, m_\ell$, and we will consider codes as subsets of $\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$. We also set $\mathbf{m} = (m_1, m_2, \ldots, m_\ell)$ and $\mathbf{n} = (n_1, n_2, \ldots, n_\ell)$. We denote by $\mathrm{MC}(\mathbf{m}, \mathbf{n}) = \{(X_i, Y_i)_{i=1}^{\ell} \mid X_i \subseteq [m_i], Y_i \subseteq [n_i]\}$ the set of multi-covers in $\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$. Finally, given $X = (X_i, Y_i)_{i=1}^{\ell} \in \mathrm{MC}(\mathbf{m}, \mathbf{n})$, we define its size as $|X| = \sum_{i=1}^{\ell}(|X_i| + |Y_i|)$ and its projection map $\pi_X : \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i} \longrightarrow \prod_{i=1}^{\ell} \mathbb{F}_q^{(m_i-|X_i|)\times(n_i-|Y_i|)}$ by removing from $C_i \in \mathbb{F}_q^{m_i\times n_i}$ the rows indexed by X_i and the columns indexed by Y_i in order to obtain $\pi_X(C_1, C_2, \ldots, C_\ell)$. Given $C \in \mathbb{F}_q^{m\times n}$ and $(C_1, C_2, \ldots, C_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$, we denote by $C_{a,b}$ and $C_{i,a,b}$ the entry in row a and column b of the matrices C and C_i, respectively. Throughout the manuscript, we will also assume, without loss of generality, that $n_i \leq m_i$, for $i = 1, 2, \ldots, \ell$, and $m_1 \geq \ldots \geq m_\ell$.

We extend the definition of the cover metric from (Roth, 1991) to the multilayer case, as follows.

Definition 1. Let $C = (C_1, C_2, \ldots, C_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$, where $C_i \in \mathbb{F}_q^{m_i\times n_i}$, for $i = 1, 2, \ldots, \ell$. We say that $(X_i, Y_i)_{i=1}^{\ell} \in \mathrm{MC}(\mathbf{m}, \mathbf{n})$ is a multi-cover of C if (X_i, Y_i) is a cover of C_i, which means that if $C_{i,a,b} \neq 0$, then $a \in X_i$ or $b \in Y_i$, for $i = 1, 2, \ldots, \ell$. We denote by $\mathrm{MC}(C)$ the set of all multi-covers of C. The multi-cover weight of C is then defined as $\mathrm{wt}_{MC}(C) = \min\{|X| \mid X \in \mathrm{MC}(C)\}$. The multi-cover metric is defined as $\mathrm{d}_{MC} : (\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i})^2 \longrightarrow \mathbb{N}$, where $\mathrm{d}_{MC}(C, D) = \mathrm{wt}_{MC}(C - D)$, for $C, D \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$. Given a code $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$, we define its minimum multi-cover distance as $\mathrm{d}_{MC}(\mathcal{C}) = \min\{\mathrm{d}_{MC}(C, D) \mid C, D \in \mathcal{C}, C \neq D\}$. When considering the minimum distance of a code $\mathcal{C}$, we implicitly assume that $|\mathcal{C}| > 1$.

The cover metric (Roth, 1991) is recovered from the multi-cover metric when $\ell = 1$ (in particular, the multi-cover metric is indeed a metric as it is a sum of metrics). Similarly, both the multi-cover metric and the Hamming metric coincide in $\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$ if $m_i = n_i = 1$, for $i = 1, 2, \ldots, \ell$. In this way, the multi-cover metric interpolates between the cover metric and the Hamming metric.

We conclude the section with a Singleton bound for the multi-cover metric. The proof is analogous to that of (Byrne et al., 2021, Th. 3.2) and is omitted.

Theorem 1. Let $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ be a code, set $d = \mathrm{d}_{MC}(\mathcal{C})$ and let δ and j be the unique integers such that $d-1 = \sum_{i=1}^{j-1} n_i + \delta$ and $0 \leq \delta \leq n_j - 1$. Then

$$|\mathcal{C}| \leq q^{\sum_{i=j}^{\ell} m_i n_i - m_j \delta}. \tag{1}$$

In particular, if $m = m_1 = \ldots = m_\ell$ and if we set $N = n_1 + n_2 + \cdots + n_\ell$, then (1) reads

$$|\mathcal{C}| \leq q^{m(N-d+1)}.$$

We may thus define maximum multi-cover distance (MMCD) codes as follows.

Definition 2. We say that a code $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ is maximum multi-cover distance (MMCD) if equality holds in (1).

3. DUALITY, PUNCTURING AND SHORTENING

In this section, we study duality, puncturing and shortening for the multi-cover metric. We will consider duality with respect to the trace product, given by

$$\langle C, D \rangle = \sum_{i=1}^{\ell} \mathrm{Tr}(C_i D_i), \tag{2}$$

where $C = (C_1, C_2, \ldots, C_\ell), D = (D_1, D_2, \ldots, D_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$, and where $\mathrm{Tr}(A)$ denotes the trace of the matrix A. Observe that $\langle \cdot, \cdot \rangle$ is nothing but the usual inner product seeing $\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ as $\mathbb{F}_q^{\sum_{i=1}^{\ell} m_i n_i}$. We then define the dual of a linear code $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ in the usual way,

$$\mathcal{C}^{\perp} = \left\{ D \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i} \;\middle|\; \langle C, D \rangle = 0, \text{ for all } C \in \mathcal{C} \right\}.$$

We now define puncturing and shortening, which extend the classical concepts of puncturing and shortening for the Hamming metric (Huffman and Pless, 2003, Sec. 1.5). As in the classical Hamming-metric case, puncturing and shortening enables us to explicitly construct shorter codes from known codes. To the best of our knowledge, these concepts have not been introduced in the classical cover metric case ($\ell = 1$).

Definition 3. Let $X = (X_i, Y_i)_{i=1}^{\ell} \in \mathrm{MC}(\mathbf{m}, \mathbf{n})$. Given a code $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$, we define its puncturing and shortening on X, respectively, as

$$\begin{aligned} \mathcal{C}_X &= \pi_X(\mathcal{C}), \\ \mathcal{C}^X &= \{\pi_X(C) \mid C \in \mathcal{C}, \text{ such that } C_{i,a,b} = 0 \\ &\qquad \text{if } a \in X_i \text{ or } b \in Y_i, 1 \leq i \leq \ell\}, \end{aligned}$$

both of which are codes in $\prod_{i=1}^{\ell} \mathbb{F}_q^{(m_i - |X_i|) \times (n_i - |Y_i|)}$.

We now describe the basic properties of punctured and shortened codes in general. The proof is left to the reader.

Proposition 4. Given a linear code $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ of dimension k and minimum multi-cover distance d, and a multi-cover $X = (X_i, Y_i)_{i=1}^{\ell} \in \mathrm{MC}(\mathbf{m}, \mathbf{n})$, the following hold:

(1) $(\mathcal{C}_X)^{\perp} = (\mathcal{C}^{\perp})^X$ and $(\mathcal{C}^X)^{\perp} = (\mathcal{C}^{\perp})_X$.
(2) $\dim(\mathcal{C}_X) \geq k - \sum_{i=1}^{\ell} (n_i |X_i| + m_i |Y_i| - |X_i| \cdot |Y_i|)$.
(3) $\dim(\mathcal{C}^X) \geq k - \sum_{i=1}^{\ell} (n_i |X_i| + m_i |Y_i| - |X_i| \cdot |Y_i|)$.
(4) $\mathrm{d}_{MC}(\mathcal{C}_X) \geq d - |X|$.
(5) $\mathrm{d}_{MC}(\mathcal{C}^X) \geq d$.

More interestingly, we may obtain shorter linear MMCD codes from known linear MMCD codes.

Theorem 2. Let $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ be a linear MMCD code. Set $d = \mathrm{d}_{MC}(\mathcal{C})$ and let δ and j be the unique integers such that $d-1 = \sum_{i=1}^{j-1} n_i + \delta$ and $0 \leq \delta \leq n_j - 1$. Let $X = (X_i, Y_i)_{i=1}^{\ell} \in \mathrm{MC}(\mathbf{m}, \mathbf{n})$. The following hold:

(1) Let $1 \leq k \leq j$, assume that $d > 1$, $X_i = \varnothing$, for all $i = 1, 2, \ldots, \ell$, $Y_i = \varnothing$ if $i \neq k$ and $|Y_k| = 1$. Further assume $\delta > 0$ if $k = j$. Then $\mathcal{C}_X$ is a linear MMCD code with $\dim(\mathcal{C}_X) = \dim(\mathcal{C})$ and $\mathrm{d}_{MC}(\mathcal{C}_X) = \mathrm{d}_{MC}(\mathcal{C}) - 1$.
(2) Let $j+1 \leq k \leq \ell$, and assume that $Y_i = \varnothing$, for all $i = 1, 2, \ldots, \ell$, $X_i = \varnothing$ if $i \neq k$ and $|X_k| = 1$. Then $\mathcal{C}^X$ is a linear MMCD code with $\dim(\mathcal{C}^X) = \dim(\mathcal{C}) - n_k$ and $\mathrm{d}_{MC}(\mathcal{C}^X) = \mathrm{d}_{MC}(\mathcal{C})$.
(3) Let $j+1 \leq k \leq \ell$, and assume that $X_i = \varnothing$, for all $i = 1, 2, \ldots, \ell$, $Y_i = \varnothing$ if $i \neq k$ and $|Y_k| = 1$. Then $\mathcal{C}^X$ is a linear MMCD code with $\dim(\mathcal{C}^X) = \dim(\mathcal{C}) - m_k$ and $\mathrm{d}_{MC}(\mathcal{C}^X) = \mathrm{d}_{MC}(\mathcal{C})$.

Proof. We start by proving Item 1. Let $n_i' = n_i$ if $i \neq k$, and let $n_k' = n_k - 1$. Note that $\mathcal{C}_X \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i'}$. Set also $\delta' = \delta - 1$ if $k = j$, and $\delta' = \delta$ otherwise. Thus $0 \leq \delta' \leq n_j' - 1$ by the assumptions. By Proposition 4, we have that

$$\mathrm{d}_{MC}(\mathcal{C}_X) - 1 \geq d - 2 = \sum_{i=1}^{j-1} n_i + \delta - 1 = \sum_{i=1}^{j-1} n_i' + \delta',$$

and since $d > 1$, we also have that

$$\dim(\mathcal{C}_X) = \dim(\mathcal{C}) = \sum_{i=j}^{\ell} m_i n_i - m_j \delta = \sum_{i=j}^{\ell} m_i n_i' - m_j \delta'.$$

Therefore, $\mathcal{C}_X$ must be MMCD and the inequalities above are equalities.

We next prove Item 2. Let $m_i' = m_i$ if $i \neq k$, and let $m_k' = m_k - 1$. Note that $\mathcal{C}^X \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i' \times n_i}$. By Proposition 4, we have that

$$\mathrm{d}_{MC}(\mathcal{C}^X) - 1 \geq d - 1 = \sum_{i=1}^{j-1} n_i + \delta, \text{ and}$$

$$\dim(\mathcal{C}^X) \geq \dim(\mathcal{C}) - n_k = \sum_{i=j}^{\ell} m_i' n_i - m_j' \delta.$$

Therefore, $\mathcal{C}^X$ must be MMCD and the inequalities above are equalities.

Finally we prove Item 3. Let $n_i' = n_i$ if $i \neq k$, and let $n_k' = n_k - 1$. Note that $\mathcal{C}^X \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i'}$. By Proposition 4, we have that

$$\mathrm{d}_{MC}(\mathcal{C}^X) - 1 \geq d - 1 = \sum_{i=1}^{j-1} n_i + \delta = \sum_{i=1}^{j-1} n_i' + \delta, \text{ and}$$

$$\dim(\mathcal{C}^X) \geq \dim(\mathcal{C}) - m_k = \sum_{i=j}^{\ell} m_i n_i' - m_j \delta.$$

Therefore, $\mathcal{C}^X$ must be MMCD and the inequalities above are equalities. □

We now discuss duality and show that, in general, the dual of a linear MMCD code is not necessarily MMCD, leading to the concept of dually MMCD codes. We also relate the duality of MMCD codes with codes which are MDS by rows and columns.

Define the column-wise Hamming weight and metric in $\mathbb{F}_q^{m\times n}$ in the natural way and denote them, respectively, by wt_H^C and d_H^C. In other words, $\mathrm{wt}_H^C(C)$ is the number of non-zero columns in the matrix $C \in \mathbb{F}_q^{m\times n}$. We may similarly define the Hamming metric by rows in $\mathbb{F}_q^{m\times n}$ by transposition, i.e., we may consider

$$\mathcal{C}^\intercal = \{C^\intercal \mid C \in \mathcal{C}\} \subseteq \mathbb{F}_q^{m\times n},$$

for $\mathcal{C} \subseteq \mathbb{F}_q^{n\times m}$, where $C^\intercal$ denotes the transposed of a matrix C. That is, $\mathrm{wt}_H^R(C) = \mathrm{wt}_H^C(C^\intercal)$. We denote the row-wise Hamming weight and metric in $\mathbb{F}_q^{m\times n}$ by wt_H^R and d_H^R, respectively. We denote the minimum Hamming distance of $\mathcal{C}$ by rows and by columns, respectively, by $\mathrm{d}_H^R(\mathcal{C})$ and $\mathrm{d}_H^C(\mathcal{C})$. Clearly, for $C \in \mathbb{F}_q^{m\times n}$ and $\mathcal{C} \subseteq \mathbb{F}_q^{m\times n}$,

$$\mathrm{wt}_{MC}(C) \leq \mathrm{wt}_H^C(C) \quad \text{and} \quad \mathrm{d}_{MC}(\mathcal{C}) \leq \mathrm{d}_H^C(\mathcal{C}), \tag{3}$$

and analogously for the row-wise Hamming weight and metric.

Consider now the square case $m = n$. The Singleton bound from Theorem 1 holds in the same way for both rows and columns, i.e.,

$$|\mathcal{C}| \leq q^{n(n-d+1)},$$

whether $d = \mathrm{d}_H^R(\mathcal{C})$ or $d = \mathrm{d}_H^C(\mathcal{C})$. A code attaining this bound for d_H^R will be called MDS by rows, and analogously for columns. Clearly, if $\mathcal{C}$ is MMCD, then it is both MDS by rows and by columns. In particular, if it is linear, then $\mathcal{C}^\perp$ is also MDS by rows and by columns, since the MDS property is preserved by duality (Huffman and Pless, 2003, Th. 2.4.3).

However, as we now show, the dual of a linear MMCD code is not necessarily MMCD itself and a linear code that is MDS by rows and by columns is not necessarily MMCD either.

Example 5. Consider $\mathcal{C} \subseteq \mathbb{F}_2^{3\times 3}$ generated by

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \text{and} \quad C = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 1 \end{pmatrix}.$$

Since $\mathcal{C} = \{0, A, B, C, A+B, B+C, C+A, A+B+C\}$ and $\dim(\mathcal{C}) = 3$, it is easy to see that $\mathcal{C}$ is MDS by columns and by rows since $\mathrm{d}_H^R(\mathcal{C}) = \mathrm{d}_H^C(\mathcal{C}) = 3$, but it is not MMCD, since $\mathrm{d}_{MC}(\mathcal{C}) = 2$. Now, $\mathcal{C}^\perp \subseteq \mathbb{F}_2^{3\times 3}$ has $\dim(\mathcal{C}^\perp) = 6$. Moreover, by inspection one can see that there is no $D \in \mathcal{C}^\perp$ with $\mathrm{wt}_{MC}(D) = 1$. Therefore, $\mathrm{d}_{MC}(\mathcal{C}^\perp) = 2$ and $\mathcal{C}^\perp$ is a linear MMCD code, even though $\mathcal{C}$ is not.

The example above motivates the following definition.

Definition 6. We say that $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$ is a dually MMCD code if it is linear and both $\mathcal{C}$ and $\mathcal{C}^\perp$ are MMCD codes.

In Section 4, we will provide some explicit constructions of dually MMCD codes for general parameters.

To conclude the subsection, we observe that the equivalence of linear MMCD codes, dually MMCD codes and MDS codes by rows and by columns holds for very small parameters. For the case $\ell > 1$, we may extend column-wise and row-wise Hamming weights and metrics to $\prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$ in a straightforward way. However, we also need to consider different combinations of transpositions in different positions. To this end, given $C = (C_1, C_2, \ldots, C_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{n_i\times n_i}$ and $\mathbf{t} \in \{0,1\}^\ell$, we define $C^{\mathbf{t}} = (D_1, D_2, \ldots, D_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{n_i\times n_i}$, where

$$D_i = \begin{cases} C_i & \text{if } t_i = 0, \\ C_i^\intercal & \text{if } t_i = 1. \end{cases}$$

We then define $\mathcal{C}^{\mathbf{t}} = \{C^{\mathbf{t}} \mid C \in \mathcal{C}\} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{n_i\times n_i}$, for $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{n_i\times n_i}$. Notice that the bounds (3) still hold for $\ell > 1$ and any vector of transpositions $\mathbf{t} \in \{0,1\}^\ell$.

The proofs of the following two propositions are based on the fact that, in the two cases, we only need to consider covers in $\mathbb{F}_q^{m\times n}$ of sizes 1 or 2, and these can always be chosen as only columns or only rows in such cases.

Proposition 7. Let $\mathcal{C} \subseteq (\mathbb{F}_q^{n\times n})^\ell$ be a linear code with $\dim(\mathcal{C}) = n(\ell n - 1)$. Then $\mathcal{C}$ is MMCD if, and only if, $\mathcal{C}^{\mathbf{t}}$ is MDS by columns for all $\mathbf{t} \in \{0,1\}^\ell$.

Proposition 8. Let $\mathcal{C} \subseteq (\mathbb{F}_q^{2\times 2})^\ell$ be a linear code. The following are equivalent:

(1) $\mathcal{C}^{\mathbf{t}}$ is MDS by columns for all $\mathbf{t} \in \{0,1\}^\ell$.
(2) $\mathcal{C}$ is MMCD.
(3) $\mathcal{C}$ is dually MMCD.

Recall that the multi-cover metric in $(\mathbb{F}_q^{1\times 1})^\ell$ is simply the classical Hamming metric in $\mathbb{F}_q^\ell$, hence the previous proposition also holds but is trivial in this case.

4. DUALLY MMCD CODE CONSTRUCTIONS

4.1 MSRD codes

Similarly to the case of the rank metric and the cover metric (Roth, 1991), we show in this subsection that sum-rank metric codes may be used as multi-cover metric codes. The sum-rank metric was formally defined in (Nóbrega and Uchôa-Filho, 2010, Sec. III-D), but it was implicitly used earlier in (Lu and Kumar, 2005, Sec. III).

Definition 9. We define the sum-rank weight of $C = (C_1, C_2, \ldots, C_\ell) \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$ as

$$\mathrm{wt}_{SR}(C) = \sum_{i=1}^{\ell} \mathrm{Rk}(C_i).$$

The sum-rank metric is then defined by $\mathrm{d}_{SR}(C, D) = \mathrm{wt}_{SR}(C - D)$, for $C, D \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i\times n_i}$.

The bound in Theorem 1 is also valid for the sum-rank metric (Byrne et al., 2021, Th. III.2), and a code attaining it is called maximum sum-rank distance (MSRD).

We have the following connections between both metrics. They constitute a trivial extension to $\ell \geq 1$ of the corresponding results for the case $\ell = 1$, observed in (Roth, 1991). We note that Item 4 follows from combining Item 3 with the fact that the dual of a linear MSRD code is again

$$\varphi\left(C^1, C^2, \ldots, C^r\right) = \left(\begin{array}{cccc|cccc|c|cccc} C_1^1 & C_1^2 & \ldots & C_1^r & C_{r+1}^1 & C_{r+1}^2 & \ldots & C_{r+1}^r & \ldots & C_{(\ell-1)r+1}^1 & C_{(\ell-1)r+1}^2 & \cdots & C_{(\ell-1)r+1}^r \\ C_2^r & C_2^1 & \ldots & C_2^{r-1} & C_{r+2}^r & C_{r+2}^1 & \ldots & C_{r+2}^{r-1} & \ldots & C_{(\ell-1)r+2}^r & C_{(\ell-1)r+2}^1 & \cdots & C_{(\ell-1)r+2}^{r-1} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ C_r^2 & C_r^3 & \ldots & C_r^1 & C_{2r}^2 & C_{2r}^3 & \ldots & C_{2r}^1 & \ldots & C_t^2 & C_t^3 & \ldots & C_t^1 \end{array}\right).$$

MSRD code under the given conditions (Byrne et al., 2021, Th. VI.1).

Proposition 10. Fix $C \in \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$ and $\mathcal{C} \subseteq \prod_{i=1}^{\ell} \mathbb{F}_q^{m_i \times n_i}$. The following hold:

(1) $\mathrm{wt}_{SR}(C) \leq \mathrm{wt}_{MC}(C)$.
(2) $\mathrm{d}_{SR}(\mathcal{C}) \leq \mathrm{d}_{MC}(\mathcal{C})$.
(3) If $\mathcal{C}$ is an MSRD code, then it is also MMCD.
(4) If $\mathcal{C}$ is a linear MSRD code and $m_1 = m_2 = \ldots = m_\ell$, then $\mathcal{C}$ is a dually MMCD code.

4.2 A nested construction

In this subsection, we provide a general method to construct codes for the multi-cover metric from other multi-cover metric codes. For simplicity, we will only work with square matrices and tuples of matrices with the same number of rows and columns, i.e., $m_1 = \ldots = m_\ell = n_1 = \ldots = n_\ell$. Throughout this subsection, we fix positive integers $n = rs$ and $t = r\ell$.

Construction 1. Let $\mathcal{C} \subseteq (\mathbb{F}_q^{s\times s})^t$ be a code. We define another code $\varphi(\mathcal{C}) \subseteq (\mathbb{F}_q^{n\times n})^\ell$ as the image of the linear map $\varphi : ((\mathbb{F}_q^{s\times s})^t)^r \longrightarrow (\mathbb{F}_q^{n\times n})^\ell$, where $\varphi\left(C^1, C^2, \ldots, C^r\right)$ is described at the top of this page, for $C^i = (C_1^i, C_2^i, \ldots, C_t^i) \in (\mathbb{F}_q^{s\times s})^t$, for $i = 1, 2, \ldots, r$.

We now relate the multi-cover metric parameters of $\mathcal{C}$ and $\varphi(\mathcal{C})$. The proof is left to the reader.

Theorem 3. Let $\mathcal{C} \subseteq (\mathbb{F}_q^{s\times s})^t$. The following hold:

(1) $\mathrm{d}_{MC}(\varphi(\mathcal{C})) = \mathrm{d}_{MC}(\mathcal{C})$ and $|\varphi(\mathcal{C})| = |\mathcal{C}|^r$.
(2) $\varphi(\mathcal{C})$ is MMCD if, and only if, so is $\mathcal{C}$.
(3) $\varphi(\mathcal{C})$ is linear if, and only if, so is $\mathcal{C}$, and in that case, $\dim(\varphi(\mathcal{C})) = r\dim(\mathcal{C})$ and $\varphi(\mathcal{C})^\perp = \varphi(\mathcal{C}^\perp)$.
(4) (If $\mathcal{C}$ is linear) $\varphi(\mathcal{C})$ is a dually MMCD code if, and only if, so is $\mathcal{C}$.

In this way, we may construct codes in $(\mathbb{F}_q^{n\times n})^\ell$ for the multi-cover metric from codes in $(\mathbb{F}_q^{s\times s})^t$ for the refined multi-cover metric. Note that, if we set $s = 1$, then we may construct multi-cover metric codes in $(\mathbb{F}_q^{n\times n})^\ell$ from Hamming-metric codes in $\mathbb{F}_q^t$.

4.3 Explicit linear MMCD codes

In this subsection, we put together the two methods for constructing multi-cover metric codes from Subsections 4.1 and 4.2 in order to give an explicit family of MMCD codes. We consider linearized Reed-Solomon codes (Martínez-Peñas, 2018) as component codes in Construction 1, for several choices of the integer t.

Theorem 4. Let $n = rs$ and $t = r\ell$ be positive integers, such that $q > t$. Let $\mathcal{C} \subseteq (\mathbb{F}_q^{s\times s})^t$ be a linearized Reed-Solomon code (Martínez-Peñas, 2018, Def. 31). Then the code $\varphi(\mathcal{C}) \subseteq (\mathbb{F}_q^{n\times n})^\ell$ obtained from $\mathcal{C}$ as in Construction 1, is an MMCD code. Using an r-folded version of the decoder from (Martínez-Peñas and Kschischang, 2019), it may correct errors of multi-cover weight at most $\lfloor(\mathrm{d}_{MC}(\mathcal{C}) - 1)/2\rfloor$ with a complexity of $\mathcal{O}(t\ell n^2)$ sums and products over the finite field of size $q^{\ell n/t} = \mathcal{O}(t)^{\ell n/t}$.

Assume that a multiplication in $\mathbb{F}_{2^b}$ costs $\mathcal{O}(b^2)$ operations in $\mathbb{F}_2$. Then if q is even, the MMCD code in Theorem 4 can be decoded with a complexity of

$$\mathcal{O}\left(t^{-1}\log_2(t+1)^2\ell^3 n^4\right)$$

operations over $\mathbb{F}_2$. This complexity is smaller for larger values of t. However, the alphabet size for the multi-cover metric needs to satisfy $q > t$. Thus we arrive at an alphabet-complexity trade-off: Codes for larger t are faster to decode but require larger alphabets, whereas codes for smaller t are less fast but can be used for a wider range of alphabets.

Finally, observe that, if $\ell = 1$ (thus $1 \leq t = r \leq n$), then the codes in Theorem 4 attain the Singleton bound for the classical cover metric (Roth, 1991). The cases $t = r = 1$ and $t = r = n$ were obtained already in (Roth, 1991), but the cases $1 < t = r < n$ of such codes constitute a new family of codes attaining the Singleton bound for the classical cover metric. Their interest resides in the alphabet-complexity trade-off mentioned above.

Keywords: Data-driven model reduction, generalized balancing, error bounds

1. INTRODUCTION

Since recently, the problem of *data-driven* model reduction is attracting increasing attention, partly motivated by the widespread availability of measurement data. Here, low-order models are constructed directly on the basis of measurement data, thus not requiring the availability of a high-order model. Nevertheless, standard (model-based) model reduction techniques have inspired various data-driven techniques.

In the class of energy-based methods for linear systems, to which this paper belongs, data-driven model reduction contributions include Rapisarda and Trentelman (2011); Markovsky et al. (2005); Gosea et al. (2022). Meanwhile, in the class of interpolatory methods, the contributions include Beattie and Gugercin (2012); Peherstorfer et al. (2017); Scarciotti and Astolfi (2017); Burohman et al. (2020).

Despite these developments, existing methods for data-driven model reduction do often not allow for guaranteeing system properties such as asymptotic stability and do not provide an error bound, especially when the available data is subject to noise. In this extended abstract, we develop a data-driven reduction technique that provides such guarantees on the low-order model, even for noisy data.

This work has the following contributions. First, we introduce the concept of *data reduction* via a Petrov-Galerkin projection. Following the data informativity framework of van Waarde et al. (2020), a class of systems explaining the data can be characterized by a quadratic matrix matrix inequality (QMI). Then, we show that projection of all systems in this class results in a class of reduced-order models that can also be characterized by a QMI, but one of smaller dimension.

The second contribution of this paper is the development of a data-driven generalized balanced truncation method. Here, we first give necessary and sufficient conditions for all systems explaining the data to have a *common* generalized controllability and *common* generalized observability Gramians. In this case, we say that the data are *informative* for generalized Lyapunov balancing. Next, we comprise the use of the common generalized Gramians to obtain the Petrov-Galerkin projection that achieves (generalized) balanced truncation (see Dullerud and Paganini (2000). This allows for the application of the data reduction concept.

As inherent advantages of using a balancing-type reduction method, all reduced-order models are guaranteed to be asymptotically stable and satisfy an *a priori* error bound. However, the ordinary a priori upper bounds from model-based reduction methods, e.g., Antoulas (2005); Dullerud and Paganini (2000), do not determine the error between a selected reduced-order model to the true system generating the data as the true system is unknown. Therefore, as the final contribution, we compute a uniform a priori upper bound, i.e., an error bound that holds for any chosen high-order system explaining the data and any reduced-order model.

The proofs of the results presented in this abstract can be found in Burohman et al. (2021).

2. PRELIMINARIES

2.1 Model reduction via a Petrov-Galerkin projection

Consider the discrete-time input/state/output system

$$\Sigma : \quad \begin{aligned} \boldsymbol{x}(k+1) &= A\boldsymbol{x}(k) + B\boldsymbol{u}(k), \\ \boldsymbol{y}(k) &= C\boldsymbol{x}(k) + D\boldsymbol{u}(k), \end{aligned} \tag{1}$$

with input $\boldsymbol{u} \in \mathbb{R}^m$, state $\boldsymbol{x} \in \mathbb{R}^n$ and output $\boldsymbol{y} \in \mathbb{R}^p$. Let $\hat{W}, \hat{V} \in \mathbb{R}^{n\times r}$ be matrices such that $\hat{W}^\top \hat{V} = I$ and $r < n$. A reduced-order model (ROM) obtained via a Petrov-Galerkin projection is given by

$$\hat{\Sigma} : \quad \begin{aligned} \hat{\boldsymbol{x}}(k+1) &= \hat{W}^\top A\hat{V}\hat{\boldsymbol{x}}(k) + \hat{W}^\top B\boldsymbol{u}(k), \\ \hat{\boldsymbol{y}}(k) &= C\hat{V}\hat{\boldsymbol{x}}(k) + D\boldsymbol{u}(k) \end{aligned} \tag{2}$$

where $\hat{\boldsymbol{x}} \in \mathbb{R}^r$ and $\hat{\boldsymbol{y}} \in \mathbb{R}^p$ denote the state and output of the ROM, respectively.

2.2 Generalized Lyapunov balancing

Consider the discrete-time system (1). Then, matrices $P = P^\top > 0$ satisfying

$$APA^\top - P + BB^\top < 0$$

and $Q = Q^\top > 0$ satisfying

$$A^\top QA - Q + C^\top C < 0,$$

are called the *generalized controllability Gramian* and *generalized observability Gramian*, respectively. This is a strict version of the definition of generalized Gramians given in Dullerud and Paganini (2000). The generalized Gramians are lower bounded by the ordinary Gramians, i.e., $P > P_0$ and $Q > Q_0$, where Q_0 and P_0 are the solutions of the corresponding Lyapunov *equations*.

As ordinary Gramians, these generalized Gramians can be used to obtain a so-called balanced realization. Specifically, by e.g., (Antoulas, 2005, Lemma 7.3), there exists a nonsingular matrix T such that $TPT^\top = T^{-\top}QT^{-1} = \Sigma_H$ where Σ_H is a diagonal matrix of the *generalized* Hankel singular values (GHSVs) of Σ in (1), i.e.,

$$\Sigma_H := \mathrm{blkdiag}(\sigma_1 I_{m_1}, \sigma_2 I_{m_2}, \ldots, \sigma_\kappa I_{m_\kappa}), \tag{3}$$

where $\sigma_1 > \sigma_2 > \cdots > \sigma_\kappa > 0$, and m_i denotes the multiplicity of σ_i for $i = 1, \ldots, \kappa$ satisfying $n = \sum_{i=1}^{\kappa} m_i$. In particular, the balanced realization is given by $A_{\mathrm{bal}} := TAT^{-1}$, $B_{\mathrm{bal}} := TB$, $C_{\mathrm{bal}} := CT^{-1}$, $D_{\mathrm{bal}} := D$. Moreover, similar to the standard balanced truncation, the corresponding model reduction error is twice the sum of the neglected GHSVs.

3. DATA-DRIVEN PETROV-GALERKIN PROJECTION

Consider the linear discrete-time input/state/output system

$$\Sigma_{\mathrm{true}}: \quad \begin{aligned} \boldsymbol{x}(k+1) &= A_{\mathrm{true}}\boldsymbol{x}(k) + B_{\mathrm{true}}\boldsymbol{u}(k) + \boldsymbol{w}(k), \\ \boldsymbol{y}(k) &= C_{\mathrm{true}}\boldsymbol{x}(k) + D_{\mathrm{true}}\boldsymbol{u}(k) + \boldsymbol{z}(k), \end{aligned} \tag{4}$$

where $(\boldsymbol{u}, \boldsymbol{x}, \boldsymbol{y}) \in \mathbb{R}^{m+n+p}$ are the input/state/output and $(\boldsymbol{w}, \boldsymbol{z}) \in \mathbb{R}^{n+p}$ are noise terms. Throughout the paper, we assume that the system matrices $(A_{\mathrm{true}}, B_{\mathrm{true}}, C_{\mathrm{true}}, D_{\mathrm{true}})$ and the noise $(\boldsymbol{w}, \boldsymbol{z})$ are *unknown*. What is known instead are a finite number of input/state/output measurements harvested from the true system (4) collected in the matrices

$$\begin{aligned} X_- &:= [x(0)\ x(1)\ \cdots\ x(L-1)], \\ X_+ &:= [x(1)\ x(2)\ \cdots\ x(L)], \\ U_- &:= [u(0)\ u(1)\ \cdots\ u(L-1)], \\ Y_- &:= [y(0)\ y(1)\ \cdots\ y(L-1)]. \end{aligned}$$

Now, we can define the set of all systems that *explain* the data as

$$\boldsymbol{\Sigma} := \left\{ (A, B, C, D) : \begin{bmatrix} X_+ \\ Y_- \end{bmatrix} - \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} X_- \\ U_- \end{bmatrix} \in \mathcal{N} \right\},$$

where $\mathcal{N} \subseteq \mathbb{R}^{(n+p)\times L}$ captures a *noise model* such that

$$(A_{\mathrm{true}}, B_{\mathrm{true}}, C_{\mathrm{true}}, D_{\mathrm{true}}) \in \boldsymbol{\Sigma}. \tag{5}$$

In this paper, we work with a noise model that is described by a quadratic matrix inequality as

$$\mathcal{N} := \left\{ Z \in \mathbb{R}^{(n+p)\times L} : \begin{bmatrix} I \\ Z^\top \end{bmatrix}^\top \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{12}^\top & \Phi_{22} \end{bmatrix} \begin{bmatrix} I \\ Z^\top \end{bmatrix} \succcurlyeq 0 \right\}, \tag{6}$$

where $\Phi_{11} = \Phi_{11}^\top \in \mathbb{R}^{(n+p)\times(n+p)}$, $\Phi_{12} \in \mathbb{R}^{(n+p)\times L}$, and $\Phi_{22} = \Phi_{22}^\top \in \mathbb{R}^{L\times L}$.

We make the following blanket assumption on the set $\mathcal{N}$.

Assumption 1. The set $\mathcal{N}$ is bounded and has nonempty interior.

As shown in van Waarde et al. (2022b), Assumption 1 holds if and only if $\Phi_{11} - \Phi_{12}\Phi_{22}^{-1}\Phi_{12}^\top > 0$ and $\Phi_{22} < 0$. It is clear from the definition of $\boldsymbol{\Sigma}$ and (6) that $(A, B, C, D) \in \boldsymbol{\Sigma}$ if and only if the following quadratic matrix inequality (QMI) is satisfied

$$\begin{bmatrix} I & 0 \\ 0 & I \\ A^\top & C^\top \\ B^\top & D^\top \end{bmatrix}^\top N \begin{bmatrix} I & 0 \\ 0 & I \\ A^\top & C^\top \\ B^\top & D^\top \end{bmatrix} \succcurlyeq 0, \tag{7}$$

where

$$N := \begin{bmatrix} I & 0 & X_+ \\ 0 & I & Y_- \\ 0 & 0 & -X_- \\ 0 & 0 & -U_- \end{bmatrix} \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{12}^\top & \Phi_{22} \end{bmatrix} \begin{bmatrix} I & 0 & X_+ \\ 0 & I & Y_- \\ 0 & 0 & -X_- \\ 0 & 0 & -U_- \end{bmatrix}^\top. \tag{8}$$

As a first step, we consider a Petrov-Galerkin projection and assuming that the projection matrices $\hat{W}$ and $\hat{V}$ satisfying $\hat{W}^\top\hat{V} = I$ are given. Then, the set of reduced-order models of systems explaining the data is defined as

$$\boldsymbol{\Sigma}_{\hat{V},\hat{W}} := \left\{ (\hat{W}^\top A\hat{V}, \hat{W}^\top B, C\hat{V}, D) : (A, B, C, D) \in \boldsymbol{\Sigma} \right\}.$$

The first main result of this paper is that the set $\boldsymbol{\Sigma}_{\hat{V},\hat{W}}$ can itself be represented as a QMI of a similar form as (7).

Theorem 1. Consider the set $\boldsymbol{\Sigma}$ of systems explaining the data. Suppose that there exists $\bar{S}$ such that

$$\begin{bmatrix} I \\ \bar{S} \end{bmatrix}^\top N \begin{bmatrix} I \\ \bar{S} \end{bmatrix} > 0 \tag{9}$$

holds and the matrix $\begin{bmatrix} X_- \\ U_- \end{bmatrix}$ has full row rank. Let $\hat{W}, \hat{V} \in \mathbb{R}^{n\times r}$ be such that $\hat{W}^\top\hat{V} = I$. Then, the set $\boldsymbol{\Sigma}_{\hat{V},\hat{W}}$ of reduced-order models of $\boldsymbol{\Sigma}$ using projection matrices $\hat{W}, \hat{V}$ satisfies

$$\boldsymbol{\Sigma}_{\hat{V},\hat{W}} = \left\{ (\hat{A}, \hat{B}, \hat{C}, \hat{D}) : \begin{bmatrix} I & 0 \\ 0 & I \\ \hat{A}^\top & \hat{C}^\top \\ \hat{B}^\top & \hat{D}^\top \end{bmatrix}^\top N_{V,W} \begin{bmatrix} I & 0 \\ 0 & I \\ \hat{A}^\top & \hat{C}^\top \\ \hat{B}^\top & \hat{D}^\top \end{bmatrix} \succcurlyeq 0 \right\},$$

where $N_{V,W}$ is given by (10) with $W := \mathrm{blkdiag}(\hat{W}, I_p)$ and $V := \mathrm{blkdiag}(\hat{V}, I_m)$.

Theorem 1 has a nice interpretation in terms of *data reduction*. Namely, the matrix $N_{V,W}$ characterizing all

$$N_{V,W} := \left[\begin{array}{c|c} W^\top(N|N_{22} + N_{12}N_{22}^{-1}V(V^\top N_{22}^{-1}V)^{-1}V^\top N_{22}^{-1}N_{12}^\top)W & W^\top N_{12}N_{22}^{-1}V(V^\top N_{22}^{-1}V)^{-1} \\ \hline (V^\top N_{22}^{-1}V)^{-1}V^\top N_{22}^{-1}N_{12}^\top W & (V^\top N_{22}^{-1}V)^{-1} \end{array}\right] \tag{10}$$

reduced-order models depends only on the projection matrices $\hat{V}, \hat{W}$ and the original data matrix N. As such, $N_{V,W}$ is constructed from the data and noise model only. Importantly, $N_{V,W}$ has a lower dimension than N and can thus be regarded as a reduced data matrix.

4. DATA-DRIVEN GENERALIZED BALANCED TRUNCATION

4.1 Data informativity for generalized Lyapunov balancing

Based on Section 2.2, one can introduce the following notion of informativity.

Definition 1. We say that the data (U_-, X, Y_-) are *informative for generalized Lyapunov balancing (GLB)* if there exist $P = P^\top > 0$ and $Q = Q^\top > 0$ such that

$$APA^\top - P + BB^\top < 0 \tag{11}$$

and

$$A^\top QA - Q + C^\top C < 0 \tag{12}$$

for all $(A, B, C, D) \in \mathbf{\Sigma}$.

From Definition 1, P and Q can be regarded as *common* generalized controllability and observability Gramian, respectively, for all systems explaining the data. We thus formalize the following problems.

Problem 1. Find necessary and sufficient conditions under which the data (U_-, X, Y_-) are informative for GLB. If the data are informative, then characterize the reduced-order models via data-driven balanced truncation and provide error bounds with respect to the true system.

Observe that the data are informative for GLB if and only if QMI (7) implies the existence of positive definite matrices P and Q such that (11) and (12) hold. Such QMI implications can be viewed as a generalization of the classical S-lemma (Yakubovich (1977)) and have been investigated in van Waarde et al. (2022a). Based on the results of van Waarde et al. (2022a) and van Waarde et al. (2022b), data informativity for GLB can be fully characterized in terms of feasibility of certain LMIs as stated next.

Theorem 2. Suppose that there exists $\bar{S}$ such that (9) holds. Define

$$N_{\mathcal{C}} := \begin{bmatrix} I_n & 0 \\ 0 & 0 \\ 0 & I_{n+m} \end{bmatrix}^\top N \begin{bmatrix} I_n & 0 \\ 0 & 0 \\ 0 & I_{n+m} \end{bmatrix}$$

and

$$N_{\mathcal{O}} := \begin{bmatrix} I_n & 0 \\ 0 & 0 \\ 0 & I_{n+p} \end{bmatrix}^\top N^\sharp \begin{bmatrix} I_n & 0 \\ 0 & 0 \\ 0 & I_{n+p} \end{bmatrix},$$

where

$$N^\sharp := \begin{bmatrix} 0 & -I_{n+m} \\ I_{n+p} & 0 \end{bmatrix} N^{-1} \begin{bmatrix} 0 & -I_{n+p} \\ I_{n+m} & 0 \end{bmatrix}.$$

Then, the data (U_-, X, Y_-) are informative for generalized Lyapunov balancing if and only if

(i) $\begin{bmatrix} X_- \\ U_- \end{bmatrix}$ has full row rank,

(ii) there exists $P = P^\top > 0$ and a scalar $\alpha > 0$ such that

$$\begin{bmatrix} P & 0 & 0 \\ 0 & -P & 0 \\ 0 & 0 & -I_m \end{bmatrix} - \alpha N_{\mathcal{C}} > 0, \tag{13}$$

(iii) there exists $Q = Q^\top > 0$ and a scalar $\beta > 0$ such that

$$\begin{bmatrix} Q & 0 & 0 \\ 0 & -Q & 0 \\ 0 & 0 & -I_p \end{bmatrix} - \beta N_{\mathcal{O}} > 0. \tag{14}$$

As a consequence, all systems in $\mathbf{\Sigma}$ are balanced by a common balancing transformation matrix T satisfying $TPT^\top = T^{-\top}QT^{-1} = \Sigma_H$ where Σ_H is a matrix of the form (3), containing the common GHSVs.

4.2 Reduced-order models

By applying the Petrov-Galerkin projection, the reduced-order models of all systems in $\mathbf{\Sigma}$ via generalized balanced truncation are contained in the set

$$\hat{\mathbf{\Sigma}} := \left\{ (\hat{W}^\top A\hat{V}, \hat{W}^\top B, C\hat{V}, D) : (A, B, C, D) \in \mathbf{\Sigma} \right\}$$

where $\hat{V} = T^{-1}\Pi$ and $\hat{W} = T^\top\Pi$ with Π given by $\Pi := \begin{bmatrix} I_r \\ 0 \end{bmatrix}$ and T is the common balancing transformation matrix.

Based on Theorem 1, we can characterize the set $\hat{\mathbf{\Sigma}}$ in terms of a quadratic matrix inequality.

Corollary 2. Suppose that there exists $\bar{S}$ such that (9) holds and the data (U_-, X, Y_-) are informative for generalized Lyapunov balancing with T the corresponding balancing transformation. Then,

$$\hat{\mathbf{\Sigma}} = \left\{ (\hat{A}, \hat{B}, \hat{C}, \hat{D}) : \begin{bmatrix} I & 0 \\ 0 & I \\ \hat{A}^\top & \hat{C}^\top \\ \hat{B}^\top & \hat{D}^\top \end{bmatrix}^\top N_{V,W} \begin{bmatrix} I & 0 \\ 0 & I \\ \hat{A}^\top & \hat{C}^\top \\ \hat{B}^\top & \hat{D}^\top \end{bmatrix} \geqslant 0 \right\},$$

where $N_{V,W}$ is given by (10) with $W = \text{blkdiag}(T^\top\Pi, I_p)$ and $V = \text{blkdiag}(T^{-1}\Pi, I_m)$.

Now, we can see that the set $\hat{\mathbf{\Sigma}}$ characterizes a *data reduction* by generalized balanced truncation. Namely, the reduced matrix $N_{V,W}$ depends only on the data matrix N and projection matrices $\hat{V} = T^{-1}\Pi$ and $\hat{W} = T^\top\Pi$, where now these projection matrices are also derived from the data only via Theorem 2.

From the definition of $\hat{\mathbf{\Sigma}}$ above, suppose that $(\hat{A}, \hat{B}, \hat{C}, \hat{D}) \in \hat{\mathbf{\Sigma}}$, then it is always a truncation of a model in $\mathbf{\Sigma}$. Therefore they satisfy

$$\|\Sigma - \hat{\Sigma}\|_{\mathcal{H}_\infty} \leqslant 2 \sum_{i=\ell+1}^{\kappa} \sigma_i \tag{15}$$

$$\left[\begin{array}{c|c} \text{blkdiag}(K_{11}, (\frac{1}{2} - \mu)I_p, -K_{11}, -\gamma^{-2}I_m) & \text{blkdiag}(K_{12}, -\mu I_p, -K_{12}, -\gamma^{-2}I_m) \\ \hline \text{blkdiag}(K_{12}^\top, -\mu I_p, -K_{12}^\top, -\gamma^{-2}I_m) & \text{blkdiag}(K_{22}, (\frac{1}{2} - \mu)I_p, -K_{22}, -\gamma^{-2}I_m) \end{array}\right] - \text{blkdiag}(\delta N, \eta N_{V,W}) > 0 \tag{16}$$

where Σ and $\hat{\Sigma}$ are systems whose realizations are in $\mathbf{\Sigma}$ and $\hat{\mathbf{\Sigma}}$, respectively, and σ_is are the neglected GHSVs. However, the bound (15) has little practical relevance as it characterizes the error between *one* reduced-order system in $\hat{\mathbf{\Sigma}}$ and its *corresponding* high-order system in $\mathbf{\Sigma}$.

Instead, recall that we are interested in a reduced-order approximation of the true system (4). This system is unknown, but is guaranteed to satisfy (5). As also the corresponding reduced-order system is unknown (but in $\hat{\mathbf{\Sigma}}$), a practical relevant error bound should hold for *any* selection of a high-order system (from $\mathbf{\Sigma}$) and *any* reduced-order system (from $\hat{\mathbf{\Sigma}}$).

4.3 Distance to the true system

Suppose that we consider a reduced-order system $\hat{\Sigma}_0$ of order $r < n$ with its realization $(\hat{A}_0, \hat{B}_0, \hat{C}_0, \hat{D}_0) \in \hat{\mathbf{\Sigma}}$. We will use $\hat{\Sigma}_0$ as an approximation of the true system Σ_{true}. To evaluate the quality of this approximation, note that

$$\|\hat{\Sigma}_0 - \Sigma_{\text{true}}\|_{\mathcal{H}_\infty} \leqslant \sup\left\{\|\hat{\Sigma} - \Sigma\|_{\mathcal{H}_\infty} : \Sigma \in \mathbf{\Sigma}, \hat{\Sigma} \in \hat{\mathbf{\Sigma}}\right\}. \quad (17)$$

Here, we have used the small abuse of notation $\Sigma \in \mathbf{\Sigma}$ to mean $(A, B, C, D) \in \mathbf{\Sigma}$, where (A, B, C, D) is a realization of Σ.

The computation of the bound on the right-hand side of (17) is stated in the following result.

Theorem 3. The bound $\|\hat{\Sigma} - \Sigma\|_{\mathcal{H}_\infty} < \gamma$ holds for any $\Sigma \in \mathbf{\Sigma}$ and any $\hat{\Sigma} \in \hat{\mathbf{\Sigma}}$ if and only if there exist a matrix $K = K^\top > 0$ in $\mathbb{R}^{(n+r)\times(n+r)}$ partitioned as

$$K = \begin{bmatrix} K_{11} & K_{12} \\ K_{12}^\top & K_{22} \end{bmatrix}, \text{ with } K_{11} \in \mathbb{R}^{n\times n},$$

and scalars $\delta > 0$, $\eta > 0$ and μ such that (16) holds, where N and $N_{V,W}$ are given by (8) and (10), respectively.

In order to obtain the smallest upper bound, i.e., the smallest γ such that the conditions in Theorem 3 hold, one may solve (16) by minimizing γ using semidefinite programming (Nesterov and Nemirovskii, 1994, Sect. 6.4). It gives $\|\hat{\Sigma}_0 - \Sigma_{\text{true}}\| < \gamma$. Note that this upper bound is uniform for any $\hat{\Sigma}_0$ picked from $\hat{\mathbf{\Sigma}}$. Therefore, it can be regarded as an *a priori* error bound.

5. CONCLUSION

In this abstract, a data-driven procedure to obtain reduced-order models from noisy data is developed. The procedure begins with introducing the concept of data reduction. We then follow up the data reduction concept by constructing specific projection matrices from data. In particular, we provide necessary and sufficient conditions such that all systems explaining the data have common generalized Gramians. Subsequently, a common balancing transformation and therefore common projection matrices for generalized balanced truncation are available to apply the data reduction. As such, a set of reduced-order models via generalized balanced truncation can then be characterized in terms of a lower-dimensional QMI. Moreover, all reduced-order models in this set are guaranteed to be asymptotically stable and computable a priori upper bound on the reduction error with respect to the true system are available.

Some extensions of this work include exploiting data reduction via other projection-based reduction methods and using this approach by input-output data only. Moreover, investigating model reduction with preserving specific system properties such as network structure and port-Hamiltonian structure is often desirable.

Braess' paradox for power flow feasibility in DC power grids with constant-power loads ⋆,⋆⋆

Mark Jeeninga *

* *DISMA, Politecnico di Torino, Torino, Italy (e-mail: mark.jeeninga@polito.it)*

Abstract: This paper studies the power flow feasibility of DC power grids with constant-power loads. We introduce and motivate the concept of Braess' paradox for power flow feasibility, and show that this phenomenon can occur in most practical power grids with at least two source nodes.

Keywords: Power systems stability, Optimal operation and control of power systems, Smart grids

1. INTRODUCTION

Braess' paradox is a phenomenon in traffic flow networks, first observed in Braess (1968), described by the counterintuitive observation that adding a road (or improving the capacity of a road) does not necessarily improve the traffic flow. This phenomenon is a prevalent property of such networks (Steinberg and Zangwill (1983)). Similar observations for power grids are known. The papers Cohen and Horowitz (1991); Nagurney and Nagurney (2016) report several physical examples of two-port DC circuits for which the current flow exhibits behavior analogous to Braess' paradox in traffic flow networks. In these papers it is shown that the addition of a line can lead to an increase of the current flows in all lines, which goes against the intuition that adding a line allows for improved flow in the network, and is referred to as Braess' paradox. These phenomena have also been studied in Baillieul et al. (2015); Wang and Baillieul (2016), which considers the effects of adding a line (or an increase of the conductance of a line) in DC circuits with voltage-controlled or current-controlled nodes.

In this paper we study the power flow of DC power grids with fixed voltage sources and constant-power loads. Such loads may appear in practical power grids, and are known to destabilize the power grid due to their negative impedance characteristic (Emadi et al. (2006)). In these power grids it may occur that the sources cannot satisfy the power demands of the loads, in which case we say that the power flow is unfeasible. The feasibility of the power flow is important for their long-term operation, since sustained unfeasible power flow may lead to unintended behavior system such as voltage oscillations, voltage collapse, and blackouts (Kundur et al. (1994); Van Cutsem and Vournas (2008)). This feasibility problem is a classical problem in the literature (Tinney and Hart (1967); Hill and Mareels (1990); Löf et al. (1993)) and has gained more attention over the past decade (Bolognani and Zampieri (2015); Barabanov et al. (2016); Simpson-Porco et al. (2016); Matveev et al. (2020)). A full characterization of this feasibility problem has been presented in Jeeninga et al. (2020a,b).

The aim of the present paper is to study how the feasibility of the power flow in these systems is affected by changes in the line conductances. This study is primarily motivated by Witthaut and Timme (2012), where it was observed that increasing the conductance of a line in an AC power grid leads to voltage oscillations, which can be attributed to unfeasibility of the power flow after this increase. The contributions of the present paper are of a theoretical nature, and show that an analogue of Braess' paradox can also occur in DC power grids with constant-power loads, and that this may occur for most practical power grids with multiple sources.

The structure of this paper is as follows. In Section 2 we state the model for DC power grids with constant-power loads at steady state. In Section 3 we formulate the Braess' paradox of power flow feasibility, and show that Braess' paradox can occur in most practical power grids. Section 4 concludes the paper.

Notation

For a vector $x = (x_1 \ \cdots \ x_k)^\top$ we denote

$$[x] := \operatorname{diag}(x_1, \ldots, x_k).$$

We let $\mathbb{1}$ and $\mathbb{0}$ denote the all-ones and all-zeros vector, respectively, and let I denote the identity matrix. We let their dimensions follow from their context. We let e_i denote the i-th column of I. All vector and matrix inequalities are taken to be element-wise.

2. THE POWER GRID MODEL

Throughout this paper we study DC power grids at steady-state, and model such systems by a resistive circuit. We model a power grid consisting of n load nodes and m source nodes as follows. If distinct nodes i and j are connected by a line, we let $G_{ij} = G_{ji} > 0$ denote the conductance of this line. If the nodes are not connected by a line we put $G_{ij} = G_{ji} = 0$. The Kirchhoff matrix $Y \in \mathbb{R}^{(n+m)\times(n+m)}$ associated to the lines in the grid is defined by

$$Y_{ij} := \begin{cases} \sum_k G_{ki} & \text{if } i = j \\ -G_{ij} & \text{if } i \neq j \end{cases}. \tag{1}$$

The voltage potentials and injected currents at the loads are collected in the vectors $V \in \mathbb{R}^{n+m}$ and $\mathcal{I} \in \mathbb{R}^{n+m}$, respectively. The quantities V, $\mathcal{I}$ and Y are partioned as

$$V = \begin{pmatrix} V_L \\ V_S \end{pmatrix}; \quad \mathcal{I} = \begin{pmatrix} \mathcal{I}_L \\ \mathcal{I}_S \end{pmatrix}; \quad Y = \begin{pmatrix} Y_{LL} & Y_{LS} \\ Y_{SL} & Y_{SS} \end{pmatrix},$$

according to whether nodes are loads (L) or sources (S). We assume that the nodes in the power grid are connected, which means that $\mathbb{1}$ spans the kernel of Y, and that the principal submatrices Y_{LL} and Y_{SS} are positive definite. Due to Kirchhoff's and Ohm's laws we have $\mathcal{I} = YV$. We define the open-circuit voltages $V_L^* > \mathbb{0}$ to be the unique vector of voltage potentials at the loads such that $\mathcal{I}_L = \mathbb{0}$, which satisfies

$$V_L^* := -{Y_{LL}}^{-1} Y_{LS} V_S \tag{2}$$

(*e.g.*, see Van der Schaft (2010)). The power injected at the nodes is given by $P = [V]\mathcal{I}$. Since $\mathcal{I} = YV$ and due to (2) we have

$$P_L = [V_L](Y_{LL}V_L + Y_{LS}V_S) = [V_L]Y_{LL}(V_L - V_L^*) \tag{3a}$$
$$P_S = [V_S](Y_{SS}V_S + Y_{SL}V_L). \tag{3b}$$

The total power injected at the nodes is given by $\mathbb{1}^\top P = V^\top \mathcal{I}$.

We assume that all loads demand a constant power. Since we study the power grid at steady state, this is to say that we want to choose V_L such that all power demands are satisfied. The constant power demands are collected in the vector $P_\mathrm{c} \in \mathbb{R}^n$. The question if such a V_L exists for a given P_c gives rise to the DC power flow feasibility problem:

Definition 2.1. Given a power grid with Kirchhoff matrix Y, source voltages $V_S > \mathbb{0}$ and constant power demands P_c, we say that the power flow (of the power grid) is *feasible* if there exists a vector $V_L > \mathbb{0}$ of load voltages such that

$$P_\mathrm{c} = -P_L = [V_L]Y_{LL}(V_L^* - V_L).$$

Put differently, feasibility of a power grid means that the constant power demands at the loads can be satisfied at steady state. It is noted from (3a) that if Y_{LL} is reducible (or equivalently, block-diagonal), then power flow feasibility can be analyzed for each reducible component separately. Hence without loss of generality we assume that Y_{LL} is irreducible, which is equivalent to saying that the subgraph induced by the load nodes is connected.

The scalar $-\mathbb{1}^\top P_L$ represents the total amount of power that is drained by the loads. Intuitively, the total amount of power that can be drained by the loads is bounded from above. Recall that the power flow is feasible if we have that $P_\mathrm{c} = -P_L$. Hence this means that also $\mathbb{1}^\top P_\mathrm{c}$, the total power demand of the load nodes, is bounded from above whenever the power flow is feasible. The *maximizing power demand*, given by

$$P_\mathrm{max} := -\tfrac{1}{4}[V_L^*]Y_{LS}V_S, \tag{4}$$

is the unique vector of constant power demands for which the power flow is feasible and the total power demand is maximized:

Proposition 2.2. ((Jeeninga et al., 2020a, Lem. 2.17)). Consider a power grid with Y and $V_S > \mathbb{0}$ given. If $P_\mathrm{c} \in \mathbb{R}^n$ is a vector of power demands such that the power flow is feasible, then

$$\mathbb{1}^\top P_\mathrm{c} \leq \mathbb{1}^\top P_\mathrm{max}, \tag{5}$$

with equality if and only if $P_\mathrm{c} = P_\mathrm{max}$. Put differently, the quantity $\mathbb{1}^\top P_\mathrm{max}$ is the maximal total power demand that can be satisfied by the power grid. The unique voltage potentials corresponding to P_max are $V_L = \frac{1}{2}V_L^*$.

Note that (5) is a necessary condition for power flow feasibility.

3. BRAESS' PARADOX IN DC POWER GRIDS WITH CONSTANT-POWER LOADS

The classical formulation of Braess' paradox from Braess (1968); Cohen and Horowitz (1991); Nagurney and Nagurney (2016) is that, after increasing line conductances or adding a line in a DC circuit, the quality of the current flow in the power grid becomes measurably worse. In this paper however we follow a stronger formulation of Braess' paradox, inspired by Witthaut and Timme (2012), by studying how adding lines or increasing conductances can destabilize the power grid, and in particular, lose power flow feasibility. We formalize this as follows:

Definition 3.1. Braess' paradox for power flow feasibility is the phenomenon that adding a line or increasing a line conductance in a power grid destroys the feasibility of the power flow and destabilizes the power grid. We say that Braess' paradox for power flow feasibility can occur in a power grid if there exists a vector of power demands P_c such that the power flow is feasible and becomes unfeasible after increasing a line conductance or adding a line.

In the remainder of this paper we refer to Definition 3.1 simply as the Braess' paradox, for the sake of brevity.

3.1 A sufficient condition for the occurrence Braess' paradox

In this section we show how Braess' paradox may occur by studying the maximal total power demand $\mathbb{1}^\top P_\mathrm{max}$. It can be shown that an increase of a line conductance can make the maximal total power demand $\mathbb{1}^\top P_\mathrm{max}$ decrease. This means that the power flow in a power grid can become unfeasible after such an increase, in particular when the total power demand $\mathbb{1}^\top P_\mathrm{c}$ is close to its maximum $\mathbb{1}^\top P_\mathrm{max}$, such as when $P_\mathrm{c} = P_\mathrm{max}$. Hence, following Definition 3.1, we have that Braess' paradox occurs. We formalize this in the following theorem, which presents a sufficient condition for the existence of a pair of loads for which Braess' paradox occurs when the line between them is altered (or added).

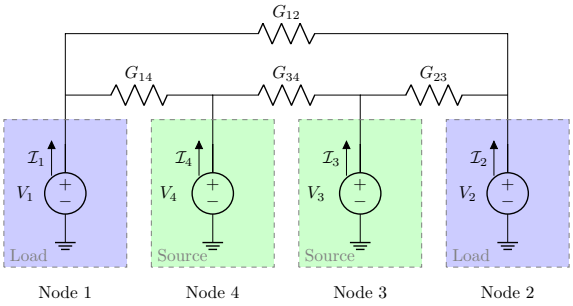

Fig. 1. A schematic depiction of a DC power grid with two loads and two sources ($n = 2$, $m = 2$) for which Braess' paradox can occur.

Theorem 3.2. Consider a power grid with Kirchhoff matrix Y, source voltages $V_S > \mathbb{0}$ and at least two loads and at least two sources. Let P_c be a vector of constant power demands such that the power flow is feasible. If there exist (distinct) load nodes i and j such that the open-circuit voltages (2) satisfy $(V_L^*)_i \neq (V_L^*)_j$, and if P_c satisfies

$$\mathbb{1}^\top P_c > \mathbb{1}^\top P_{\max} - \frac{(\frac{1}{2}(V_L^*)_i - \frac{1}{2}(V_L^*)_j)^2}{(e_i - e_j)^\top {Y_{LL}}^{-1}(e_i - e_j)}, \qquad (6)$$

then there exists a scalar $c > 0$ such that the power flow becomes unfeasible after increasing G_{ij} by c, either through increasing the conductance of the line between loads i and j, or adding a new line between loads i to j. In particular, if we consider $P_c = P_{\max}$, then the power flow becomes unfeasible for any increase of G_{ij}.

Theorem 3.2 tells us that if the open-circuit voltages are not all equal (*i.e.*, $V_L^* \notin \text{span}\{\mathbb{1}\}$), then Braess' paradox can occur when the power demands are close to the maximizing power demands $P_{\max}$. We illustrate this by the following example.

Example 3.3. Consider the power grid with two loads and two sources, as depicted in Figure 1, where $V_S = (1\ 3)^\top$, $G_{12} = 0.3$, $G_{14} = 1$, $G_{23} = 5$ and $G_{34} = 1$. The corresponding open-circuit voltages are $V_L^* = \frac{1}{6.8}(17.4\ 7.4)^\top$, and are not a multiple of $\mathbb{1}$. The blue area in Figure 2 depicts the set of all vectors P_c such that the power flow is feasible. Since $(V_L^*)_1 \neq (V_L^*)_2$, Theorem 3.2 states that we will observe Braess' paradox if we increase the line between load 1 and load 2. We increase the conductance of this line by 0.7. This results in the green area in Figure 2 corresponding to the set $\widehat{F}$ of P_c such that the power flow is feasible. It is observed that the blue area is not contained in the green area. Hence there are vectors of power demands for which the power flow has become unfeasible after increasing the conductance of the line. In particular we see that $P_{\max}$ is no longer feasible after the conductance is increased.

It should be noted that whenever only one source node is present, then all open-circuit voltages are equal and Theorem 3.2 cannot be applied. This is for example the case in distribution grids where all loads are constant-power loads, where the slack bus acts as the only source node in the grid.

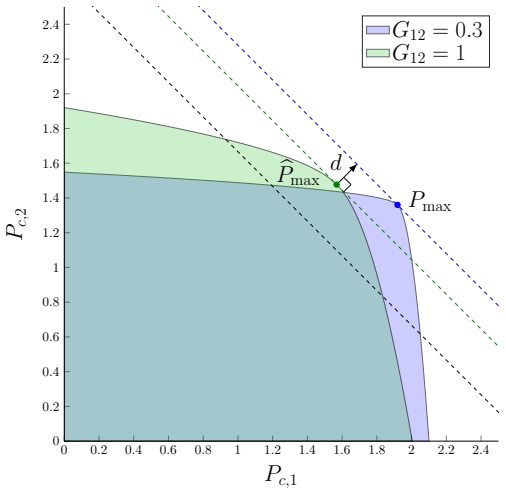

Fig. 2. Plots for the sets of constant power demands P_c for which the power flow of the power grid in Example 3.3 is feasible. Throughout this paper the plots of such sets have been obtained through the parametrization of the feasibility boundary presented in Jeeninga et al. (2020b). The blue and green regions correspond to respectively $G_{12} = 0.3$ and $G_{12} = 1$. This corresponds to increasing the conductance G_{12} of the line between node 1 and node 2 by 0.7 (see Figure 1). The blue and green dashed lines are the points for which equality holds in (5) for the respective power grids. The decrease of the maximal total power demand is indicated by d. We observe that $P_{\max}$ is no longer feasible after the conductance is increased. The black dashed line corresponds the points for which equality in (6) holds. Theorem 3.2 shows that Braess' paradox may occur for all feasible vectors of constant power demands beyond the black dashed line, such as for $P_{\max}$.

3.2 Prevalence of Braess' paradox for power flow feasibility

In Steinberg and Zangwill (1983) it was shown that Braess' paradox is a widespread phenomenon which can occur in most traffic flow networks. Similarly, Coletta and Jacquod (2016) showed that Braess' paradox may occur in any coupled-oscillator network such as AC power grids. In this section we validate that Braess' paradox is also common for DC power flow feasibility, and can occur in most practical DC power grids with constant-power loads, regardless of the grid topology.

It can be shown that the condition on the open-circuit voltages V_L^* may be restated in terms of the source voltages

Theorem 3.4. Consider a power grid with Y and $V_S > \mathbb{0}$ given and with at least two load nodes and at least two sources. If Y_{LS} has full column rank and the source voltages are not all equal (*i.e.*, $V_S \notin \text{span}\{\mathbb{1}\}$), then there exist a vector of power demands P_c and a line between two load nodes such that the power flow is feasible and becomes unfeasible after increasing the line conductance.

Theorem 3.4 shows that Braess' paradox may occur if Y_{LS} has full column rank and not all source voltages are equal. Apart from the condition on Y_{LS}, this statement does

not depend on the topology of the grid. Hence, Braess' paradox may occur in both radial (tree) and meshed grid topologies.

The condition that Y_{LS} has full column rank can be interpreted as the property that there are no redundant voltage sources, in the sense that the removal of one source cannot be compensated by other sources. A study on benchmark power grids was performed to illustrate that the condition that Y_{LS} has full-rank is prevalent in practical power grids. The results of this study are omitted for spatial considerations, but are available in the full version of the article.

For all power grids with a single source node we have that Y_{LS} has full column rank. This shows that the premises of Theorem 3.2 and Theorem 3.4 do not hold for power grids with a single source. However, since practical power grids commonly have multiple sources [1], and all source voltages are not likely to be the same, we conclude that Braess' paradox for power flow feasibility may occur in most practical DC power grids.

4. CONCLUSION AND DISCUSSION

In this paper we have shown that an analogue of Braess' paradox may occur in the power flow feasibility of a DC power grid. The observed phenomenon states that an increase of a line conductance has the potential to destroy the feasibility of the power flow in a power grid. We have shown that this phenomenon may occur in most practical power grids with multiple sources.

An interesting further direction of research is studying if Braess' paradox for power flow feasibility could also occur in the case where there is only one source node. Moreover, the full article of this abstract also studies what the implications are for the occurrence of Braess' paradox when only bounds of the line conductances are known. A sufficient condition is presented in that article, but the search for a necessary and sufficient condition is still open.

ACKNOWLEDGMENT

The author would like to thank Claudio De Persis and Arjan van der Schaft for their valuable suggestions and discussions.

Guaranteeing a minimum distance to infeasibility in DC power grids with constant-power loads

Mark Jeeninga *

* *Politecnico di Torino, Corso Duca degli Abruzzi, 24 10129 Torino, Italy (e-mail: mark.jeeninga@polito.it)*

Abstract: This paper is concerned with the feasibility of the power flow in DC power power grids with constant power loads. Necessary and sufficient matrix inequalities are derived that guarantee a minimal p-norm distance between a configuration of power demands and the infeasibility boundary in the space of power demands. The (non)convexity of these matrix inequalities is studied subsequently.

Keywords: DC power grids, Power flow analysis, Matrix inequalities.

1. INTRODUCTION

Over the last decade, DC power grids have found an increasing interest among applications such as smart grids and high-voltage DC (HVDC) transmission. Currently, a major challenge in DC power grids is the presence of constant-power loads, which demand a constant amount of power from the grid. Such loads are known to destabilize the grid by selfishly extracting more power from the grid, which can lead to a collapse of nodal voltages known as voltage collapse. A particular example of such an event results from the case where the power demands cannot be met at steady state.

The power flow feasibility problem studies under which conditions constant-power demands can be satisfied at steady state. The problem has been fully characterized in Jeeninga et al. (2022a,b), resulting in necessary and sufficient conditions for power flow feasibility. Although these results are able to assess this feasibility problem, one shortcoming is that the robustness of power flow feasibility cannot be guaranteed. Such a guarantee is required when power grids should not be operated close to the feasibility boundary, or when the parameters of the system are uncertain. Sufficient conditions have been presented in Bolognani and Zampieri (2015) for a p-norm ball around the point where all power demands are zero, and a similar result concerning a polyhedral set was obtained in Simpson-Porco et al. (2016). To the best of the author's knowledge no other advances have been made. In the current paper, necessary and sufficient conditions are presented that guarantee the feasibility of the power demands within a p-norm ball around a given configuration of power demands.

Notation and matrix definitions

For a vector $x = (x_1 \ \cdots \ x_k)^\top$ we denote

$$[x] := \operatorname{diag}(x_1, \dots, x_k).$$

We let $\mathbb{1}$ and $\mathbb{0}$ denote the all-ones and all-zeros vector, respectively. We let their dimensions follow from their context. All vector and matrix inequalities are taken to be element-wise. We let e_i denote the i-th column of the identity matrix. We write $A \succeq B$ when $A - B$ is a symmetric positive semi-definite matrix, and $A \succneqq B$ when in addition $A \neq B$. We let $\|x\|_p$ denote the p-norm of $x \in \mathbb{R}^k$.

2. THE DC POWER GRID MODEL

This paper considers DC power grids with constant-power loads at steady state, which are modeled as a resistive circuit. Nodes (buses) in the grid are either sources (S) or loads (L). A source is a node at which the nodal voltage potentials of the network are fixed, such as a slack bus. A load is a node that demands a given quantity of power from the grid. The power flow feasibility problem asks if the nodal voltage potentials at the loads can be chosen such that all the power demands are satisfied.

To give a mathematical formulation of this problem we define the following quantities. We let $V = \begin{pmatrix} V_L^\top & V_S^\top \end{pmatrix}^\top \in \mathbb{R}^{n+m}$ be the voltage potentials at the nodes, which we assume to be positive. We let $Y \in \mathbb{R}^{(n+m)\times(n+m)}$ denote the Kirchhoff matrix of the power grid, which relates the voltage potentials in the grid to the nodal current $I \in \mathbb{R}^{n+m}$ injected into the network by $I = YV$. The power that is injected into the network at the loads is therefore given by

$$P_L = [V_L](Y_{LL}V_L + Y_{LS}V_S). \tag{1}$$

Let $P_c \in \mathbb{R}^n$ denote the power demands of the load nodes. The power flow feasibility problem asks if the demands P_c can be satisfied for some $V_L > \mathbb{0}$, in which case $P_L + P_c = \mathbb{0}$. We formalize this as follows.

Definition 2.1. Given Y and V_S, we say that P_c is feasible if there exists $V_L > \mathbb{0}$ such that

$$[V_L](Y_{LL}V_L + Y_{LS}V_S) + P_c = \mathbb{0}.$$

The set of all feasible P_c is denoted by $\mathcal{F}$.

2.1 Power flow feasibility as an LMI

It has been shown in Jeeninga et al. (2022b) that the set $\mathcal{F}$ is closed and convex, and that feasibility of P_c is equivalent to the feasibility of an LMI in terms of the matrix

$$Q_{P_c}(\lambda) := \begin{pmatrix} \frac{1}{2}([\lambda]Y_{LL} + Y_{LL}[\lambda]) & \frac{1}{2}[\lambda]Y_{LS}V_S \\ \frac{1}{2}([\lambda]Y_{LS}V_S)^\top & \lambda^\top P_c \end{pmatrix}.$$

We repeat the result for the sake of completeness.

Theorem 2.2. (LMI for power flow infeasibility). Given Y and V_S, the vector P_c is not feasible if and only if there exists a vector $\lambda > \mathbb{0}$ such that $Q_{P_c}(\lambda)$ is positive definite.

Theorem 2.2 tells us that power flow infeasibility is equivalent to the feasibility of an LMI. This equivalence may be rephrased by using the alternative of the LMI, *e.g.*. see Balakrishnan and Vandenberghe (2003). By doing so we obtain the following LMI condition which is equivalent to power flow feasibility.

Theorem 2.3. (LMI for power flow feasibility). Given Y and V_S, the vector P_c is feasible if and only if there exists a nonzero positive semi-definite matrix $Z = Z^\top \in \mathbb{R}^{(n+1)\times(n+1)}$ such that

$$\operatorname{trace}(Z\ Q_{P_c}(e_i)) \leq 0$$

for all $i = 1, \ldots, n$.

3. THE MINIMAL DISTANCE TO THE POWER FLOW FEASIBILITY BOUNDARY

In a practical setting it is desirable that a feasible P_c does not lie close to the feasibility boundary, for example in the case when only estimates of P_c are available. This note is therefore concerned with finding conditions that guarantee a minimal distance of P_c to the feasibility boundary $\partial\mathcal{F}$. Equivalently, we are interested in conditions that guarantee the feasibility of all vectors of power demands that lie in a neighborhood of P_c. To this end we let the p-norm ball centered at y be defined by

$$\mathcal{B}_{p,\gamma}(y) := \{\ z \mid \|y - z\|_p \leq \gamma\ \}, \quad \gamma > 0.$$

Additionally we would like to know if such conditions are computationally attractive, as in the case of Theorem 2.2 and Theorem 2.3. Our main problem is formalized as follows.

Problem 3.1. Let Y, V_S and P_c be given. Under what conditions do we have that any vector $\widehat{P}_c \in \mathcal{B}_{p,\gamma}(P_c)$ is feasible? Put differently, under what conditions does the inclusion $\mathcal{B}_{p,\gamma}(P_c) \subseteq \mathcal{F}$ hold? This is to say that the distance between a feasible P_c and the power flow feasibility boundary $\partial\mathcal{F}$ is at least γ.

This note answers Problem 3.1 by presenting matrix inequalities that are analogous to Theorem 2.2 and Theorem 2.3, and necessary and sufficient for the feasibility of a ball $\mathcal{B}_{p,\gamma}(P_c)$. In addition we prove that these matrix inequalities are (multiple) LMIs when $p = 1$ or $p = \infty$, and lead to non-convex matrix inequalities for other p.

3.1 The ∞-norm distance to $\partial\mathcal{F}$

For a given P_c, the ∞-norm ball $\mathcal{B}_{\infty,\gamma}(P_c)$ is the set of the vectors $\widehat{P}_c$ of the power demand such that

$$|P_{c,i} - \widehat{P}_{c,i}| \leq \gamma,$$

which is equivalent to the condition

$$P_c - \gamma\mathbb{1} \leq \widehat{P}_c \leq P_c + \gamma\mathbb{1}.$$

Note that the inequalities are element-wise. The following result from Jeeninga et al. (2022b) states that any vector that is element-wise dominated by a feasible vector of power demands is also feasible.

Lemma 3.2. If $y \in \mathcal{F}$ and $\widehat{y} \leq y$, then also $\widehat{y} \in \mathcal{F}$.

In particular Lemma 3.2 implies the equivalence

$$P_c + \gamma\mathbb{1} \in \mathcal{F} \ \Leftrightarrow\ \mathcal{B}_{\infty,\gamma}(P_c) \subseteq \mathcal{F}.$$

Consequently, to verify that all $\widehat{P}_c \in \mathcal{B}_{\infty,\gamma}(P_c)$ are feasible, it suffices to verify the feasibility of $P_c + \gamma\mathbb{1}$. Theorem 2.2 and Theorem 2.3 therefore imply the following characterization.

Theorem 3.3. Given Y and V_S and P_c, then some $\widehat{P}_c \in \mathcal{B}_{\infty,\gamma}(P_c)$ is not feasible if and only if there exists a vector $\lambda > \mathbb{0}$ such that $Q_{P_c+\gamma\mathbb{1}}(\lambda)$ is positive definite.

Theorem 3.4. Given Y and V_S and P_c, then all $\widehat{P}_c \in \mathcal{B}_{\infty,\gamma}(P_c)$ are feasible if and only if there exists a nonzero positive semi-definite matrix $Z = Z^\top \in \mathbb{R}^{(n+1)\times(n+1)}$ such that

$$\operatorname{trace}(Z\ Q_{P_c+\gamma\mathbb{1}}(e_i)) \leq 0$$

for all $i = 1, \ldots, n$.

In summary, we may check if the ∞-norm distance between a vector P_c and the power flow infeasibility boundary $\partial\mathcal{F}$ is at least γ by solving the LMI condition in either Theorem 3.3 or Theorem 3.4.

3.2 The 1-norm distance to $\partial\mathcal{F}$

For a given P_c, the 1-norm ball $\mathcal{B}_{1,\gamma}(P_c)$ is equivalent to the convex hull of the vectors

$$P_c - \gamma e_i, \quad P_c + \gamma e_i,$$

with $i = 1, \ldots, n$. Recall that the set $\mathcal{F}$ is convex, and we therefore have that

$$\mathcal{B}_{1,\gamma}(P_c) \subseteq \mathcal{F} \ \Leftrightarrow\ P_c \pm \gamma e_i \in \mathcal{F} \tag{2}$$

for all $i = 1, \ldots, n$. Moreover, since $P_c - \gamma e_i \leq P_c + \gamma e_i$, Lemma 3.2 implies that it suffices to take only the positive signs in (2). By virtue to Theorem 2.2 and Theorem 2.3 we obtain the following characterization.

Theorem 3.5. Given Y and V_S and P_c, then some $\widehat{P}_c \in \mathcal{B}_{1,\gamma}(P_c)$ is not feasible if and only if there exists a vector $\lambda > \mathbb{0}$ such that $Q_{P_c+\gamma e_i}(\lambda)$ is positive definite for some $i \in \{1, \ldots, n\}$.

Theorem 3.6. Given Y and V_S and P_c, then all $\widehat{P}_c \in \mathcal{B}_{1,\gamma}(P_c)$ are feasible if and only if for each $i \in \{1, \ldots, n\}$ there exists a nonzero positive semi-definite matrix $Z_i = Z_i^\top \in \mathbb{R}^{(n+1)\times(n+1)}$ such that

$$\operatorname{trace}(Z_i\ Q_{P_c+\gamma e_i}(e_j)) \leq 0$$

for all $j = 1, \ldots, n$.

Note that Theorem 3.5 or Theorem 3.6 are equivalent to solving n separate LMIs. To summarize, we may check if the 1-norm distance between a vector P_c and the power flow infeasibility boundary $\partial\mathcal{F}$ is at least γ by solving the n LMI conditions in either Theorem 3.5 or Theorem 3.6.

3.3 The p-norm distance to $\partial\mathcal{F}$

In the remainder of this section we assume that p lies in the open interval $(1,\infty)$ and we let $q := \frac{p}{p-1}$ such that

$$\tfrac{1}{p} + \tfrac{1}{q} = 1.$$

For a given P_c, the p-norm ball $\mathcal{B}_{p,\gamma}(P_\mathrm{c})$ is the set of the vectors $\widehat{P}_\mathrm{c}$ of the power demand such that

$$\|P_\mathrm{c} - \widehat{P}_\mathrm{c}\|_p \leq \gamma. \tag{3}$$

We define $\delta = \widehat{P}_\mathrm{c} - P_\mathrm{c}$ for the sake of brevity. By Hölder's inequality (*e.g.*, see Roman (2008)) we know that

$$\sum_{i=1}^{n} |\lambda_i \delta_i| \leq \|\delta\|_p \|\lambda\|_q. \tag{4}$$

Moreover, equality holds in (4) for some λ_δ that lies in the same quadrant as δ, in which case the left-hand side of (4) equals ${\lambda_\delta}^\top \delta$. Using (3) we therefore have the inequality

$${\lambda_\delta}^\top \delta \leq \gamma \|\lambda_\delta\|_q.$$

Finally, by recalling that $\delta = \widehat{P}_\mathrm{c} - P_\mathrm{c}$ we conclude that

$${\lambda_\delta}^\top \widehat{P}_\mathrm{c} = {\lambda_\delta}^\top P_\mathrm{c} + {\lambda_\delta}^\top \delta \leq {\lambda_\delta}^\top P_\mathrm{c} + \gamma \|\lambda_\delta\|_q. \tag{5}$$

In the context of Theorem 2.2, inequality (5) implies that if $\widehat{P}_\mathrm{c}$ is not feasible then there exists a $\lambda > \mathbb{0}$ such that

$$Q_{P_\mathrm{c},q,\gamma}(\lambda) := \begin{pmatrix} \frac{1}{2}([\lambda]Y_{LL} + Y_{LL}[\lambda]) & \frac{1}{2}[\lambda]Y_{LS}V_S \\ \frac{1}{2}([\lambda]Y_{LS}V_S)^\top & \lambda^\top P_\mathrm{c} + \gamma\|\lambda\|_q \end{pmatrix}.$$

is positive definite. In fact, by considering all $\widehat{P}_\mathrm{c}$ in the ball $\mathcal{B}_{p,\gamma}(P_\mathrm{c})$ we may prove the following equivalence condition.

Theorem 3.7. Given Y and V_S and P_c, then some $\widehat{P}_\mathrm{c} \in \mathcal{B}_{p,\gamma}(P_\mathrm{c})$ is not feasible if and only if there exists a vector $\lambda > \mathbb{0}$ such that $Q_{P_\mathrm{c},q,\gamma}(\lambda)$ is positive definite, where $\frac{1}{p} + \frac{1}{q} = 1$.

Note that the above argumentation is not complete, and that a full proof is omitted for the same of brevity. An analogous condition to Theorem 2.3 may also be obtained by virtue of Hölder's inequality.

Theorem 3.8. Given Y and V_S and P_c, then all $\widehat{P}_\mathrm{c} \in \mathcal{B}_{p,\gamma}(P_\mathrm{c})$ are feasible if and only if there exists a nonzero positive semi-definite matrix $Z = Z^\top \in \mathbb{R}^{(n+1)\times(n+1)}$ such that

$$\operatorname{trace}\left(Z\ Q_{P_\mathrm{c},q,\gamma}(\lambda)\right) \leq 0$$

for all $\lambda \geq \mathbb{0}$, where $\frac{1}{p} + \frac{1}{q} = 1$.

To conclude we section we will analyze the (non)convexity of the matrix inequalities in Theorem 2.2 and Theorem 2.3. The matrix inequalities in Theorem 3.7 and Theorem 3.8 are not LMIs since the map $\lambda \mapsto Q_{P_\mathrm{c},q,\gamma}(\lambda)$ is not linear. Linear matrix inequalities are computationally attractive since they describe a convex problem, which have the property that local optima are also global optima. Moreover, algorithms to find these optima are well-studied.

Focusing on Theorem 3.7, the corresponding matrix inequality would be convex if the map $\lambda \mapsto Q_{P_\mathrm{c},q,\gamma}(\lambda)$ would have to satisfy

$$\begin{aligned}\alpha Q_{P_\mathrm{c},q,\gamma}(\lambda_1) + (1-\alpha) Q_{P_\mathrm{c},q,\gamma}(\lambda_2) \\ \preceq Q_{P_\mathrm{c},q,\gamma}(\alpha\lambda_1 + (1-\alpha)\lambda_2)\end{aligned} \tag{6}$$

for $\alpha \in (0,1)$, where we let λ_1, λ_2 such that $\mathbb{1}^\top \lambda_i = 1$. This relationship implies the existence of a $\widehat{\lambda}$ that satisfies $\mathbb{1}^\top \widehat{\lambda} = 1$ and for which $Q_{P_\mathrm{c},q,\gamma}(\widehat{\lambda})$ is the unique maximal element of the partial ordering induced by $\preceq$. Consequently, the matrix inequality in Theorem 3.7 may be evaluated by finding this $\widehat{\lambda}$ and checking if $Q_{P_\mathrm{c},q,\gamma}(\widehat{\lambda})$ is positive definite. However, we will show that the inequality (6) only holds when $\lambda_1 = \lambda_2$.

The triangle inequality implies that for vectors λ_1, λ_2 such that $\mathbb{1}^\top \lambda_i = 1$ we have

$$\alpha\|\lambda_1\|_q + (1-\alpha)\|\lambda_2\|_q \geq \|\alpha\lambda_1 + (1-\alpha)\lambda_2\|_q \tag{7}$$

for $\alpha \in (0,1)$. Moreover, since $q \in (1,\infty)$ we have that if $\lambda_1 \neq \lambda_2$ then the inequality in (7) is strict (*e.g.*, see Chapter 11 of Carothers (2004)). For such $\lambda_1 \neq \lambda_2$ we therefore have

$$\begin{aligned}\alpha Q_{P_\mathrm{c},q,\gamma}(\lambda_1) + (1-\alpha) Q_{P_\mathrm{c},q,\gamma}(\lambda_2) \\ \succneqq Q_{P_\mathrm{c},q,\gamma}(\alpha\lambda_1 + (1-\alpha)\lambda_2)\end{aligned}$$

for $\alpha \in (0,1)$, which implies that the matrix inequality is strictly concave, and that (6) only holds when $\lambda_1 = \lambda_2$.

By a similar argumentation it can be shown that Theorem 3.8 is a non-convex problem.

In summary, for $p \in (1,\infty)$ we may check if the p-norm distance between a vector P_c and the power flow infeasibility boundary $\partial\mathcal{F}$ is at least γ by solving the non-convex matrix inequality in either Theorem 3.7 or Theorem 3.8.

Although the matrix inequality in Theorem 3.7 is not convex, it is remarked that in special cases a unique maximizer of the partial ordering induced by $\preceq$ may exist. If this is the case, an algorithm that obtains a local maximizer will therefore also obtain the global maximizer.

4. CONCLUSION

This note studied the distance of a feasible vector of power demands to the power flow feasibility boundary. A p-norm ball around a given vector of power demands was considered, and it was shown that to verify that all vectors of power demands that lie within the ball are feasible, one may solve one of two matrix inequalities. In the case of $p = \infty$ this gives rise to a single LMI, in the case of $p = 1$, this gives rise to n LMIs, and in the case of $p \in (1,\infty)$ this gives rise to a non-convex (strictly concave) matrix inequality.

Abstract: We will consider the multidimensional truncated $p \times p$ Hermitian matrix-valued moment problem. We will prove a characterisation of truncated $p \times p$ Hermitian matrix-valued multisequence with a minimal positive semidefinite matrix-valued representing measure via the existence of a flat extension, i.e., a rank preserving extension of a multivariate Hankel matrix (built from the given truncated matrix-valued multisequence). Moreover, the support of the representing measure can be computed via the intersecting zeros of the determinants of matrix-valued polynomials which describe the flat extension. We will also use a matricial generalisation of Tchakaloff's theorem due to the first author together with the above result to prove a characterisation of truncated matrix-valued multisequences which have a representing measure. When $p = 1$, our result recovers the celebrated flat extension theorem of Curto and Fialkow. The bivariate quadratic matrix-valued problem and the bivariate cubic matrix-valued problem are explored in detail.

Keywords: Sum-of-squares, semigroup and operator theory (47A57)

We will investigate the *multidimensional truncated matrix-valued moment problem*. Given a truncated multisequence $S = (S_\gamma)_{\substack{0 \le |\gamma| \le m \\ \gamma \in \mathbb{N}_0^d}}$, where $S_\gamma \in \mathcal{H}_p$ (i.e., S_γ is a $p \times p$ Hermitian matrix), we wish to find necessary and sufficient conditions on S for the existence of a $p \times p$ positive matrix-valued measure T on $\mathbb{R}^d$, with convergent moments, such that

$$S_\gamma = \int_{\mathbb{R}^d} x^\gamma dT(x) := \int \cdots \int_{\mathbb{R}^d} \prod_{j=1}^d x_j^{\gamma_j} dT(x_1, \ldots, x_d) \tag{1}$$

for all $\gamma = (\gamma_1, \ldots, \gamma_d) \in \mathbb{N}_0^d$ such that $0 \le |\gamma| \le m$. We would also like to find a positive matrix-valued measure $T = \sum_{a=1}^\kappa Q_a \delta_{w^{(a)}}$ on $\mathbb{R}^d$ such that (1) holds and and

$$\sum_{a=1}^\kappa \operatorname{rank} Q_a \text{ is as small as possible,} \tag{2}$$

i.e., T is a finitely atomic measure of the form

$$T = \sum_{a=1}^\kappa \delta_{w^{(a)}} Q_a$$

with

$$\sum_{a=1}^\kappa \operatorname{rank} Q_a = \operatorname{rank} M(n).$$

If (1) holds, then T is called a *representing measure* for S. If (1) and (2) are in force, then T is called a *minimal representing measure for* S.

Before proceeding any further, we will first introduce frequently used notation. Commonly used sets are $\mathbb{N}_0, \mathbb{R}, \mathbb{C}$ denoting the sets of nonnegative integers, real numbers and complex numbers respectively. Given a nonempty set E, we let

$$E^d = \{(x_1, \ldots, x_d) : x_j \in E \text{ for } j = 1, \ldots, d\}.$$

Next, we let $\mathbb{C}^{p \times p}$ denote the set of $p \times p$ matrices with entries in $\mathbb{C}$ and $\mathcal{H}_p \subseteq \mathbb{C}^{p \times p}$ denote the set of $p \times p$ Hermitian matrices with entries in $\mathbb{C}$. Given

$$x = (x_1, \ldots, x_d) \in \mathbb{R}^d \quad \text{and} \quad \lambda = (\lambda_1, \ldots, \lambda_d) \in \mathbb{N}_0^d,$$

we define

$$x^\lambda = \prod_{j=1}^d x_j^{\lambda_j} \quad \text{and} \quad |\lambda| = \lambda_1 + \cdots + \lambda_d$$

and

$$\Gamma_{m,d} := \{\gamma \in \mathbb{N}_0^d : 0 \le |\gamma| \le m\}.$$

We shall let $\mathbb{C}^{p \times p}[x_1, \ldots x_d]$ denote the set of *matrix polynomials* in the indeterminates $x_1, \ldots, x_d$, i.e., the set of all polynomials $P(x) = \sum_{\lambda \in \Gamma_{n,d}} x^\lambda P_\lambda$, where $P_\lambda \in \mathbb{C}^{p \times p}$ and n is arbitrary. We will also let

$$\mathbb{C}_n^{p \times p}[x_1, \ldots, x_d] := \{P \in \mathbb{C}^{p \times p}[x_1, \ldots, x_d] : \text{the total degree of } P(x) \le n\}.$$

In order to communicate our main contributions, we will need the notion of a d-Hankel matrix. Let $S := (S_\gamma)_{\gamma \in \Gamma_{2n,d}}$ be a given truncated $\mathcal{H}_p$-valued multisequence and $M(n)$ be the corresponding *d-Hankel matrix* based on S and defined as follows. We label the block rows and block columns by a family of monomials $(x^\gamma)_{\gamma \in \Gamma_{n,d}}$ ordered by the grader lexicographic ordering $\prec_{\text{grlex}}$. We let the entry in the block row indexed by x^γ and in the block column indexed by $x^{\tilde{\gamma}}$ be given by

$$S_{\gamma + \tilde{\gamma}}.$$

For example if $d = n = 2$, then

$$M(2) = \begin{array}{c} \\ 1 \\ X \\ Y \\ X^2 \\ XY \\ Y^2 \end{array} \begin{array}{c} \begin{array}{cccccc} 1 & X & Y & X^2 & XY & Y^2 \end{array} \\ \begin{pmatrix} S_{00} & S_{10} & S_{01} & S_{20} & S_{11} & S_{02} \\ S_{10} & S_{20} & S_{11} & S_{30} & S_{21} & S_{12} \\ S_{01} & S_{11} & S_{02} & S_{21} & S_{12} & S_{03} \\ S_{20} & S_{30} & S_{21} & S_{40} & S_{31} & S_{22} \\ S_{11} & S_{21} & S_{12} & S_{31} & S_{22} & S_{13} \\ S_{02} & S_{12} & S_{03} & S_{22} & S_{13} & S_{04} \end{pmatrix} \end{array}.$$

If we are given $S := (S_\gamma)_{\gamma \in \mathbb{N}_0^d}$, then shall let $M(\infty)$ denote the *infinite d-Hankel matrix* based on S, which can be defined analogously by letting the block rows and columns be indexed by $(x^\lambda)_{\lambda \in \mathbb{N}_0^d}$ (ordered by $\preceq_{\text{grlex}}$). If $d = 2$, then

$$M(\infty) = \begin{array}{c} \\ 1 \\ X \\ Y \\ X^2 \\ XY \\ Y^2 \\ \vdots \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & X & Y & X^2 & XY & Y^2 & \cdots \end{array} \\ \begin{pmatrix} S_{00} & S_{10} & S_{01} & S_{20} & S_{11} & S_{02} & \cdots \\ S_{10} & S_{20} & S_{11} & S_{30} & S_{21} & S_{12} & \cdots \\ S_{01} & S_{11} & S_{02} & S_{21} & S_{12} & S_{03} & \cdots \\ S_{20} & S_{30} & S_{21} & S_{40} & S_{31} & S_{22} & \cdots \\ S_{11} & S_{21} & S_{12} & S_{31} & S_{22} & S_{13} & \cdots \\ S_{02} & S_{12} & S_{03} & S_{22} & S_{13} & S_{04} & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix} \end{array}.$$

Let $S := (S_\gamma)_{\gamma \in \Gamma_{2n,d}}$ be a truncated $\mathcal{H}_p$-valued multisequence and let $M(n)$ be the corresponding d-Hankel matrix. Corresponding to any $P(x) = \sum_{\lambda \in \Gamma_{n,d}} x^\lambda P_\lambda \in \mathbb{C}_n^{p \times p}[x_1, \ldots, x_d]$, let $P(X)$ denote the element of $\mathbb{C}^{\binom{(n+d)!}{n!\,d!} p \times p}$ arising from $\sum_{\lambda \in \Gamma_{n,d}} x^\lambda P_\lambda$ when we replace x^λ by the corresponding block column in $M(n)$. The *variety of* $M(n)$, denoted by $\mathcal{V}(M(n))$, is given by

$$\mathcal{V}(M(n)) := \bigcap_{\substack{P \in \mathbb{C}_n^{p \times p}[x_1, \ldots, x_d] \\ P(X) = \operatorname{col}(0_{p \times p})_{\gamma \in \Gamma_{n,d}}}} \mathcal{Z}(\det(P(x))).$$

Main contributions

(C1) We will characterise positive infinite d-Hankel matrices with finite rank based on a $\mathcal{H}_p$-valued multisequence via an integral representation. Indeed, we will see that $S^{(\infty)} = (S_\gamma)_{\gamma \in \mathbb{N}_0^d}$ gives rise to a positive infinite d-Hankel matrix $M(\infty)$ with finite rank if and only if there exists a finitely atomic positive $\mathcal{H}_p$-valued measure T on $\mathbb{R}^d$ such that

$$S_\gamma = \int_{\mathbb{R}^d} x^\gamma \, dT(x) \qquad \text{for} \quad \gamma \in \mathbb{N}_0^d.$$

In this case, the support of the positive $\mathcal{H}_p$-valued measure T agrees with

$$\mathcal{V}(\mathcal{I}) := \bigcap_{P \in \mathcal{I} \subseteq \mathbb{C}^{p \times p}[x_1, \ldots, x_d]} \mathcal{Z}(\det P(x)),$$

where $\mathcal{V}(\mathcal{I})$ is the variety of a right ideal of matrix-valued polynomials based on the kernel of $M(\infty)$ and the cardinality of the support of T is exactly $\operatorname{rank} M(\infty)$.

(C2) Let $S = (S_\gamma)_{\gamma \in \Gamma_{2n,d}}$ be a given truncated $\mathcal{H}_p$-valued multisequence. We will see that S has a minimal representing measure $T = \sum_{a=1}^{\kappa} Q_a \delta_{w^{(a)}}$, i.e., $\sum_{a=1}^{\kappa} \operatorname{rank} Q_a = \operatorname{rank} M(n)$, if and only if the corresponding d-Hankel matrix $M(n)$ based on S has a *flat extension* $M(n+1)$, i.e., a positive rank preserving extension. In this case, the support of T agrees with $\mathcal{V}(M(n+1))$, where $\mathcal{V}(M(n+1))$ is the variety of the d-Hankel matrix $M(n+1)$ and $\sum_{a=1}^{\kappa} \operatorname{rank} Q_a = \operatorname{rank} M(n)$.

(C3) Let S be as in (C2). S has a representing measure if and only if the corresponding d-Hankel matrix $M(n)$ have an eventual extension $M(n+k)$ which admits a flat extension.

(C4) Let $S = (S_{00}, S_{10}, S_{01}, S_{20}, S_{11}, S_{02})$ be a given $\mathcal{H}_p$-valued truncated bisequence. We will see that necessary and sufficient conditions for S to have a minimal representing measure consist of $M(1)$ being positive semidefinite and a system of matrix equations having a solution. More precisely, if $M(1) \succeq 0$ and there exist $S_{30}, S_{21}, S_{12}, S_{03} \in \mathcal{H}_p$ such that

$$\operatorname{Ran} \begin{pmatrix} S_{20} & S_{11} & S_{02} \\ S_{30} & S_{21} & S_{12} \\ S_{21} & S_{12} & S_{03} \end{pmatrix} \subseteq \operatorname{Ran} M(1)$$

(hence, there exists $W = (W_{ab})_{a,b=1}^3 \in \mathbb{C}^{3p \times 3p}$ such that $M(1)W = B$, where

$$B = \begin{pmatrix} S_{20} & S_{11} & S_{02} \\ S_{30} & S_{21} & S_{12} \\ S_{21} & S_{12} & S_{03} \end{pmatrix})$$

and moreover, the following matrix equations hold:

$$W_{11}^* S_{11} + W_{21}^* S_{21} + W_{31}^* S_{12} = S_{11} W_{11} + S_{21} W_{21} + S_{12} W_{31}, \tag{3}$$

$$W_{13}^* S_{20} + W_{23}^* S_{30} + W_{33}^* S_{21} = W_{12}^* S_{11} + W_{22}^* S_{21} + W_{32}^* S_{12} \tag{4}$$

and

$$W_{12}^* S_{02} + W_{22}^* S_{12} + W_{32}^* S_{03} = S_{02} W_{12} + S_{12} W_{22} + S_{03} W_{32}, \tag{5}$$

then S has a minimal representing measure.

We will also see that if $M(1)$ is positive definite and obeys an extra condition (which is automatically satisfied if $p = 1$), then S has a minimal representing measure. However, if $M(1)$ is singular and $p \geq 2$, then S need not have a minimal representing measure.

Extended Abstract

The Classical Truncated Moment Problem (TMP) dates back to the start of the twentieth century, and was initially developed by a number of mathematicians, including A.A. Markov, H. Hamburger, N.I. Akhiezer, M.G. Krein, A.A. Nudel'man, M. Riesz and I.S. Iohvidov. The theory ran parallel to the developments in the full moment problem, where the main focus was placed. Many decades later, renewed interest in TMP arose in connection with the so-called Subnormal Completion Problem (SCP) for unilateral weighted shifts. In 1966, J. Stampfli (52) proved that for any three positive numbers $a < b < c$, it is always possible to build a unilateral weighted shift W_α acting on $\ell^2(\mathbf{N}_0)$, with $\alpha \in \ell^\infty(\mathbf{N}_0)$, having initial weights $\alpha_0 = a$, $\alpha_1 = b$, $\alpha_2 = c$, and such that W_α is subnormal. In (9; 10), R.E. Curto and L.A. Fialkow solved the SCP for unilateral weighted shifts, by finding necessary and sufficient conditions for a finite collection of positive numbers to be the initial segment of weights of a subnormal unilateral weighted shift. Their approach was based on the fact that subnormality is detected by the existence of a positive Radon measure on the closed interval $[0, \|W_\alpha\|^2]$ whose moments are the moments γ_k of the weight sequence α, defined recursively as $\gamma_0 := 1$ and $\gamma_{k+1} := \alpha_k^2 \gamma_k$ (for all $k \in \mathbf{N}_0$). Thus, the subnormality of W_α is intrinsically related to a TMP. In the process, Curto and Fialkow proved the so-called Flat Extension Theorem for moment matrices, which is an essential component of their TMP theory in one and several real or complex variables.

A few years after the Curto-Fialkow results were published, J.B. Lasserre discovered some significant connections between real algebraic geometry, moment problems and polynomial optimization; he introduced a method known as semidefinite relaxations (see, e.g., (34)), which led to renewed interest in solutions of TMP, especially those with finitely atomic representing measures. The importance of polynomial optimization problems and the convenience of working with polynomials as algebraic and computational objects as well as intensive research on this area, is one of the main motivations for the study of moment problems for the algebra of polynomials. For ample information on the above mentioned developments, the reader is referred to (11; 12; 13; 14; 15; 16; 17; 18; 23; 24; 29; 30; 31; 34; 35; 36; 37; 38; 43; 47; 48; 50; 54; 57).

A fundamental tool in all those works is positivity. Given a closed subset K of ^{n}, a linear functional L defined on a subspace of $[\underline{X}] := [X_1, \ldots, X_n]$ is said to be $K-$*positive* when it assumes nonnegative values in all the elements of its domain which are nonnegative on K. For a set $\mathcal{A}$ of monomials in $[\underline{X}]$, a closed subset K of ^{n}, and a $K-$positive linear functional L on the Span($\mathcal{A}$), the $\mathcal{A}$–truncated K–moment problem is the question of establishing whether L can be represented as an integral with respect to a positive Radon measure whose support is contained in K. If such a measure exists then it is called a K–representing measure for L. The $\mathcal{A}-$Truncated $K-$Moment Problem terminology was introduced by J. Nie in (45), although he only considered the case when the set $\mathcal{A}$ is finite. When $\mathcal{A} = \{\underline{X}^\alpha : \alpha \in \mathbf{N}_0^n, |\alpha| \leq d\}$, for some $d \in \mathbf{N}$, the $\mathcal{A}$–truncated K–moment problem is usually known as the Classical K–TMP.

The Full K–Moment Problem, for closed $K \subseteq ^n$, corresponds to the case when $\mathcal{A} = \{\underline{X}^\alpha : \alpha \in \mathbf{N}_0^n\}$; that is, given a $K-$positive linear functional L on $[\underline{X}]$, find a criterion for the existence of a positive Radon measure μ whose support is contained in K, and such that L is represented as $L(p) = \int p \, d\mu$, for all $p \in [\underline{X}]$.

Partial answers to the $\mathcal{A}$–truncated K–moment problem are known. For example, when K is a closed subset of ^{n} and $\mathcal{A}$ is the set of all monomials up to a certain degree $2d$ or $2d+1$, the existence of such a K–representing measure is proved to be equivalent to the K–positive extendability of L to the set of all polynomials of degree at most $2d+2$, (16, Theorem 2.2). When K is compact and Span($\mathcal{A}$) contains a polynomial that is strictly positive on K, the existence of a K–representing measure is known to be equivalent to the K–positivity of L (see (56, Theorem I, p.129), (16, p. 2710), (19, Theorem 2.2) and (45, Algorithm 4.2)).

Our research deals with an abstract version of the truncated moment problem. We show that all the abovementioned solutions can be considered as particular cases of a general result about the existence of positive extensions of linear functionals to larger linear subspaces containing an element that dominates all the members of the original domain. The scope of our study is also much broader as we consider unital commutative –algebras instead of $[\underline{X}]$ and arbitrary linear subspaces of the algebra in lieu of finite dimensional ones. Thus, our setting is general enough to encompass also infinite dimensional instances of the moment problem, e.g. when the algebra is not finitely generated or when the representing measure is supported on an infinite dimensional vector space.

Let A be a unital commutative -algebra, K a closed subset of the character space of A, and B a linear subspace of A. For a linear functional $L : B \to$, we investigate conditions under which L admits an integral representation with respect to a positive Radon measure supported in K. When A is equipped with a submultiplicative seminorm, we employ techniques from the theory of positive extensions of linear functionals to prove a criterion for the existence of such an integral representation for L. When no topology is prescribed on A, we identify suitable assumptions on A, K, B and L which allow us to construct a seminormed structure on A, so as to exploit our previous result to get an integral representation for L. Our main theorems allow us to extend some well-known results on the Classical Truncated Moment Problem, the Truncated Moment Problem for point processes, and the Subnormal Completion Problem for 2–variable weighted shifts. We also analyze the relation between the Full and the Truncated Moment Problem in our general setting; we obtain a suitable generalization of Stochel's Theorem which readily applies to Full Moment Problems for localized algebras.

Infinite dimensional moment problems have been studied already in the sixties (see e.g. (8; 46; 20; 42; 3; 5; 39; 4; 49)) motivated by fundamental questions in applied areas such as statistical physics and quantum mechanics. Since then there has been an extensive production on the infinite dimensional moment problems appearing in the analysis of interacting particle systems as well as in stochastic geometry, spatial ecology, neural spike trains, heterogeneous materials and random packing (see, e.g., (1; 40; 33; 44; 6; 53; 55)). Despite the vast literature devoted to the theory of the infinite dimensional moment problem, and more generally of the moment problem on unital commutative algebras (see (32; 21; 2; 7; 22; 41; 25; 51; 27; 28), just to mention a few recent developments), several questions remain open (cf. (26)).

We also consider several applications of our main results, ranging from the Classical TMP to the TMP for point processes, and to the SCP for 2–variable weighted shifts. In particular, in the case of bivariate polynomials, our novel approach allows us to deal with not only the cases of the Rectangular, Triangular, and Sparse Connected TMP, but also with a new hybrid case which includes the presence of infinitely many moments in one of the variables.

On the exact neural approximations of MPC laws ⋆

Filippo Fabiani * **Paul J. Goulart** *

* *Department of Engineering Science, University of Oxford, OX1 3PJ, United Kingdom (e-mail: {filippo.fabiani, paul.goulart}@eng.ox.ac.uk)*

Abstract: In this extended abstract we present a general procedure to quantify the performance of rectified linear unit (ReLU) neural network (NN) controllers that preserve the desirable properties of a designed model predictive control (MPC) scheme. First, by quantifying the approximation error between NN and MPC state-to-input mappings, we establish suitable conditions involving the worst-case error and the Lipschitz constant that guarantee the stability of the closed-loop system. Then, we develop an offline, mixed-integer (MI) optimization-based method to compute those quantities exactly, thus providing an analytical tool to certify the stability and performance of a ReLU-based approximation of an MPC control law.

Keywords: Model predictive control, Neural networks, Linear systems in control theory, Mixed-integer programming.

1. INTRODUCTION

Model predictive control (MPC) is one of the most popular control strategies for linear systems with operational and physical constraints (Rawlings et al., 2017) and is based on the repeated solution of constrained optimal control problems. Although the theory underlying MPC provides practical stability and performance guarantees, implementations of both *implicit* and *explicit* MPC suffer from well-known practical difficulties (i.e., solving optimization problems in real-time and complexity of the resulting piecewise-affine (PWA) controller, respectively).

As a result, the idea of *approximating* an MPC policy using (deep) NNs (Goodfellow et al., 2016) is particularly attractive in view of their universal approximation capabilities (Hornik, 1991). Starting from the pioneering work in (Parisini and Zoppoli, 1995), indeed, interest in NN-based approximations of MPC laws has increased rapidly in recent years (Chen et al., 2018; Hertneck et al., 2018; Karg and Lucia, 2020a,b; Zhang et al., 2021; Maddalena et al., 2020; Paulson and Mesbah, 2020). Despite their computationally demanding offline training requirements, the online evaluation of NN-based approximations to MPC laws is computationally inexpensive, since it only requires the evaluation of an input-output mapping. However, unless one assumes a certain structure, NNs are generally hard to analyze due to their nonlinear, large-scale structure.

In this extended abstract we provide a means to assess the training quality of a ReLU network in replicating the action of an MPC policy. First, by considering the approximation error between a ReLU network and an MPC law, we give sufficient conditions involving the maximal approximation error and the associated Lipschitz constant that guarantee the closed-loop stability of a discrete-time linear time-invariant (LTI) system when the ReLU approximation replaces the MPC law. Successively, we formulate a mixed-integer linear program (MILP) to compute the Lipschitz constant of an MPC policy exactly. Finally, we develop an optimization-based technique to exactly compute the worst-case approximation error and the Lipschitz constant characterizing the approximation error. The outcome is a set of conditions involving the optimal value of two MILPs that are sufficient to allow us to certify the reliability of the ReLU-based controller, thus proposing a unifying theoretical framework for analyzing NN-based approximations of MPC policies (the proofs of the technical results are in (Fabiani and Goulart, 2021)).

2. MOTIVATIONS, PROBLEM FORMULATION AND PRELIMINARY RESULTS

We will consider the problem of stabilizing the constrained, discrete-time, LTI system

$$x^+ = Ax + Bu, \tag{1}$$

with state variable $x \in \mathcal{X}$, control input $u \in \mathcal{U}$, $A \in \mathbb{R}^{n\times n}$ and $B \in \mathbb{R}^{n\times m}$. We will assume that the constraint sets $\mathcal{X} \subseteq \mathbb{R}^n$ and $\mathcal{U} \subseteq \mathbb{R}^m$ are bounded polyhedral. A popular control choice for constrained systems is MPC that requires one to solve, at every iteration, the following multi-parametric quadratic program (mp-QP) over a time horizon of length $T \geq 1$, $\mathcal{T} \coloneqq \{0, \dots, T-1\}$,

$$V_T(x) = \begin{cases} \min\limits_{(v_i)_{i\in\mathcal{T}}} & \frac{1}{2}\|x_T\|_P^2 + \sum\limits_{i\in\mathcal{T}} \frac{1}{2}(\|x_i\|_Q^2 + \|v_i\|_R^2) \\ \text{s.t.} & x_{i+1} = Ax_i + Bv_i,\ i \in \mathcal{T}, \\ & x_i \in \mathcal{X},\ v_i \in \mathcal{U},\ i \in \mathcal{T}, \\ & x_0 = x. \end{cases} \tag{2}$$

Starting from some $x(0) \in \mathcal{X}$, the receding horizon implementation of an MPC law computes an optimal solution $(v_i^\star)_{i\in\mathcal{T}}$, and then applies the control input $u(0) = v_0^\star$ taken from the first part of the optimal sequence (*implicit*

version). This process is then repeated at every time k with initial condition $x_0 = x(k)$, so that the procedure amounts to the implicit computation of a mapping $x \mapsto v_0^\star$, defined as

$$u_{\text{MPC}}(x) \coloneqq v_0^\star(x).$$

Under standard assumptions, it is well known that the associated MPC control law $u(k) = u_{\text{MPC}}(x(k))$ stabilizes the constrained LTI system (1) about the origin (Borrelli et al., 2017; Rawlings et al., 2017) while, at the same time, respecting state and input constraints. In some applications the dynamics of the underlying system may be too fast relative to the time required to compute the solution to the mp-QP in (2). One may then rely on the *explicit* version of the MPC law in (2), i.e., explicit model predictive control (eMPC) (Bemporad et al., 2002), whose closed form expression can be computed offline. The optimal solution mapping $u_{\text{MPC}}(\cdot)$ enjoys a PWA structure (Rockafellar and Wets, 2009, Def. 2.47)) that maps any $x \in \mathcal{X}$ into an affine control action according to some polyhedral partition of $\mathcal{X}$. The partition and associated affine functions for $u_{\text{MPC}}(\cdot)$ can be computed offline, e.g. using MPC Toolbox (Bemporad et al., 2021). However, the computational effort required for this offline computation may itself be too demanding, since the number of regions in the optimal partition can grow exponentially with the number of states and constraints in (2) (Alessio and Bemporad, 2009). In addition, even if computable offline, the online implementation of the explicit solution may require excessive memory storage or processing power.

2.1 Approximation of MPC laws via ReLU networks

The aforementioned limitations motivate the design of an approximation for $u_{\text{MPC}}(\cdot)$ that can be implemented with minimal computation and storage requirements while still maintaining stability and good performance of the closed-loop system. We focus on controllers implemented using ReLU neural networks, which provide a natural means for approximating $u_{\text{MPC}}(\cdot)$ since the output mapping of such a network has a PWA structure (Montufar et al., 2014). An L-layered, feedforward ReLU network that defines a mapping $F : \mathbb{R}^n \to \mathbb{R}^m$ can be formally described by the following recursive equations across layers (Hagan et al., 1997):

$$\begin{cases} x^0 = x, \\ x^{j+1} = \max(W^j x^j + b^j, 0), \ j \in \{0, \dots, L-1\}, \\ F(x) = W^L x^L + b^L, \end{cases} \tag{3}$$

where $x^0 = x \in \mathbb{R}^{n_0}$, $n_0 = n$, is the input to the network, and $W^j \in \mathbb{R}^{n_{j+1} \times n_j}$, $b^j \in \mathbb{R}^{n_{j+1}}$ are the weight matrix and bias vector of the $(j+1)$-th layer, respectively (defined during some offline training phase). The total number of neurons is thus $N \coloneqq \sum_{j=1}^{L} n_j + m$, since $n_{L+1} = m$.

Thus, after training a ReLU network to produce a mapping $u_{\text{NN}} : \mathcal{X} \to \mathbb{R}^m$, $u_{\text{NN}}(x) \coloneqq F(x)$, to approximate $u_{\text{MPC}}(\cdot)$, we ask whether the training was sufficient to ensure stability of the closed-loop system in (1) with piecewise-affine neural network (PWA-NN) controller $u_{\text{NN}}(\cdot)$ in place of $u_{\text{MPC}}(\cdot)$. We characterize next the features of the approximation error function $e(x) \coloneqq u_{\text{NN}}(x) - u_{\text{MPC}}(x)$ that are key to guarantee the stability of the closed-loop system in (1) with the PWA-NN controller $u_{\text{NN}}(\cdot)$.

2.2 Closed-loop stability with neural network controllers

We hence investigate the robust stability of (1) with MPC policy, $u_{\text{MPC}}(\cdot)$, subject to an additive disturbance:

$$x^+ = Ax + Bu_{\text{NN}}(x) = Ax + Bu_{\text{MPC}}(x) + Be(x). \tag{4}$$

For some $\alpha \in \{1, \infty\}$, we assume that there exist finite constants $\bar{e}_\alpha$, $\mathcal{L}_\alpha(e, \mathcal{X}_\infty) \geq 0$ such that $\|e(x)\|_\alpha \leq \bar{e}_\alpha$, for all $x \in \mathcal{X}$, and $\|e(x) - e(y)\|_\alpha \leq \mathcal{L}_\alpha(e, \mathcal{X}_\infty)\|x - y\|_\alpha$, for all x, $y \in \mathcal{X}_\infty$, where the set $\mathcal{X}_\infty$ will be defined later. In §4, we will show how these conditions can be made to hold, providing a MI optimization-based method to compute $\bar{e}_\alpha$ and $\mathcal{L}_\alpha(e, \mathcal{X}_\infty)$ exactly. For the remainder we make the following mild assumption:

Standing Assumption 1. For the LTI system (1) under the action of the MPC based controller u_{MPC}:

i) the origin is exponentially stable;
ii) the mp-QP in (2) is recursively feasible starting from any $x \in \mathcal{X}$. □

By exploiting the optimal cost $V_T(\cdot)$ of the mp-QP in (2), with $\Omega_c \coloneqq \{x \in \mathcal{X} \mid V_T(x) \leq c\}$ denoting the sublevel set $c \coloneqq \max\{a \geq 0 \mid \Omega_a \subseteq \mathcal{X}\}$, we first establish that the closed-loop system in (1) with an approximated MPC law is input-to-state stable (ISS) (Jiang and Wang, 2001) when the worst-case approximation error $\bar{e}_\alpha$ is sufficiently small.

Lemma 1. There exists $\zeta > 0$ such that, if $\bar{e}_\alpha < \zeta$, the system in (1) with $u = u_{\text{NN}}(x)$ converges exponentially to some set $\Omega_b \subset \Omega_c$, for all $x(0) \in \Omega_c$. □

Thus, if the maximal approximation error over $\mathcal{X}$ is strictly smaller than ζ, which is tunable through a nonnegative parameter also affecting the size of Ω_b, then the closed-loop in (1) with PWA-NN controller $u_{\text{NN}}(\cdot)$ is ISS and its state trajectories satisfy the constraints, since Ω_c is robust positively invariant. Now, define $\mathcal{X}_\infty$ as the set of states for which the stabilizing unconstrained linear gain (typically the linear quadratic regulator (LQR)), $\bar{K}_{\text{MPC}} \in \mathbb{R}^{m \times n}$, satisfies both state and control constraints, i.e., $\mathcal{X}_\infty \coloneqq \{x \in \mathcal{X} \mid x(0) = x \in \mathcal{X}, Ax(k) + B\bar{K}_{\text{MPC}}x(k) \in \mathcal{X}, \bar{K}_{\text{MPC}}x(k) \in \mathcal{U}, k \in \mathcal{T}, x(T) \in \mathcal{X}\}$ (maximal output admissible set – see (Gilbert and Tan, 1991)). Within $\mathcal{X}_\infty$, the system (4) still enjoys exponential convergence if the local Lipschitz constant of $e(\cdot)$ meets a certain condition:

Lemma 2. There exists $\vartheta > 0$ such that, if $\mathcal{L}_\alpha(e, \mathcal{X}_\infty) < \vartheta$, the system in (1) with $u = u_{\text{NN}}(x)$ converges exponentially to the origin for all $x(0) \in \mathcal{X}_\infty$. □

Putting the previous results together gives us our main stability result, upon which subsequent requirements on the fidelity of our ReLU-based controllers will be based:

Theorem 2.1. If $\bar{e}_\alpha < \zeta$, $\mathcal{L}_\alpha(e, \mathcal{X}_\infty) < \vartheta$, and $b \geq 0$ is chosen so that $\Omega_b \subseteq \mathcal{X}_\infty$, the system in (1) with $u = u_{\text{NN}}(x)$ converges exponentially to the origin, for all $x(0) \in \Omega_c$. □

In the remainder, we provide a MI optimization-based method to compute the maximum approximation error and the (local) Lipschitz constant of $e(\cdot)$ exactly, thus providing conditions sufficient to certify the stability and performance of a ReLU-based approximation of an MPC control law.

3. EXACTL LIPSCHITZ CONSTANT COMPUTATION VIA MIXED-INTEGER LINEAR PROGRAM

We next develop a method of computing the maximum gain (Darup et al., 2017) (and hence the Lipschitz constant, according to (Gorokhovik et al., 1994, Prop. 3.4)) of the MPC policy $u_{\text{MPC}}(\cdot)$ directly via MI programming.

Note that the maximum gain can also be computed by means of available tools that compute the complete explicit solution to mp-QP in (2) directly, e.g., the MPC Toolbox (Bemporad et al., 2021). However, from (Jordan and Dimakis, 2020) we know that the Lipschitz constant of a ReLU network, which we will use to approximate the MPC policy in (2), can itself be computed through a MILP. We therefore require a technique compatible with the one proposed in (Jordan and Dimakis, 2020), which will also allow us subsequently to compute key quantities characterizing the approximation error $e(\cdot)$, according to §2. For the results we are about to introduce, we make a further standard assumption characterizing the constraints of (2) to rule out pathological cases when computing the (unique) solution to the mp-QP in (2).

Standing Assumption 2. (Linear independence constraint qualification (Borrelli et al., 2017, Def. 2.1)) For all $x \in \mathcal{X}$, the linear independence constraint qualification (LICQ) is assumed to hold for the mp-QP in (2). □

Proposition 1. Suppose $\mathcal{X} \subseteq \mathbb{R}^n$ is a polytope and $K : \mathcal{X} \to \mathbb{R}^{m\times n}$ an affine function. Then computing $\mathcal{L}_\alpha(K, \mathcal{X}) = \max_{x\in\mathcal{X}} \|K(x)\|_\alpha$ amounts to an MILP. □

Proposition 1 says that the norm of a matrix whose entries are affine in $x \in \mathcal{X}$ can be computed through an MILP. We now state the main result of this section, which says that the maximum matrix norm taken over the entire partition induced by $u_{\text{MPC}}(\cdot)$ can also be computed via an MILP:

Theorem 3.2. Computing $\mathcal{L}_\alpha(u_{\text{MPC}}, \mathcal{X})$ amounts to an MILP. □

In Table 1 we contrast numerically our proposed approach in Theorem 3.2 with the solution obtained via the MPC Toolbox (Bemporad et al., 2021). Here, the column "# of $\mathcal{R}_\mathcal{A}$" reports the number of polyhedral partitions characterizing eMPC.

4. QUANTIFYING THE APPROXIMATION QUALITY OF PIECEWISE-AFFINE NEURAL NETWORKS

We can now develop computational results that ensure the stability of a ReLU-based control policy u_{NN} constructed based on approximation of a stabilizing MPC law u_{MPC}.

Since the MPC policy u_{MPC} is designed to (exponentially) stabilize the LTI system in (1) to the origin, then we may expect that the ReLU based policy should also be stabilizing if the approximation error $e(\cdot) = u_{\text{NN}}(\cdot) - u_{\text{MPC}}(\cdot)$ is sufficiently small. This error function is the difference of PWA functions, and so also PWA (Gorokhovik et al., 1994, Prop. 1.1). Thus, it can similarly be shown to be bounded and Lipschitz continuous on $\mathcal{X}$, and we can therefore apply the results of §2 to find conditions under which stability is preserved. Whether or not the error can be made sufficiently small to do so depends on both the amount (and quality) of training data and the complexity of the network (i.e., number of neurons and layers).

Theorem 4.3. The approximation error $e(\cdot) = u_{\text{NN}}(\cdot) - u_{\text{MPC}}(\cdot)$ has the following properties:

i) The maximal error $\max_{x\in\mathcal{X}}\|e(x)\|_\alpha =: \bar{e}_\alpha$ can be computed by solving an MILP;
ii) The Lipschitz constant $\mathcal{L}_\alpha(e, \mathcal{X})$ can be computed by solving an MILP. □

By combining known results available in the machine learning literature and the ones developed in this extended abstract, Theorem 4.3 provides an offline, optimization-based procedure to compute exactly both the worst-case approximation error between the PWA mappings associated with the ReLU network in (3) and the MPC law in (2), as $\|e(x)\|_\alpha \le \bar{e}_\alpha$, for all $x \in \mathcal{X}$, and the associated Lipschitz constant over $\mathcal{X}$, $\mathcal{L}_\alpha(e, \mathcal{X})$, for $\alpha \in \{1, \infty\}$. These quantities are precisely of the type required to apply the stability results of §2, and thus allow us to certify the reliability, in terms of stability of the closed-loop system, of a ReLU-based approximation of a given MPC law.

We finally stress that, while $u_{\text{NN}}(\cdot)$ can guarantee state constraint satisfaction for any initial state $x(0) \in \Omega_c$ if some prescribed conditions are met (§2), the input constraints may not be satisfied. This issue can be accommodated either during the training phase by adopting the available techniques in, e.g., (Chen et al., 2018; Karg and Lucia, 2020a,b; Paulson and Mesbah, 2020), or directly after the training process through output verification methods (Bunel et al., 2018; Fazlyab et al., 2020).

5. CONCLUSION

We have shown that the design of ReLU-based approximations with provable stability guarantees require one to construct and solve two MILPs offline, whose associated optimal values characterize key quantities of the approximation error. We have provided a systematic way to encode the maximal gain of a given MPC law through binary and continuous variables subject to MI constraints. This optimization-based result is compatible with existing results from the machine learning literature on computing the Lipschitz constant of a trained ReLU network. Taken together they provide sufficient conditions to assess the reliability, in terms of stability of the closed-loop system, of a given ReLU-based approximation of an MPC scheme.

Abstract: We derive fundamental limitations on the performance that can be achieved by intrinsic averaging algorithms in open multi-agent systems, which are systems subject to random arrivals and departures of agents. Each agent holds an intrinsic value, and their objective is to collaboratively estimate the average of the values of the agents presently in the system. We provide a lower bound on the expected Mean Square Error for such algorithms where we assume that the size of the system remains constant. Our derivation is based on the error obtained with an algorithm that achieves optimal performance under a set of restrictions on the way agents obtain information about one another. This error represents a lower bound on the error obtained with any other algorithm that can be implemented under the same restrictions. This approach is then applied to derive lower bounds on the performance of the well-known Gossip algorithm by considering restrictions that allow implementing it.

Keywords: Systems theory; control, Probability theory and stochastic processes, Average consensus, Open systems

1. PRELIMINARY NOTE

This work is a resubmission of the extended abstract that was accepted for MTNS 2020.

2. INTRODUCTION

Multi-agent systems are being largely studied in various application fields, including *e.g.*, formation control or opinion dynamics, especially for their robustness, flexibility and scalability. Yet, most results obtained in that framework build on the assumption that the composition of the systems remains unchanged throughout the whole process. This assumption is getting increasingly challenged by the growing size of the systems, as it slows down the process, and makes small individual probabilities of arrivals or departures within the system non-negligible. Such systems, called *open*, can also naturally arise when the process is slow enough or chaotic by nature and where communications can be difficult or happen at a time-scale similar to that of the process, e.g. collaborative multi-vehicle systems where vehicles share a stretch of road for a time before heading to different destinations.

In such configurations, analyses and algorithm design become challenging as the state, size, and at some extent objective pursued by the system vary over time with arrivals and departures of agents. Those incessant perturbations require designing algorithms able to deal with a variable objective, and prevent them to achieve the usual convergence. On top of that, results obtained for closed systems do not easily extend to open ones, see e.g. Hendrickx and Martin (2016); Abdelrahim et al. (2017). Little work exists around open systems, including simulation-based analyses performed by Sen and Chakrabarti (2013) or through size-independent quantities in Hendrickx and Martin (2016), and algorithm design for MAX consensus from Abdelrahim et al. (2017). In this work, we extend the results presented in Monnoyer de Galland and Hendrickx (2019) by proposing a general formulation of fundamental performance limitations for algorithms that can be implemented under some restrictions on the exchange of information within the system, and apply it to the Gossip algorithm.

3. PROBLEM STATEMENT

We consider a multi-agent system constituted of N agents labelled from 1 to N, where each agent j owns a constant intrinsic value x_j drawn from some zero-mean distribution of variance σ^2. Every agent j is randomly replaced according to a Poisson process of individual rate $\lambda_r^{(j)}$ resulting in the erasure of the memory of the agent, and to the attribution of a new value x_j to that agent, so that the system is open and its size is constant. Hence the value held by the agents can be seen as a time varying quantity $x_j(t)$ which is modified at replacements. Observe however that our model differs from fixed-size systems with time-varying states and/or topologies: as replacements also induce the erasure of the memory of the replaced agent, they actually correspond to a new agent connecting for the first time to the system, without having access to any information about the past of the process.

Moreover, we consider the agents can collect information about each other at some times in a distributed manner through local interactions. Based on these, their objective is to collaboratively compute the time-varying average of the intrinsic values of the system defined as $\bar{x}(t) := \frac{1}{N}\sum_{j=1}^{N} x_j(t)$. In this work we study the performance of algorithms solving this problem which agents can implement in that setting.

One such algorithm is the well-known Gossip algorithm (see e.g. Boyd et al. (2006)) designed for closed systems. This algorithm relies on pairwise interactions in order to update an estimation of the average: an agent i initializes its estimate to its own value $y_i(t) = x_i$, and then updates it each time it interacts with some agent j at some time t as follows:

$$y_i(t^+) = y_j(t^+) = \frac{y_i(t^-) + y_j(t^-)}{2}. \tag{1}$$

Unlike closed systems, open systems do not allow averaging algorithms to converge to the exact average, and we need to design an alternative way to measure their performance. One possible standard criterion, which we consider in this work, is the Mean Square Error (MSE) defined as

$$C(t) := \frac{1}{N}\sum_{i=1}^{N} \left(\bar{x}(t) - y_i(t)\right)^2. \tag{2}$$

More precisely, we derive lower bounds on

$$\mathbb{E}\left[C(t)\right] = \frac{1}{N}\sum_{i=1}^{N} \mathbb{E}\left[\left(\bar{x}(t) - y_i(t)\right)^2\right] \tag{3}$$

for a set of algorithms that can be implemented under some restrictions on the way agents obtain information about one another. For that purpose, we will evaluate the performance achieved by an algorithm that is provably optimal in a more favorable setting than what is typically allowed. To that end we provide agents with additional knowledge about the dynamics of the system, such as its size and the way replacements and interactions take place, or the distribution from which their values are drawn. The bounds we obtain are then *fundamental performance limitations* for any algorithms that can be implemented under the same restrictions, even if they do not make use of all the available information, and are thus a quality criterion for those algorithms.

In what follows, we propose a generic expression for the lower bound on (3) provided a set of restrictions on the way agents obtain information about one another. We then define such sets that allow implementing the Gossip algorithm presented in equation (1) and derive the corresponding bounds, which are thus valid lower bounds on the performance of that algorithm.

4. MAIN RESULT

In order to derive a lower bound on (3), we define the algorithm that achieves optimal performance under restrictions on the way agents acquire information about each other. This leads to the following definition of that algorithm:

$$y_i^*(t) := \arg\min_{y_i(t)} \left\{ \mathbb{E}\left[\left(\bar{x}(t) - y_i(t)\right)^2 | \omega_i^*(t)\right] \right\}, \tag{4}$$

where $\omega_i^*(t)$ refers to the set containing all the information potentially accumulated by agent i at time t about the other agents in the system under a set of restrictions noted $*$, which characterizes the way that information is obtained by i.

By computing the MSE of algorithm (4), one can by definition obtain a lower bound on that of any other algorithm that can be implemented under the restrictions $*$. This computation relies on a decomposition of the MSE allowing the reduction of its analysis to that of the error of estimation of a single agent j made by another agent i, which is entirely characterized by the most recent information about that agent j available to i. It ultimately leads to

$$\mathbb{E}\left[C(t)\right] \geq \frac{1}{N^3}\sum_{i=1}^{N}\sum_{j=1}^{N} \left(1 - \int_0^t f_{j\to(i)}^{t,*}(s) e^{-2\lambda_r^{(j)} s}\, \mathrm{d}s\right) \sigma^2, \tag{5}$$

where $f_{j\to(i)}^{t,*}(s)$ is a probability density function which characterizes the age of the most recent information about agent j available to i at time t under the restrictions $*$. Observe that this function encapsulates the way information travels in the system, so that one can virtually model any specific graph topology by properly defining it.

The bound (5) is thus a time-dependent lower bound on the MSE of any algorithm that can be implemented under a given set of restrictions $*$. This bound is generic, and properly defining such restrictions $*$ allows instantiating $f_{j\to(i)}^{t,*}(s)$ and then deriving a proper expression for (5).

One can also refine that expression by considering a more particular class of open systems. Typically, one could consider systems characterized by a common replacement rate $\lambda_r^{(j)} = \lambda_r$ and by a probability density function independent of the agents and the time $f_{j\to(i)}^{t,*}(s) = f^*(s)$. Exploiting these properties and taking the limit as $t \to \infty$, a few algebraic steps starting from (5) yield the following reduced expression in steady state for this class of systems:

$$\liminf_{t\to\infty} \mathbb{E}\left[C(t)\right] \geq \frac{N-1}{N^2}\left(1 - \int_0^\infty f^*(s) e^{-2\lambda_r s}\, \mathrm{d}s\right)\sigma^2. \tag{6}$$

5. APPLICATION TO THE GOSSIP ALGORITHM

We finally propose several restriction sets that allow implementing the Gossip algorithm in order to instantiate (5) and (6). This will lead to properly defined bounds that are valid for the Gossip algorithm, and for any other algorithm that can be implemented under those restrictions. We focus on restrictions allowing the agents to gather information through random pairwise interactions happening according to a Poisson process of pairwise rate λ_c (*i.e.* a given pair of agents interacts on average λ_c times per unit of time). One can show that those restrictions indeed allow implementing the Gossip algorithm.

Ping restrictions: The first model relies on a strong assumption which corresponds to the presence of a central unit perfectly knowing the state of the system at all times, and to the absence of erasure of an agent's memory at its replacements. At a communication between two agents, they share what they know, and learn the exact state of the whole system at that time from the central unit. This model is called "*Ping*" in reference to the software testing the reachability of machines in a network, and the corresponding bound is given in steady state and under assumptions of symmetry by the following expression:

$$\liminf_{t\to\infty} \mathbb{E}\left[C(t)\right] \geq \frac{N-1}{N^2}\left(\frac{1}{1 + \frac{N-1}{2}\frac{\lambda_c}{\lambda_r}}\right)\sigma^2. \tag{7}$$

Infection restrictions: The second model is less permissive as it considers that agents only exchange everything they know at the time they communicate to build their estimates. One observes that the travel of information under those restrictions reduces to an infection process where the disease is the information about an agent, and the infection rate is the communication rate λ_c. Two variants of that model arise: respectively with and

without healing (which corresponds to the memory erasure at the replacement of an agent) that respectively lead to the "*SIS*" and "*SI*" models. One then obtains the steady state bound (8) under symmetry assumptions, where w and A contain the information related to the continuous time Markov chains defining the infection process, either for the SI or SIS model:

$$\liminf_{t\to\infty} \mathbb{E}\left[C(t)\right] \geq \frac{N-1}{N^2}\left(1 - w^T A\left(2\lambda_r - A\right)^{-1}\mathbf{e_1}\right)\sigma^2. \quad (8)$$

Those bounds are depicted in Fig. 1, which compares the performance of the Gossip algorithm simulated for ten agents with all the bounds that were obtained above in steady state.

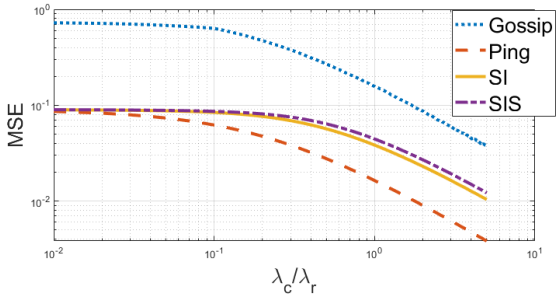

Fig. 1. Steady state MSE comparison showing the validity of (6) for the Gossip performance (blue), where *Ping*, *SI* and *SIS* refer to valid models to instantiate $f^*(s)$ in (6).

It appears that tighter restrictions lead to higher lower bounds on the Mean square Error. More precisely, working with restrictions closer to what the Gossip algorithm actually allows provides a bound that is closer to the actual performance of that algorithm. Moreover, one observes that even though there is a gap between the performance of the Gossip algorithm (in blue) and the different bounds, the general behavior of the MSE is qualitatively well captured. The Gossip is indeed one of the most naive algorithms that can be implemented for achieving average consensus, and does not take into account the openness of the system nor some provided information such as identifiers in its implementation. Hence, it appears that most of the information that was provided to the agents while computing the bounds may be unnecessary in the design of efficient averaging algorithms in open systems in the sense of the Mean Square Error.

6. CONCLUSION

We considered the possibility for agents to join and leave the system in the study of multi-agent systems, and highlighted several challenges that arise in that framework. In particular, this property prevents algorithms to achieve the usual convergence, making their design and analysis challenging.

We focused on averaging algorithms in open systems, for which we obtained a generic formulation of fundamental limitations on their performance given restrictions on the way information is exchanged within the system. Properly defining these restrictions allows deriving lower bounds on the performance of algorithms that are implemented under those restrictions, and thus serve as a quality criterion for them. This was then performed for restrictions allowing implementing the Gossip algorithm, leading to performance limitations for that algorithm.

It appears that defining more restrictive constraints on the information exchange leads to tighter bounds when evaluating the performance of an algorithm. Interestingly, even naive algorithms such as the Gossip show satisfying performance in comparison with rather strong bounds, questioning the possible impact of several parameters that were assumed to be known by the agents when building the bounds, such as identifiers.

Finally, the generalization of our results to systems of time-varying size $N(t)$, *i.e.*, subject to decoupled arrivals and departures is a very interesting yet challenging follow-up for this work. Most on the present analysis relies on the assumption that agents know the system size N, which would be a very strong assumption if that size changes as it gives a significant amount of information about the system. More generally, this extension would require estimating that size in parallel, which is a significant challenge left for future research.

Abstract: The $\mathcal{H}_2$ norm of an exponentially stable system described by Delay Differential Algebraic Equations (DDAEs) might be infinite, due to the existence of hidden feedthrough terms and it might become infinite as a result of infinitesimal changes to the delay parameters. We first introduce the notion of strong $\mathcal{H}_2$ norm of semi-explicit DDAEs, a robustified measure that takes into account delay perturbations, and we analyze its properties. Next, we discuss necessary and sufficient finiteness criteria for the strong $\mathcal{H}_2$ norm in terms of a frequency sweeping test over a hypercube, and in terms of a finite number of equalities involving multi-dimensional powers of a finite set of matrices. Finally, we show that if the $\mathcal{H}_2$ norm of the DDAE is finite, it is possible to construct an exponentially stable neutral delay-differential equation which has the same transfer matrix as the DDAE, without any need for differentiation of inputs or outputs. This connected with a neutral system enables the framework of Lyapunov matrices for computing the $\mathcal{H}_2$ norm.

1. NOTION OF STRONG $\mathcal{H}_2$ NORM

We consider systems described by semi-explicit linear delay-differential algebraic equations (also called coupled delay differential -difference equations) of the form

$$\begin{aligned}\frac{d}{dt}x_1(t) =& A_0^{(11)}x_1(t) + A_0^{(12)}x_2(t) + \sum_{j=1}^{m} A_j^{(11)}x_1(t-h_i)\\ &+ \sum_{j=1}^{m} A_j^{(12)}x_2(t-h_j) + B_1u(t)\\ x_2(t) =& A_0^{(21)}x_1(t) + \sum_{j=1}^{m} A_j^{(21)}x_1(t-h_j)\\ &+ \sum_{j=1}^{m} A_j x_2(t-h_j) + Bu(t)\\ y(t) =& C_1x_1(t) + Cx_2(t),\end{aligned} \tag{1}$$

where $x_1(t) \in \mathbb{R}^r$, $x_2(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^{n_i}$ and $y(t) \in \mathbb{R}^{n_o}$ are state-variables, inputs and outputs at time t. The delays are denoted by $\boldsymbol{h} := (h_1, \ldots, h_m)$.

⋆ This work was supported by project C14/17/072 the KU Leuven Research Council and project G092721N of the Research Foundation-Flanders (FWO - Vlaanderen).

The $\mathcal{H}_2$ norm is an important performance measure in the field of control theory. For an exponentially stable system of the form (1), it is defined as

$$\|G\|_{\mathcal{H}_2} := \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{tr}(G^*(\imath\omega)G(\imath\omega))d\omega},$$

where G is the transfer matrix of system (1).

In contrast to other classes of systems, the $\mathcal{H}_2$ norm of system (1) might be infinite even if the system is exponentially stable, as the DDAE formulation might hide a nontrivial feedthrough term from $u(t)$ to $y(t)$. Furthermore, the function

$$\mathbb{R}^m_{\geq 0} \ni \boldsymbol{h} \mapsto \|G(\cdot;\boldsymbol{h})\|_{\mathcal{H}_2}$$

may not be continuous, even if the system is strongly exponentially stable, as illustrated with the following example.

Example 1. Consider a system of the form

$$\begin{aligned}x_1(t) &= -x_1(t) + u(t),\\ x_2(t) &= A_1x_2(t-h_1) + A_2x_2(t-h_2) + A_3x_2(t-h_3)\\ &\quad + Bu(t),\\ y(t) &= x_1(t) + Cx_2(t),\end{aligned}$$

with matrices

$$A_1 = \begin{pmatrix} 0 & 0 & 0\\ \frac{1}{4} & 0 & -\frac{1}{4}\\ 0 & 0 & 0\end{pmatrix},\ A_2 = \begin{pmatrix} 0 & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & \frac{1}{8}\end{pmatrix},$$

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

$$A_3 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & \frac{1}{32} \\ 0 & 0 & 0 \end{pmatrix}, B = \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix}, C = (0\ 1\ 0)\,.$$

The characteristic equation is given by

$$(s+1)\left(1 - \frac{1}{8}e^{-sh_2}\right) = 0,$$

from which we conclude exponential stability for all delay values. The transfer function of the system is given by

$$G(s) = \frac{1}{s+1} - \frac{1}{4}\frac{\left(e^{-s(h_1+h_2)} - e^{-sh_3}\right)}{8 - e^{-sh_2}}.$$

It is clear from this expression that $\|G\|_{\mathcal{H}_2}$ is finite if and only if $h_3 = h_1 + h_2$, while otherwise we have $\|G\|_{\mathcal{H}_2} = +\infty$. Thus, $\|G\|_{\mathcal{H}_2}$ has a discontinuity at each tuple (h_1, h_2, h_3) for which $h_3 = h_1 + h_2$. ⋄

When defining

$$\mathcal{B}(\boldsymbol{h}, \varepsilon) := \{\boldsymbol{\vartheta} \in \mathbb{R}^m_{\geq 0} : \|\boldsymbol{\vartheta} - \boldsymbol{h}\| < \varepsilon\},$$

the strong $\mathcal{H}_2$ norm of a strongly explonentially stable system of the form 1 is defined as

$$|||G(\cdot;\boldsymbol{h})|||_{\mathcal{H}_2} := \lim_{\varepsilon \to 0+} \sup\{\|G(\cdot;\boldsymbol{h}_\varepsilon)\|_{\mathcal{H}_2} : \boldsymbol{h}_\varepsilon \in \mathcal{B}(\boldsymbol{h}, \varepsilon)\}.$$

In order to characterize its finiteness, we define matrix polynomials $P_{k_1,\ldots,k_m}(A_1, \ldots, A_m)$, with $k_j \in \mathbb{Z}_{\geq 0}, j = 1, \ldots, m$, which are recursively defined through the following expressions:

$$P_{0,\ldots,0}(A_1, \ldots, A_m) := I,$$

$$\begin{aligned} P_{k_1,\ldots,k_m}(A_1, \ldots, A_m) &:= A_1 P_{k_1-1,k_2,\ldots,k_m}(A_1, \ldots, A_m) \\ &+ A_2 P_{k_1,k_2-1,\ldots,k_m}(A_1, \ldots, A_m) + \ldots + \\ &+ A_m P_{k_1,k_2,\ldots,k_m-1}(A_1, \ldots, A_m) \end{aligned}$$

and

$P_{k_1,\ldots,k_m}(A_1, \ldots, A_m) := 0$ if any $k_j \in \mathbb{Z}_{<0}, j = 1, \ldots, m$.

For instance, for $m = 2$ and $k_1 + k_2 \leq 3$, these matrix polynomials are

$$\begin{aligned} &P_{0,0} = I, \\ &P_{1,0} = A_1, \quad P_{0,1} = A_2, \\ &P_{2,0} = A_1^2, \quad P_{1,1} = A_1A_2 + A_2A_1, \quad P_{0,2} = A_2^2, \\ &P_{3,0} = A_1^3, \quad P_{2,1} = A_1^2A_2 + A_1A_2A_1 + A_2A_1^2, \\ &P_{1,2} = A_1A_2^2 + A_2A_1A_2 + A_2^2A_1, \quad P_{0,3} = A_2^3. \end{aligned}$$

We can now formulate the following result.

Theorem 1. Assume that system (1) is strongly stable. The following statements are equivalent.

(1) The strong $\mathcal{H}_2$ norm of (1) is finite.
(2) Condition

$$C\left(I - \sum_{j=1}^m A_j e^{-\imath\vartheta_j}\right)^{-1} B = 0, \tag{2}$$

$\forall(\vartheta_1, \ldots, \vartheta_m) \in [0,\ 2\pi]^m$, is satisfied, with $\imath = \sqrt{-1}$.
(3) Conditions

$$CP_{k_1,\ldots,k_m}(A_1, \ldots, A_m)B = 0, \tag{3}$$

$\forall(k_1, \ldots, k_m) \in \mathbb{Z}^m_{\geq 0}$ are satisfied.
(4) Condition (3) hold $\forall(k_1, \ldots, k_m) \in \mathbb{Z}^m_{\geq 0}$ such that

$$\sum_{j=1}^m k_j < n. \tag{4}$$

Furthermore, if the strong $\mathcal{H}_2$ norm of (1) is finite, it equals its $\mathcal{H}_2$ norm.

Determining whether (2) holds, corresponds to checking a semi-infinite equality over a hyper-cube, that can be reduced to checking an infinite but countable number of equalities (3) and finally to a finite number of equalities determined by (4). As shall be discussed in the presentation, the equivalence between statements (1) and (2) follows from an analysis of the feedthrough terms in the transfer matrix, the equivalence between (1) and (3) from an explicit expression of the impulse response. Finally, the restriction (4) in the numbers of equalities to be checked stems from the observation that $\left\{P_{k_1,\ldots,k_m}(A_1, \ldots, A_m) : \sum_{j=1}^m k_j = \ell\right\}$, with $\ell \geq 0$, are the coefficients of the expansion of the multi-variable matrix polynomial $(A_1z_1 + \ldots + A_mz_m)^\ell$, followed by an application of the Cayley-Hamilton theorem.

It is at this point not yet clear how to compute the $\mathcal{H}_2$ norm whenever it is finite. These observations motivate the developments in the next section.

2. TRANSFORMATION TO A NEUTRAL TYPE SYSTEM

For the sake of a clear presentation, let us first recall the two approaches that exist to perform the transformation of (1) to a delay equation of neutral type, which we will refer to in what follows as *regularization mechanisms* (RMs):

RM1 If $B = 0$, then one can apply the operator $\left(\frac{d}{dt} + I\right)$ to the second set of equations, leading to

$$\begin{aligned} &\dot{x}_2(t) - \sum_{i=1}^m A_i\dot{x}_2(t-h_i) - \sum_{i=0}^m A_i^{(21)}\dot{x}_1(t-h_i) = \\ &- x_2(t) + \sum_{i=1}^m A_i x_2(t-h_i) + \sum_{i=0}^m A_i^{(21)} x_1(t-h_i), \end{aligned}$$

which corresponds to a multiplication with $(s+1)$ in the frequency domain. The reason for combining differentiation with addition to the original equation lies in the preservation of internal stability.

RM2 If $C = 0$, one can define a new variable $\hat{x}_2$ via the stable differential equation $\dot{\hat{x}}_2 + \hat{x}_2 = x_2$ and subsequently substituting x_2 in (1), leading to

$$\begin{aligned} \dot{x}_1(t) - \sum_{i=0}^m A_i^{(12)}\dot{\hat{x}}_2(t-h_i) &= \sum_{i=0}^m A_i^{(11)} x_1(t-h_i) \\ &+ \sum_{i=0}^m A_i^{(12)}\hat{x}_2(t-h_i) + B_1u(t) \\ \dot{\hat{x}}_2(t) - \sum_{i=1}^m A_i\dot{\hat{x}}_2(t-h_i) &= -\hat{x}_2(t) + \sum_{i=1}^m A_i\hat{x}_2(t-h_i) \\ &+ \sum_{i=0}^m A_i^{(21)} x_1(t-h_i) + Bu(t), \\ y(t) &= C_1x_1(t). \end{aligned}$$

It should be noted that RM2 is equivalent to applying RM1 to the dual (transposed) system of (1), followed by taking the transposed system again.

If $B \neq 0$ in RM1, differentiation of the difference part leads to derivatives of the input, whereas if $C \neq 0$ in RM2, the change of variable implies taking derivatives of the output. Derivatives of the input and output signals in the regularized system are not desired, and their absence is also of prime importance for the computation of $\|G\|_{\mathcal{H}_2}$, as shall become clear from Corollary 3.

The presented approach to handle the general case, where $B \neq 0$ and $C \neq 0$, consists of proving first that if the $\mathcal{H}_2$ norm is finite, system (1) has the same transfer matrix as the augmented system

$$\begin{aligned}
\frac{d}{dt}x_1(t) =& A_0^{(11)}x_1(t) + A_0^{(12)}x_2(t) + \sum_{j=1}^{m} A_j^{(11)}x_1(t-h_i) \\
&+ \sum_{j=1}^{m} A_j^{(12)}x_2(t-h_j) + B_1u(t) \\
x_2(t) =& A_0^{(21)}x_1(t) + \sum_{j=1}^{m} A_j^{(21)}x_1(t-h_j) \\
&+ \sum_{j=1}^{m} A_j x_2(t-h_j) + Bu(t) \\
x_3(t) =& A_0^{(21)}x_1(t) + \sum_{j=1}^{m} A_j^{(21)}x_1(t-h_j) \\
&+ \sum_{j=1}^{m} A_j x_3(t-h_j) \\
y(t) =& C_1x_1(t) + Cx_3(t),
\end{aligned} \tag{5}$$

where an additional variable x_3 is introduced, which allows to alternatively express the output equation (in terms of x_1 and x_3 instead of x_1 and x_2).

Next, the structure of (5) is such that we can apply RM1 and RM2 without differentiation of input or output. More precisely, since the equation for x_3 does not depend on the input we can turn it into a differential equation by applying RM1. Since the alternative output equation does not depend on x_2 we can apply RM2 and substitute x_2 by $\hat{\dot{x}}_2 + \hat{x}_2$. The additional dynamics, introduced by differentiation, are stable and either not controllable or not observable. In this way, we arrive at the following result.

Theorem 2. Let system (1) be strongly stable and condition (3)-(4) be satisfied. Consider the neutral type system

$$\begin{aligned}
\mathcal{D}_0\dot{x}(t) - \sum_{i=1}^{m} \mathcal{D}_i\dot{x}(t-h_i) =& \sum_{i=0}^{m} \mathcal{F}_i x(t-h_i) + \mathcal{B}u(t), \\
y(t) =& \mathcal{C}x(t),
\end{aligned} \tag{6}$$

where $x(t) \in \mathbb{R}^{2n+r}$ is a extended state vector composed by x_1, $\hat{x}_2$ and x_3, $\mathcal{B}^T := \begin{bmatrix} B_1^T & B^T & 0 \end{bmatrix}$, $\mathcal{C} := \begin{pmatrix} C_1 & 0 & C \end{pmatrix}$,

$$\mathcal{D}_0 = \begin{pmatrix} I & -A_0^{(12)} & 0 \\ 0 & I & 0 \\ -A_0^{(21)} & 0 & I \end{pmatrix}, \; \mathcal{D}_i = \begin{pmatrix} 0 & A_i^{(12)} & 0 \\ 0 & A_i & 0 \\ A_i^{(21)} & 0 & A_i \end{pmatrix}$$

and

$$\mathcal{F}_0 = \begin{pmatrix} A_0^{(11)} & A_0^{(12)} & 0 \\ A_0^{(21)} & -I & 0 \\ A_0^{(21)} & 0 & -I \end{pmatrix}, \; \mathcal{F}_i = \begin{pmatrix} A_i^{(11)} & A_i^{(12)} & 0 \\ A_i^{(21)} & A_i & 0 \\ A_i^{(21)} & 0 & A_i \end{pmatrix},$$

$i = 1, \ldots, m$, and its transfer matrix

$$\mathcal{G}(s) := \mathcal{C}\mathcal{H}^{-1}(s)\mathcal{B} \;\; s \in \mathbb{C} \setminus \Lambda_n$$

with $\Lambda_n := \{s \in \mathbb{C} : \det(\mathcal{H}(s)) = 0\}$, and

$$\mathcal{H}(s) = s\mathcal{D}_0 - s\sum_{i=1}^{m} \mathcal{D}_i e^{-sh_i} - \sum_{i=0}^{m} \mathcal{F}_i e^{-sh_i}.$$

It holds that

$$G(s) = \mathcal{G}(s), \; s \in \mathbb{C} \setminus \Lambda_n.$$

Moreover, the spectrum of system (6) satisfies

$$\Lambda_n = \Lambda \cup \Lambda_d \cup \{-1\}, \tag{7}$$

where $\Lambda_d := \{s \in \mathbb{C} : \det(A_{22}(s)) = 0\}$.

This result is particularly relevant for providing a formula for the computation of the $\mathcal{H}_2$ norm, as shown in the next corollary. Note that if the strong $\mathcal{H}_2$ norm is finite, it equals the $\mathcal{H}_2$ norm for the nominal delay values; see Theorem 1.

Corollary 3. If system (1) is strongly stable and condition (3)-(4) are satisfied, then we have

$$|||G|||_{\mathcal{H}_2} = \|G\|_{\mathcal{H}_2} = \|\mathcal{G}\|_{\mathcal{H}_2} = \sqrt{\mathrm{Tr}\,(\mathcal{B}^T U(0)\mathcal{B})},$$

where $U : [-h_m, h_m] \mapsto \mathbb{R}^{n\times n}$ is the so-called delay Lyapunov matrix associated with $\mathcal{C}^T\mathcal{C}$ of neutral type system (6).

Abstract: We consider orthogonal transformations of arbitrary square matrices to a form where all diagonal entries are equal. In our main results we treat the simultaneous transformation of two matrices and the symplectic orthogonal transformation of one matrix. A relation to the joint real numerical range is worked out, efficient numerical algorithms are developed and applications to stabilization by rotation and by noise are presented.

Keywords: Matrix methods, simultaneous stabilization, stochastic systems, 15A21, 15B57, 93D15

1. INTRODUCTION

A square matrix whose diagonal entries are all zero, is sometimes called a *hollow matrix*, e.g. Charles et al. (2013); Farber and Johnson (2015); Kurata and Bapat (2016); Neven and Bastin (2018). By a theorem of Fillmore (1969), which is closely related to older results of Schur (1923); Horn (1954), every real square zero-trace matrix is orthogonally similar to a hollow matrix. Taken with a pinch of salt, the structure of a hollow matrix can be viewed as the negative of the spectral normal form (e.g. of a symmetric matrix), where the zeros are placed outside the diagonal. While the spectral form reveals an orthogonal basis of eigenvectors, a hollow form reveals an orthogonal basis of neutral vectors, i.e. vectors for which the quadratic form associated to the matrix vanishes.
This property turns out to be relevant in asymptotic eigenvalue considerations. More concretely, we use it to extend and give new proofs for results on stabilization of linear systems by rotational forces or by noise. Since the pioneering work of Arnold et al. (1983) these phenomena have received ongoing attention, with current interest e.g. in stochastic partial differential equations or Hamiltonian systems, Sri Namachchivaya and Vedula (2000); Caraballo and Robinson (2004); Kolba et al. (2019). Our new contribution concerns simultaneous stabilization by noise and features a new method of proof, which relies on an orthogonal transformation of matrices to hollow form.
It is easy to see that – in contrast to the spectral transformation – the transformation to hollow form leaves a lot of freedom to require further properties. In the present note, we first show that it is possible to transform two zero-trace matrices simultaneously to an almost hollow form, as will be specified in Section 2. In a non-constructive manner, the proof can be based on Brickman's theorem Brickman (1961) that the real joint numerical range of two real matrices is convex. Moreover, the simultaneous transformation result allows to prove a stronger version of Fillmore's theorem, namely that every real square zero-trace matrix is orthogonal-symplectically similar to a hollow matrix.
As an application, we show that a number of linear dissipative systems can be stabilized simultaneously by the same stochastic noise process, provided the coefficient matrices can be made almost hollow simultaneously by an orthogonal transformation.
The basis of this contribution is the paper Damm and Fassbender (2020), from which essential parts of this extended abstract are taken. But we also consider some more recent extensions and examples.

2. HOLLOW MATRICES AND ORTHOGONAL TRANSFORMATIONS

We first review some known facts on hollow matrices and then present our main results.

Definition 1. Let $A = (a_{ij}) \in \mathbb{R}^{n\times n}$.

(i) We call A *hollow*, if $a_{ii} = 0$ for all $i = 1, \dots, n$.
(ii) We call A *almost hollow*, if $a_{ii} = 0$ for $i = 3, \dots, n$ and $a_{11} = -a_{22}$.
(iii) We say that A is 2×2-*block hollow*, if $a_{ii} = -a_{i+1,i+1}$ for $i = 1, 3, \dots$ and $a_{nn} = 0$ in the case that n is odd.
(iv) If $\operatorname{trace} A = 0$, then A is called a *zero trace* matrix.

Obviously, 'hollow' $\Rightarrow$ 'almost hollow' $\Rightarrow$ '2×2-block hollow' $\Rightarrow$ 'zero trace'. Vice versa, $\operatorname{trace} A = 0$ implies that A is orthogonally similar to a hollow matrix. This result has been proven in Fillmore (1969). We add a proof, because similar arguments will be used later.

Lemma 2. Let $A \in \mathbb{R}^{n\times n}$ with $\operatorname{trace} A = 0$.

(a) There exists a vector $v \in \mathbb{R}^n$ with $v \neq 0$, such that $v^T A v = 0$.
(b) There exists an orthogonal matrix $V \in \mathbb{R}^{n\times n}$, such that $V^T A V$ is hollow.

Proof. (a) If $a_{11} = 0$, then we can choose $v = e_1$. Otherwise let (after possibly dividing A by a_{11}) w.l.o.g. $a_{11} = 1$. Since $\operatorname{trace} A = 0$, there exists $j \in \{2, \dots, n\}$ with $a_{jj} < 0$. For $v = xe_1 + e_j$ with $x \in \mathbb{R}$, we have

$$v^T A v = x^2 + (a_{1j} + a_{j1})x + a_{jj}$$

which has two real zeros. Hence (a) follows.
(b) Extend $v_1 = v/\|v\|$ with v from (a), to an orthonormal matrix $V_1 = [v_1, \ldots, v_n]$. Then $V^T A V = \begin{bmatrix} 0 & \star \\ \star & A_1 \end{bmatrix}$ with $A_1 \in \mathbb{R}^{(n-1)\times(n-1)}$ and $\operatorname{trace} A_1 = \operatorname{trace} A = 0$. Therefore we can proceed with A_1 as with A.

Corollary 3. For $A \in \mathbb{R}^{n\times n}$, there exists an orthogonal matrix $V \in \mathbb{R}^{n\times n}$, such that all diagonal entries of $V^T A V$ are equal.

Proof. We set $A_0 = A - \frac{\operatorname{trace} A}{n} I$. By Lemma 2 there exists an orthogonal matrix V such that $V^T A_0 V$ is hollow. Then $V^T A V = V^T A_0 V + \frac{\operatorname{trace} A}{n} I$.

Remark 4. (a) A transformation matrix V making $V^T A V$ hollow as in Lemma 2 will sometimes be called an *(orthogonal) hollowiser (for A).*
(b) As is evident from the construction, the hollowiser V is not unique. In the following we will exploit this freedom to transform two matrices simultaneously or to replace V by an orthogonal symplectic matrix.
(c) Since $V^T A V$ is hollow, if and only if $V^T(A + A^T)V$ is hollow, there is no restriction in considering only symmetric matrices.
(d) We are mainly interested in the real case, but it is possible to transfer our results to the complex case, where $A \in \mathbb{C}^{n\times n}$ and V is unitary.

2.1 Simultaneous transformation of two matrices

Simultaneous transformation of several matrices to a certain form (e.g. spectral form) usually requires quite restrictive assumptions. Therefore it is remarkable that an arbitrary pair of zero trace matrices can simultaneously be transformed to an almost hollow pair. This is a consequence of a Brickman's theorem.

Theorem 5. (Brickman (1961)). Let $A, B \in \mathbb{R}^{n\times n}$ with $n \geq 3$. Then the set

$$W(A,B) = \{(x^T A x, x^T B x) \mid x \in \mathbb{R}^n, \|x\| = 1\}$$

is convex.

Proposition 6. Let $A, B \in \mathbb{R}^{n\times n}$ be zero trace matrices.

(a) If $n \geq 3$, there exists a nonzero vector $v \in \mathbb{R}^n$, such that $v^T A v = v^T B v = 0$.
(b) There exists an orthogonal matrix $V \in \mathbb{R}^{n\times n}$ such that $V^T A V$ is hollow and $V^T B V$ is almost hollow.

Proof. (a): By Lemma 2, we can assume w.l.o.g. that A is hollow. If $b_{jj} = 0$ for some j, then we can choose $v = e_j$. Otherwise, since $\operatorname{trace} B = 0$, not all the signs of the b_{jj} are equal. For simplicity of notation assume that $b_{11} > 0$ and $b_{22} < 0$. The points $(e_1^T A e_1, e_1^T B e_1) = (0, b_{11})$ and $(e_2^T A e_2, e_2^T B e_2) = (0, b_{22})$ lie in the joint real numerical range of A and B, defined as

$$W(A,B) = \{(x^T A x, x^T B x) \mid x \in \mathbb{R}^n, \|x\| = 1\} \subset \mathbb{R}^2 .$$

According to Theorem 5 the set $W(A,B)$ is convex for $n \geq 3$. Hence it also contains $(0,0) = (v^T A v, v^T B v)$ for some unit vector $v \in \mathbb{R}^n$.
(b): Apply (a) repeatedly as in the proof of Lemma 2(b) until the remaining submatrix is smaller than 3×3 (where (a) is applied only for A).

Remark 7. The assumption in Proposition 6(a) that $n \geq 3$ is essential. As the standard counterexample consider $A = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$ and $B = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$. For $v = \left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right]$, we have $v^T A v = x^2 - y^2$ and $v^T B v = 2xy$. If both forms are zero, then necessarily $x = y = 0$. Therefore, in general, a pair of symmetric matrices with zero trace is not simultaneously orthogonally similar to a pair of hollow matrices.

2.2 Symplectic transformation of a matrix

Symplectic transformations play an important role in Hamiltonian systems, e.g. Meyer et al. (2009). We briefly recapitulate some elementary facts. A real *Hamiltonian matrix* has the form

$$H = \begin{bmatrix} A & P \\ Q & -A^T \end{bmatrix} \in \mathbb{R}^{2n\times 2n} ,$$

where $A \in \mathbb{R}^{n\times n}$ is arbitrary, while $P, Q \in \mathbb{R}^{n\times n}$ are symmetric. If $J = \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix}$, then all real Hamiltonian matrices are characterized by the property that JH is symmetric. A real matrix $U \in \mathbb{R}^{2n\times 2n}$ is called *symplectic* if $U^T J U = J$. If U is symplectic, then the transformation $H \mapsto U^{-1} H U$ preserves the Hamiltonian structure. Amongst other things, symplectic orthogonal transformations are relevant for the Hamiltonian eigenvalue problem, e.g. Paige and van Loan (1981); van Loan (1984); Fassbender (2000). There is a rich theory on normal forms of Hamiltonian matrices under orthogonal symplectic transformations (e.g. Byers (1986); Lin et al. (1999)). It is, however, a surprising improvement of Lemma 2 that an arbitrary zero trace matrix can be hollowised by a symplectic orthogonal transformation.

Theorem 8. Consider a matrix $A \in \mathbb{R}^{2n\times 2n}$ with $n \geq 1$. Then there exists a symplectic orthogonal matrix U, such that $U^T A U$ has constant diagonal.

Proof. W.l.o.g. we can assume that A is symmetric with $\operatorname{trace} A = 0$. The transformation U is constructed in several steps, where we make use of the orthogonal symplectic transformations above.

1st step: Let $d_1, \ldots, d_{2n}$ denote the diagonal entries of A. Using a suitable symplectic Givens matrix $G_k(c,s)$ for the transformation $A^+ = G_k(c,s)^T A G_k(c,s)$ we can achieve that $d_k^+ = d_{k+n}^+$. After n such transformations we have

$$A^+ = \begin{bmatrix} A_1^+ & \star \\ \star & A_2^+ \end{bmatrix} = \begin{bmatrix} d_1^+ & & \star & & & \\ & \ddots & & \star & & \\ \star & & d_n^+ & & & \\ & & & d_1^+ & & \star \\ & \star & & & \ddots & \\ & & & \star & & d_n^+ \end{bmatrix} .$$

In particular $\operatorname{trace} A_1^+ = \operatorname{trace} A_2^+ = 0$.

2nd step: By Proposition 6, there exists an orthogonal matrix $V \in \mathbb{R}^{n\times n}$, such that $V^T A_1^+ V$ and $V^T A_2^+ V$ are (almost) hollow. Thus, for the symplectic orthogonal matrix $U = \begin{bmatrix} V & 0 \\ 0 & V \end{bmatrix}$, we have (with $d_1 = 0$)

$$U^T A^+ U = \left[\begin{array}{cc|cc} \begin{bmatrix} d_1 & a \\ a & -d_1 \end{bmatrix} & \star & & \star \\ & \ddots & & \\ \star & 0 & & \\ \hline & & \begin{bmatrix} d_2 & b \\ b & -d_2 \end{bmatrix} & \star \\ \star & & & \ddots \\ & & \star & 0 \end{array}\right] .$$

3rd step: It suffices now to consider 4×4 matrices of the form $A = \begin{bmatrix} d_1 & a & \star & \star \\ a & -d_1 & \star & \star \\ \star & \star & d_2 & b \\ \star & \star & b & -d_2 \end{bmatrix}$. For these, a symplectic orthogonal transformation can be computed explicitly, but the details are omitted here.

3. APPLICATIONS TO STABILIZATION PROBLEMS

In this section we present two related stabilization problems. Both deal with unstable linear ordinary differential equations, whose coefficient matrix has negative trace. Such systems have stable and unstable modes, but the stable ones dominate. By a mixing of the modes the system can be stabilized. This mixing can be achieved e.g. by adding rotational forces or stochastic terms. For both cases we extend known results from the literature. The basic idea lies in an asymptotic analysis based on the hollow forms constructed in the previous sections.

3.1 Hamiltonian stabilization by rotation

A linear autonomous system $\dot{x} = Ax$ is called asymptotically stable, if all solutions $x(t)$ converge to 0 for $t \to \infty$. It is well known, that this is equivalent to the spectrum of A being contained in the open left half plane, $\sigma(A) \subset \mathbb{C}_-$. In this case, necessarily $\operatorname{trace} A < 0$. Vice versa, one can ask, whether for any matrix A with $\operatorname{trace} A < 0$, there exists a zero trace matrix M of a certain type, such that $\sigma(A + M) \subset \mathbb{C}_-$. In Crauel et al. (2007) it has been shown, that such a matrix M can always be chosen to be skew-symmetric. Then we say that M stabilizes A or by rotation, see e.g. Baxendale and Hennig (1993). The following theorem extends this result.

Theorem 9. Let $A \in \mathbb{R}^{2n\times 2n}$ with $\operatorname{trace} A < 0$. Then there exists a skew-symmetric Hamiltonian matrix M, such that $\sigma(A + M) \subset \mathbb{C}_-$.

3.2 Simultaneous stabilization by noise

Stabilization of a dynamic system by noise processes is an interesting phenomenon, which was analyzed in Arnold et al. (1983) (see also e.g. Arnold (1990); Caraballo and Robinson (2004)). As a particular situation, we consider the Stratonovich equation

$$dx = Ax\,dt + Mx \circ dw\ .$$

For a given matrix $A \in \mathbb{R}^{n\times n}$ we want to construct M such that this system is asymptotically mean square stable. It follows from results in Arnold et al. (1983) that this is possible (with a skew-symmetric M), if and only if $\operatorname{trace} A < 0$. Here we derive the following generalization.

Theorem 10. Let $A_1, A_2 \in \mathbb{R}^{n\times n}$ with $\operatorname{trace} A_1 < 0$ and $\operatorname{trace} A_2 < 0$ be given. Then there exists a common skew-symmetric matrix M, such that the systems

$$dx_1 = A_1 x_1\,dt + Mx_1 \circ dw_1$$
$$dx_2 = A_2 x_2\,dt + Mx_2 \circ dw_2$$

are both asymptotically mean square stable.

Remark 11. The proof of Theorem 10 exploits a simultaneous orthogonal transformation of $A_j - \frac{\operatorname{trace} A_j}{n} I$, $j = 1, 2$ to 2×2-block hollow form, which exists by Proposition 6. If, more generally, such a simultaneous transformation is possible for $m > 2$ matrices $A_j \in \mathbb{R}^{n\times n}$ with $\operatorname{trace} A_j < 0$ for $j = 1, \ldots, m$, then by the same argument there exists a common matrix M, such that all systems

$$dx_j = A_j x_j\,dt + Mx_j \circ dw_j \quad j = 1, \ldots, m$$

are asymptotically mean square stable.

4. OUTLOOK

Remark 11 raises the following question: How many zero-trace $n \times n$ matrices can be transformed simultaneously to 2×2-block hollow form by an orthogonal matrix V? Let us call such a set now briefly 2×2-hollowisable.

Note that the set of $n \times n$ orthogonal matrices constitutes a manifold of dimension $N = \frac{1}{2}n(n-1)$. We can view this as the number of degrees of freedom. To count the number of constraints let us assume n to be even. For a zero trace matrix $A \in \mathbb{R}^{n\times n}$, the condition that $\tilde{A} = V^T AV$ is 2×2-block hollow imposes the $C = \frac{1}{2}(n-1)$ conditions $\tilde{a}_{11} = -\tilde{a}_{22}, \tilde{a}_{33} = -\tilde{a}_{44}, \ldots, \tilde{a}_{n-3,n-3} = -\tilde{a}_{n-2,n-2}$. The last condition $\tilde{a}_{n-1,n-1} = -\tilde{a}_{n,n}$ is then satisfied automatically by the zero trace condition.
Thus, we might hope for $N/C = n$ zero trace $n \times n$ matrices to be 2×2-hollowisable. This is endorsed by numerical experiments with randomly generated zero trace matrices. On the other hand, the following lemmas provide counterexamples of, respectively, four 4×4 zero trace matrices and five zero trace matrices of arbitrary dimensions that are not 2×2-hollowisable. These results follow by elementary but tedious calculations, which are omitted.

Lemma 12. The set of matrices

$$\begin{bmatrix} 0&1&0&0\\1&0&0&0\\0&0&0&0\\0&0&0&0 \end{bmatrix}, \begin{bmatrix} 0&0&1&0\\0&0&0&0\\1&0&0&0\\0&0&0&0 \end{bmatrix}, \begin{bmatrix} 1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&-1 \end{bmatrix}, \begin{bmatrix} 1&0&0&1\\0&-1&0&0\\0&0&0&0\\1&0&0&0 \end{bmatrix} .$$

is not 2×2 hollowisable.

Lemma 13. For the matrices $B_1, \ldots, B_5$ given by

$$\begin{bmatrix} 1&0&0\\0&-1&0\\0&0&0 \end{bmatrix}, \begin{bmatrix} 1&0&0\\0&0&0\\0&0&-1 \end{bmatrix}, \begin{bmatrix} 0&1&0\\1&0&0\\0&0&0 \end{bmatrix}, \begin{bmatrix} 0&0&1\\0&0&0\\1&0&0 \end{bmatrix}, \begin{bmatrix} 0&0&0\\0&0&1\\0&1&0 \end{bmatrix}$$

let $A_j = \left[\begin{array}{c|c} B_j & 0 \\ \hline 0 & 0 \end{array}\right] \in \mathbb{R}^{n\times n}$ with $n \geq 3$ and $j = 1, \ldots, 5$.
Then the set $\{A_1, \ldots, A_5\}$ is not 2×2-hollowisable.

This gives rise to further connections and questions. For instance, a simultaneous transformation to a 2×2-block hollow form is related to the real 2-nd joint numerical range (cf. Fillmore and Williams (1971); Li and Poon (2000)). General conditions on the convexity of the real 2-nd numerical range (like e.g. in Gutkin et al. (2004)) do not seem to be available.
In particular, we have to discuss the following questions:

- Are three zero trace matrices always 2×2-hollowisable?
- Are four zero trace $n \times n$ matrices with $n > 4$ always 2×2-hollowisable?
- What general condition makes n zero trace $n \times n$ matrices 2×2-hollowisable?

Abstract: In this work, we study economic model predictive control (MPC) in situations where the optimal operating behavior is periodic. In such a setting, the performance of a plain economic MPC scheme without terminal conditions can generally be far from optimal even with arbitrarily long prediction horizons. Whereas there are modified economic MPC schemes that guarantee optimal performance, all of them are based on prior knowledge of the optimal period length or of the optimal periodic orbit itself. In contrast to these approaches, we propose to achieve optimality by multiplying the stage cost by a linear discount factor. This modification is not only easy to implement but also independent of any system- or cost-specific properties, making the scheme robust against online changes therein. Under standard dissipativity and controllability assumptions, we can prove that the resulting linearly discounted economic MPC without terminal conditions achieves optimal asymptotic average performance up to an error that vanishes with growing prediction horizons. Moreover, we can guarantee practical asymptotic stability of the optimal periodic orbit under slightly stronger assumptions.

Keywords: Economic model predictive control, Optimal periodic operation, Turnpike property.

1. INTRODUCTION

Economic model predictive control (MPC) (see, e.g., (Ellis et al., 2014), (Grüne and Pannek, 2017), (Faulwasser et al., 2018)) is an appealing control strategy for process control and other engineering applications due to its ability to directly optimize an economic criterion. In MPC, the control input is computed at each time step by solving a finite-horizon optimal control problem (OCP) online, in which the cost to be optimized can represent energy consumption, production amounts, or other physical or virtual costs. Whereas this control strategy is intuitive and in some examples very successful, its closed-loop performance can generally be far from optimal.

It is known that optimal operation at a steady state or at a periodic orbit is under a mild controllability condition equivalent to a certain dissipativity property (Müller et al., 2015). This property can be used to prove convergence of the closed loop to the optimal operating behavior by adding suitable terminal cost or terminal constraints to the OCP (see, e.g., (Amrit et al., 2011) for steady states, or (Zanon et al., 2017) for periodic orbits). Whereas this modification leads to an optimal asymptotic average performance of the closed loop, it requires significant offline design efforts including knowledge of a local control Lyapunov function with respect to the optimal steady state or optimal periodic orbit. A different approach is to implement the OCP without any terminal conditions. In case that steady-state operation is optimal, this plain MPC scheme achieves suboptimal asymptotic average performance under a similar dissipativity and controllability assumption, where the suboptimality is vanishing with growing prediction horizons (Grüne, 2013), (Grüne and Stieler, 2014). However, a fundamental limitation of this scheme is observed in (Müller and Grüne, 2016, Ex. 4): In case that periodic operation is optimal, the closed-loop asymptotic average performance can generally be far from optimal even for arbitrarily long prediction horizons. The problem is when the value function varies on the optimal periodic orbit, an unrewarding first step (e.g., waiting) may be preferred just to have a certain phase at the end of the prediction horizon. Since in MPC only the first step is actually implemented, it can cause a severe performance loss in closed loop if the first step is unrewarding. As solution, Müller and Grüne (2016) propose to implement a $p^\star$-step MPC scheme, where $p^\star$ is the optimal period length. Alternatively, Köhler et al. (2018) require the stage cost and the value function to be constant on the optimal periodic orbit. However, both solutions are not entirely satisfying since they either only work in a particular special case or still depend on the system and cost specific knowledge of the optimal period length such that an offline

Bayreuth, Germany, 12-16 September 2022

design is necessary and needs to be repeated whenever the system or the economic cost change during operation.

In this work, we provide a solution to this latter problem and propose to mitigate the troubling effects at the end of the prediction horizon by multiplying the cost with a linear discount factor, which does not require any offline design and must not be adapted if the system or the cost change online. The main contribution of this work is a mathematical proof that this linearly discounted economic MPC scheme without terminal conditions achieves optimal asymptotic average performance up to an error vanishing with growing prediction horizons in situations where the optimal operating behavior is periodic. Moreover, we show that the MPC scheme renders the optimal orbit practically asymptotically stable. Both results are established based on a weaker version of the well known turnpike property, which is commonly used to analyze economic MPC without terminal conditions (e.g., (Grüne and Pannek, 2017)). However, due to space limitations, all proofs and numerical examples are omitted in this extended abstract and can be found in the journal version (Schwenkel et al., 2022).

The extended abstract is structured as follows: After denoting the problem setup more formally in Sec. 2 and defining the discounted OCP in Sec. 3, we state the main results in Sec. 4 and discuss our conclusions in Sec. 5.

Notation. We denote the set of naturals including 0 by $\mathbb{N}$, the set of reals by $\mathbb{R}$, and the set of integers in the interval $[a,b]$ by $\mathbb{I}_{[a,b]}$ for $a \leq b$ and define $\mathbb{I}_{[a,b]} = \emptyset$ for $a > b$. Further, we define the notation $[k]_p$ for the modulo operation, i.e., for the remainder when dividing k by p. Let $\mathcal{K}_\infty$ denote the set of continuous and monotonically increasing functions $\alpha : [0,\infty) \to [0,\infty)$ that satisfy $\alpha(0) = 0$ and $\lim_{t\to\infty} \alpha(t) = \infty$. Moreover, let $\mathcal{L}$ denote the set of continuous and monotonically decreasing functions $\delta : [0,\infty) \to [0,\infty)$ that satisfy $\lim_{t\to\infty} \delta(t) = 0$.

2. PROBLEM SETUP

In this section, we state the problem setup, which is to optimize the asymptotic average performance when controlling a nonlinear system that is optimally operated at a periodic orbit. As in (Müller and Grüne, 2016), (Zanon et al., 2017), and (Köhler et al., 2018), we consider a nonlinear discrete-time system

$$x(k+1) = f(x(k), u(k)) \tag{1}$$

subject to the constraints $x(k) \in \mathbb{X} \subset \mathbb{R}^n$ and $u(k) \in \mathbb{U} \subset \mathbb{R}^m$. We denote the trajectory resulting from a specific input sequence $u \in \mathbb{U}^N$ and the initial condition $x_0 \in \mathbb{X}$ with $x_u(k, x_0)$, defined by $x_u(0, x_0) = x_0$ and $x_u(k+1, x_0) = f(x_u(k, x_0), u(k))$ for $k \in \mathbb{I}_{[0,N-1]}$. Occasionally, we will use this notation also for feedback laws $\mu : \mathbb{X} \to \mathbb{U}$, in the natural sense $u(k) = \mu(x_\mu(k, x_0))$. Further, for each $x \in \mathbb{X}$ we denote the set of feasible control sequences of length N starting at x with $\mathbb{U}^N(x) := \{u \in \mathbb{U}^N | \forall k \in \mathbb{I}_{[0,N]} : x_u(k,x) \in \mathbb{X}\}$. The system is equipped with a stage cost function $\ell : \mathbb{X} \times \mathbb{U} \to \mathbb{R}$ and the control objective is to operate the system such that ℓ is minimized. To be more precise, for each $x \in \mathbb{X}$ and $u \in \mathbb{U}^T(x)$ we can define the accumulated cost

$$J_T(x,u) := \sum_{k=0}^{T-1} \ell(x_u(k,x), u(k)). \tag{2}$$

We are interested in finding a controller that generates in closed loop a sequence of inputs $u \in \mathbb{U}^\infty(x)$ such that the asymptotic average performance

$$J_\infty^{\mathrm{av}}(x,u) = \limsup_{T\to\infty} \frac{1}{T} J_T(x,u) \tag{3}$$

is minimized. All assumptions in this paper are equivalent to assumptions in Müller and Grüne (2016), especially the main results are stated under the same assumptions.

Assumption 1. (Continuity and compactness). *The functions f and ℓ are continuous, and the constraints $\mathbb{X} \times \mathbb{U}$ are compact. The set $\mathbb{X}$ is control invariant, i.e., $\mathbb{U}^\infty(x) \neq \emptyset$ for all $x \in \mathbb{X}$.*

The assumption of control invariance of $\mathbb{X}$ is commonly assumed in economic MPC without terminal conditions (e.g., in (Grüne, 2013), (Müller and Grüne, 2016), or (Köhler et al., 2018)) to simplify the analysis with the argument that it can be relaxed using methods similar to (Grüne and Pannek, 2017, Chapter 7.2 and 7.3).

Let us formally define (optimal, minimal) periodic orbits [1].

Definition 2. (Optimal periodic orbit). *A p-tuple $\Pi \in (\mathbb{X}\times\mathbb{U})^p$, $p \in \mathbb{N}$ is called a* feasible p-periodic orbit*, if its projection $\Pi_\mathbb{X}$ onto $\mathbb{X}^p$ satisfies*

$$\Pi_\mathbb{X}([k+1]_p) = f(\Pi(k)) \tag{4}$$

for all $k \in \mathbb{I}_{[0,p-1]}$. A p-periodic orbit Π is called minimal, if $\Pi_\mathbb{X}(k) = \Pi_\mathbb{X}(j) \Rightarrow k = j$ for all $k, j \in \mathbb{I}_{[0,p-1]}$. The distance of a pair $(x,u) \in \mathbb{X} \times \mathbb{U}$ to the orbit Π is defined as $\|(x,u)\|_\Pi := \inf_{k\in\mathbb{I}_{[0,p-1]}} \|(x,u) - \Pi(k)\|$. The set of all feasible p-periodic orbits is denoted by S_Π^p. The average cost at $\Pi \in S_\Pi^p$ is defined as $\ell^p(\Pi) := \frac{1}{p}\sum_{k=0}^{p-1} \ell(\Pi(k))$. If a feasible $p^\star$-periodic orbit $\Pi^\star$ satisfies

$$\ell^{p^\star}(\Pi^\star) = \inf_{p\in\mathbb{N},\, \Pi\in S_\Pi^p} \ell^p(\Pi) =: \ell^\star, \tag{5}$$

then $\Pi^\star$ is called an optimal periodic orbit *and $p^\star$ is called an* optimal period length*.*

Note that Ass. 1 guarantees that $\ell^\star$ in (5) is finite and that a minimizer $\Phi^\star$ exists. Further, note that in general there might be several (minimal) optimal orbits not only differing in their phase. However, if the following assumption of strict dissipativity (taken from (Köhler et al., 2018, Ass. 1)) is satisfied for a minimal orbit $\Pi^\star$, then this orbit is optimal and unique up to phase shifts. Further, strict dissipativity implies that the system is optimally operated at a periodic orbit, i.e., the best achievable asymptotic average performance is $\ell^\star$ (Müller et al., 2015).

Assumption 3. (Strict dissipativity). *There exists a storage function $\lambda : \mathbb{X} \to \mathbb{R}$ bounded on $\mathbb{X}$ and a function $\underline{\alpha}_{\tilde{\ell}} \in \mathcal{K}_\infty$, such that the rotated stage cost*

$$\tilde{\ell}(x,u) = \ell(x,u) - \ell^\star + \lambda(x) - \lambda(f(x,u)) \tag{6}$$

satisfies for all $x \in \mathbb{X}$ and all $u \in \mathbb{U}^1(x)$

$$\tilde{\ell}(x,u) \geq \underline{\alpha}_{\tilde{\ell}}(\|(x,u)\|_{\Pi^\star}). \tag{7}$$

[1] We use p-tuples $\Pi \in (\mathbb{X}\times\mathbb{U})^p$ as in (Zanon et al., 2017) instead of subsets $\Pi \subseteq \mathbb{X} \times \mathbb{U}$ with p elements as in (Müller and Grüne, 2016). The definition of *minimal* orbits, however, is analogous to (Müller and Grüne, 2016) to not only exclude multiple laps of the same orbit as in (Zanon et al., 2017) but to also exclude, e.g., 8-shaped orbits.

Additionally, we need the following two controllability conditions taken from (Müller and Grüne, 2016, Ass. 10 and 11).

Assumption 4. (Local controllability at $\Pi^\star$). *There exists $\kappa > 0, M' \in \mathbb{N}$ and $\rho \in \mathcal{K}_\infty$ such that for all $z \in \Pi^\star_{\mathbb{X}}$ and all $x, y \in \mathbb{X}$ with $\|x - z\| \leq \kappa$ and $\|y - z\| \leq \kappa$ there exists a control sequence $u \in \mathbb{U}^{M'}(x)$ such that $x_u(M', x) = y$ and*

$$\|(x_u(k,x), u(k))\|_{\Pi^\star} \leq \rho\big(\max\{\|x\|_{\Pi^\star_{\mathbb{X}}}, \|y\|_{\Pi^\star_{\mathbb{X}}}\}\big) \tag{8}$$

holds for all $k \in \mathbb{I}_{[0,M'-1]}$.

Assumption 5. (Finite-time reachability [2] of $\Pi^\star$). *For $\kappa > 0$ from Ass. 4 there exists $M'' \in \mathbb{N}$ such that for each $x \in \mathbb{X}$ there exists $K \in \mathbb{I}_{[0,M'']}$ and $u \in \mathbb{U}^K(x)$ such that $\|x_u(K,x)\|_{\Pi^\star_{\mathbb{X}}} \leq \kappa$.*

In (Köhler et al., 2018, Cor. 2) it is shown that the local controllability (Ass. 4) guarantees equivalence of the strict dissipativity assumptions from our setup (Ass. 3) and from (Müller and Grüne, 2016, Ass. 9). Hence, we impose equivalent assumptions as Müller and Grüne (2016).

3. LINEARLY DISCOUNTED MPC SCHEME

In this section, we define the linearly discounted economic MPC scheme starting with the finite-horizon discounted cost functional

$$J_N^\beta(x,u) := \sum_{k=0}^{N-1} \beta_N(k)\ell(x_u(k,x), u(k)) \tag{9}$$

with the linear discount function $\beta_N(k) := \frac{N-k}{N}$. Further, the corresponding optimal value function is

$$V_N^\beta(x) := \inf_{u \in \mathbb{U}^N(x)} J_N^\beta(x,u). \tag{10}$$

Due to Ass. 1 we know that J_N^β is continuous and that for each $x \in \mathbb{X}$ the set $\mathbb{U}^N(x)$ is nonempty and compact. Therefore, there exists for each $x \in \mathbb{X}$ a possibly non-unique input sequence $u^\beta_{N,x} \in \mathbb{U}^N(x)$ that attains the infimum, i.e., $V_N^\beta(x) = J_N^\beta(x, u^\beta_{N,x})$. Then we can define the standard MPC feedback law

$$\mu_N^\beta(x) := u^\beta_{N,x}(0), \tag{11}$$

that is, for a given x we minimize $J_N^\beta(x,u)$ and take the first element of the, or if non-unique of some, minimizing sequence $u^\beta_{N,x}$.

Before we start analyzing the closed-loop performance of this scheme, we want to share some intuition how discounting can be beneficial when dealing with a periodic optimal behavior. In the counter example in (Müller and Grüne, 2016, Exmp. 4) a plain economic MPC scheme without terminal conditions fails to converge to the optimal periodic orbit for all (arbitrarily long) odd prediction horizons. The problem occurring therein is that a certain phase at the end of the prediction horizon is preferred such that for any odd prediction horizon, it is better to first wait one time step before approaching the 2-periodic orbit. In closed loop, the control law (11) leads to waiting forever. A discount can overcome this problem, as the reward of ending at the right phase is discounted more than the cost of waiting at the first time step.

The idea of discounting the stage cost function is not new, however, in the context of economic MPC there are only a few works considering exponential discounts, such as, for example, (Grüne et al., 2016), (Grüne et al., 2021), (Zanon and Gros, 2022). In our setup, an exponential discount $\beta_N(k) = \beta^k$ for some $\beta \in (0,1)$ would decrease too fast as we need $\lim_{N\to\infty} \sum_{k=0}^{N-1} \beta_N(k) = \infty$ to make sure that the reward in the discounted cost function of being at the optimal orbit is larger than any transient cost of approaching it as long as the prediction horizon is sufficiently large. As the following section shows, a linear discount factor provides not only this property but is also appealing to analyze since we can exploit the linearity. Linear discounts are much less common than exponential discounts, nonetheless, a similar linear discount factor has also been used by Soloperto et al. (2022), however, in a different context of learning-based MPC.

4. OPTIMAL AVERAGE PERFORMANCE

In this section, we discuss the key contribution of this paper: The linearly discounted economic MPC schemes without terminal conditions from Sec. 3 achieves an asymptotic average performance that is optimal up to an error vanishing with growing prediction horizons. This performance result is analogous to the results known from other economic MPC schemes without terminal conditions, compare (Grüne and Stieler, 2014) in case of optimal steady-state operation or (Müller and Grüne, 2016) in case of optimal periodic operation using a p-step MCP scheme. In these works, the proof of the performance bound is heavily based on the so-called *turnpike-property*, which states that solutions of the OCP stay for all but a fixed number (independent of the length of the prediction horizon) of time steps in the neighborhood of the optimal behavior. Unfortunately, when discounting the stage cost we jeopardize this property as due to the small weights at the end of the horizon, more and more points could lie outside the neighborhood, hence, this number now depends on the length of the prediction horizon. The following theorem shows that the number of points in the neighborhood still grows faster than the number of points outside, which we therefore call the *weak turnpike property*.

Theorem 6. (Weak turnpike property). *Let Ass. 1, 3, 4, and 5 hold. For $\varepsilon > 0$, $N \in \mathbb{N}$ and $x \in \mathbb{X}$, define the number of points of the optimal trajectory $u^\beta_{N,x}$ in an ε-neighborhood of the optimal orbit $\Pi^\star$ as*

$$Q_\varepsilon^\beta(N,x) = \# \left\{ k \in \mathbb{I}_{[0,N-1]} \;\middle|\; \left\| \left(x_{u^\beta_{N,x}}(k,x), u^\beta_{N,x}(k)\right) \right\|_{\Pi^\star} \leq \varepsilon \right\}. \tag{12}$$

Then, there exist $\alpha_1 \in \mathcal{K}_\infty$ such that

$$Q_\varepsilon^\beta(N,x) \geq N - \frac{\sqrt{N}}{\alpha_1(\varepsilon)} \tag{13}$$

holds for all $x \in \mathbb{X}$, $N \in \mathbb{N}$, and $\varepsilon > 0$.

Remember that in the commonly known turnpike property (see, e.g., (Grüne and Pannek, 2017)) the $\sqrt{N}$ term in (13) is a constant independent of N. Hence, whereas the

[2] Technically, Ass. 5 guarantees finite-time reachability of a neighborhood of $\Pi^\star$. Together with the local controllability Ass. 4, reachability of $\Pi^\star$ in $M'' + M'$ steps follows.

weak turnpike property does not imply that the number of points outside the ε-neighborhood $N - Q_\varepsilon^\beta(N,x)$ is bounded by a constant, it still satisfies that the proportion of points inside is growing to 1, i.e., $\lim_{N\to\infty} \frac{1}{N} Q_\varepsilon^\beta(N,x) = 1$. This weaker property is actually still enough to show the following performance bound, which is analogous to the one from (Müller and Grüne, 2016).

Theorem 7. (Asymptotic average performance). *Let Ass. 1, 3, 4, and 5 hold. Then there exists $\delta \in \mathcal{L}$ such that for each prediction horizon length $N \in \mathbb{N}$, the MPC feedback law μ_N^β defined in* (11) *results in an asymptotic average performance that is not worse than*

$$J_\infty^{\mathrm{av}}(x, \mu_N^\beta) \leq \ell^\star + \delta(N). \tag{14}$$

If the storage function λ is continuous and the optimal orbit $\Pi^\star$ is minimal, we can even guarantee practical asymptotic stability of the optimal periodic orbit $\Pi^\star$.

Theorem 8. (Practical asymptotic stability). *Let Ass. 1, 3, 4, and 5 hold with a continuous storage function λ and assume that Π^* is a minimal orbit. Then there exists $\varepsilon \in \mathcal{L}$ such that the optimal periodic orbit $\Pi^\star$ is practically asymptotically stable under the MPC feedback μ_N^β w.r.t. $\varepsilon(N)$, i.e., there exists $\beta \in \mathcal{KL}$ and $l \in \mathbb{I}_{[0,p-1]}$ such that for all $x \in \mathbb{X}$ and $k \in \mathbb{N}$ we have*

$$\|x_\mu(k,x) - \Pi_{\mathbb{X}}([k+l]_p)\| \leq \max\{\beta(\|x\|_{\Pi_{\mathbb{X}}}, k), \varepsilon(N)\}. \tag{15}$$

5. DISCUSSION AND CONCLUSION

In this work, we have shown that a linearly discounted economic MPC scheme without terminal conditions achieves an asymptotic average performance that is optimal up to any desired level of suboptimality when the prediciton horizon is sufficiently large. The main novelty of this work is that both the proposed scheme and the performance guarantee are independent of the optimal period length $p^\star$ (compared to (Grüne, 2013), which only holds for $p^\star = 1$, i.e., steady states, and (Müller and Grüne, 2016), which uses a $p^\star$-step MPC scheme).

When facing real world applications, it is in most cases very difficult or even impracticable to design terminal conditions. Often, the only practicable solution is to omit terminal conditions and increase the prediction horizon N until the closed-loop behavior is satisfactory. The work of Grüne (2013) provides a theoretical justification for this procedure in the case where optimal operation is a steady state. Similarly, in the case where optimal operation is a steady state *or* a periodic orbit, the present work provides a theoretical justification to implement a linearly discounted economic MPC schemes without terminal conditions and increase its prediction horizon N until the desired performance is reached.

Future work will need to investigate what length of the prediction horizon is actually needed for a decent performance. We expect that the stronger theoretical guarantees come at a price. In cases where both discounted and non-discounted schemes guarantee near-optimal asymptotic average performance (e.g., when the optimal behavior is a steady state) the discount might lead to an increase in the suboptimality bound $\delta(N)$. On the other hand, having practical asymptotic stability (Theorem 8) is expected to result in a better transient performance compared to having only practical convergence as in the $p^\star$-step MPC scheme from (Müller and Grüne, 2016). This expectation can be justified with (Grüne and Stieler, 2014), where transient performance guarantees are based on practical asymptotic stability. The simulation study in (Schwenkel et al., 2022) sheds more light on the differences between the schemes and supports our expectations. Moreover, the results of this work suggest that also other discount functions may guarantee the same qualitative performance bound, which could lead to interesting insights how different discounts affect the performance.

Towards a Stochastic Fundamental Lemma for LTI Systems

Timm Faulwasser, Guanru Pan, and Ruchuan Ou

Institute for Energy Systems, Energy Efficiency and Energy Economics, TU Dortmund University, Dortmund, Germany (e-mail: timm.faulwasser@ieee.org).

Abstract: Jan Willems and co-authors introduced the characterization of finite-time behaviors of linear systems via the image of Hankel matrices already in 2005. The increasing popularity and research interest of data-driven control techniques has catalyzed the use of this result—which is commonly known as Willems' fundamental lemma—for predictive control and beyond. In this note, we recap recent results on a stochastic extension of the fundamental lemma from (Pan et al., 2021). Specifically, we leverage the framework of polynomial chaos expansions to derive a computationally tractable stochastic extension of the fundamental lemma.

Keywords: Stochastic systems, Hankel matrices, data-driven control, polynomial chaos expansions

1. INTRODUCTION

Data-driven system descriptions based on the fundamental lemma by Willems et al. (2005) are subject to continued research interest. Essentially, the lemma states that the trajectories of any controllable Linear Time Invariant (LTI) system can be represented without explicit knowledge of a state-space model. Specifically, provided persistency of excitation holds, over any finite horizon the manifest system behavior is contained in the column space of a Hankel matrix constructed from recorded input-output data. In absence of process and measurement noise, this representation is exact. There are recent variants of the original result, e.g., extensions to nonlinear systems (Alsalti et al., 2021; Lian et al., 2021), to linear parameter-varying and time-varying systems (Verhoek et al., 2021; Nortmann and Mylvaganam, 2020), to linear network systems (Allibhoy and Cortés, 2020), and to linear descriptor systems (Schmitz et al., 2022). We refer to De Persis and Tesi (2019); Markovsky and Dörfler (2021) for recent overviews. Data-driven control design and system analysis with not necessarily persistently exciting data has been investigated by van Waarde et al. (2020b).

Beyond the LTI setting, Coulson et al. (2019) propose a heuristic approach to deal with measurement noise and mild system nonlinearities by introducing slack variables and regularization in the objective function. There is also a line of research focusing on the robustness with respect to measurement noise and/or process noise. While Berberich et al. (2020); De Persis and Tesi (2021); van Waarde et al. (2020a) consider the design of robust state feedback controllers to deal with process noise, Yin et al. (2020) uses maximum likelihood concepts to obtain an optimal Hankel representation, and Coulson et al. (2021) views the noise entering the Hankel matrix as a problem of distributional robustness.

However, to the best of the authors' knowledge, so far there appears to be no stochastic variant of the fundamental lemma. Hence, this note recalls the main results of a recent submission (Pan et al., 2021), wherein we presented a stochastic fundamental lemma for LTI systems. To this end, we rely on Polynomial Chaos Expansion (PCE) which is an established method that can be applied in Markovian and non-Markovian settings. Its core idea is based on the observation that random variables can be regarded as elements of an $\mathcal{L}^2$ probability space and hence they admit representations in appropriately chosen polynomial bases (Sullivan, 2015).

This note recaps main results of Pan et al. (2021). The remainder is structured as follows: In Section 2 we recall the problem statements, while in Section 3 we present selected results without proofs. Finally, the note ends with conclusions in Section 4.

2. PROBLEM STATEMENT

We consider LTI systems of the following form

$$x_{k+1} = Ax_k + Bu_k + Ew_k, \quad x_0 = x_{\text{init}} \in \mathbb{R}^{n_x} \tag{1a}$$

$$y_k = Cx_k + Du_k \tag{1b}$$

where $x \in \mathbb{R}^{n_x}$, $u \in \mathbb{R}^{n_u}$, $w \in \mathbb{R}^{n_u}$, and $y \in \mathbb{R}^{n_y}$ refer to the state, the input, the disturbance, and the output.

Definition 1. (Persistency of excitation). Let $T, t \in \mathbb{N}^+$. A sequence of inputs $\mathbf{u}_{[0,T-1]}$ is said to be persistently exciting of order t if the Hankel matrix

$$\mathcal{H}_t(\mathbf{u}_{[0,T-1]}) \doteq \begin{bmatrix} u_0 & u_1 & \cdots & u_{T-t} \\ u_1 & u_2 & \cdots & u_{T-t+1} \\ \vdots & \vdots & \ddots & \vdots \\ u_{t-1} & u_t & \cdots & u_{T-1} \end{bmatrix}$$

is of full row rank. □

⋆ RO and TF acknowledge funding by the German Federal Ministry of Education and Research (BMBF) in the course of the 6GEM research hub under grant number 16KISK038.

Moreover, since (1) is driven by the inputs and the process noise realizations, the extension of the fundamental lemma of Willems et al. (2005) to the exogenous input data $(\mathbf{u}, \mathbf{w})_{[0,T-1]}$ is immediate. Below we use the notation $\forall \mathbf{z} \in \{\mathbf{x}, \mathbf{u}, \mathbf{w}, \mathbf{y}\}$ to highlight equations which have to hold for a set of variables.

Lemma 1. (Deterministic fundamental lemma). Let $T, t \in \mathbb{N}^+$. If $(\mathbf{u}, \mathbf{w})_{[0,T-1]}$ is persistently exciting of order $n_x + t$ and (1) is controllable with respect to the exogenous inputs (u, w), then $(\tilde{\mathbf{x}}, \tilde{\mathbf{u}}, \tilde{\mathbf{w}}, \tilde{\mathbf{y}})_{[0,t-1]}$ is an element of the behavior of (1) if and only if there exists a $g \in \mathbb{R}^{T-t+1}$ such that

$$\mathcal{H}_t(\mathbf{z}_{[0,T-1]})g = \tilde{\mathbf{z}}_{[0,t-1]}, \quad \forall \mathbf{z} \in \{\mathbf{x}, \mathbf{u}, \mathbf{w}, \mathbf{y}\}. \qquad \square$$

The above result provides a non-parametric system description of the LTI system (1). It allows to capture the dynamics, once the uncertainty surrounding the disturbance w has realized (or when it is sampled). Hence, we refer to (1) as *realization dynamics*. The crux is, however, that the future evolution of the disturbance $w \in \mathbb{R}^{n_w}$ is usually not known or difficult to predict.

Thus, an alternative modelling can be done in terms of random variables. This yields

$$X_{k+1} = AX_k + BU_k + EW_k, \quad X_0 = X_{\text{init}} \tag{2a}$$
$$Y_k = CX_k + DU_k, \tag{2b}$$

with state $X_k \in \mathcal{L}^2(\Omega, \mathcal{F}_k, \mu; \mathbb{R}^{n_x})$, where Ω is the sample space, $\mathcal{F}$ is a σ-algebra, $\mathbb{F} \doteq (\mathcal{F}_k)_{k=0,\dots,N}$ is a stochastic filtration, and μ is the considered probability measure. In the underlying filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mu)$, the σ-algebra contains all available historical information. Likewise, the stochastic input U_k is modelled as a stochastic process that is adapted to the filtration $\mathbb{F}$, that is, U_k only depends on $X_0, X_1, ..., X_k$. Note that the influence of the noise $W_i, i \leq k$ is implicitly handled via the state recursion. For more details on filtrations we refer to Fristedt and Gray (2013).

The process noise W_k, $k \in \mathbb{N}$ is considered as *i.i.d.* random variables whose underlying probability distribution is assumed to be known. Additionally, the distribution of the initial condition X_{init} is also assumed to be known. We remark that neither the distribution of X_{init} nor the one of W_k, $k \in \mathbb{N}$ needs to be Gaussian. Indeed, under mild assumptions, our proposed framework is applicable to random variables of finite variance.

3. SELECTED RESULTS

Considering the stochastic system (2), we are interested in deriving a counterpart to Lemma 1. To this end, we recap the basics of Polynomial Chaos Expansion (PCE).

3.1 Basics of Polynomial Chaos Expansion

PCE enables the propagation of uncertainties through dynamics and it provides a finite dimensional representation of random variables. Its origins date back to Wiener (1938); for a general introduction to PCE see Sullivan (2015).

The main idea of PCE is that an $\mathcal{L}^2$ random variable can be expressed in a suitable polynomial basis. To this end, an orthogonal polynomial basis $\{\phi^j(\omega)\}_{j=0}^{\infty}$ which spans $\mathcal{L}^2(\Omega, \mathcal{F}, \mu; \mathbb{R})$, i.e.,

$$\langle \phi^i, \phi^j \rangle \doteq \int_\Omega \phi^i(\omega)\phi^j(\omega)\,\mathrm{d}\mu(\omega) = \delta^{ij}\langle \phi^j, \phi^j \rangle,$$

where δ^{ij} is the Kronecker delta, is considered. The PCE of a real-valued random variable $V \in \mathcal{L}^2(\Omega, \mathcal{F}, \mu; \mathbb{R})$ with respect to this basis is given by

$$V = \sum_{j=0}^{\infty} \mathsf{v}^j \phi^j \text{ with } \mathsf{v}^j = \frac{\langle V, \phi^j \rangle}{\langle \phi^j, \phi^j \rangle}, \tag{3}$$

where $\mathsf{v}^j \in \mathbb{R}$ is called the j-th PCE coefficient.

Applying PCE component-wise the j-th PCE coefficient of a vector-valued random variable $V \in \mathcal{L}^2(\Omega, \mathcal{F}, \mu; \mathbb{R}^n)$ is

$$\mathsf{v}^j = \begin{bmatrix} \mathsf{v}^{1,j} & \mathsf{v}^{2,j} & \dots & \mathsf{v}^{n,j} \end{bmatrix}^\top,$$

where $\mathsf{v}^{i,j}$ is the j-th PCE coefficient of component V^i.

In numerical implementations the series has to be terminated after a finite number of terms, i.e., one works with

$$V = \sum_{j=0}^{L-1} \mathsf{v}^j \phi^j, \tag{4}$$

where $L \in \mathbb{N}$. Naturally, this may lead to truncation errors. For the purpose of this note, we assume that all considered PCE series are exact with finite expansion order $L-1$ (in the $\mathcal{L}^2$-equivalence sense). For a detailed investigation of how exactness of the uncertainty propagation for the LTI system (2) we refer to Mühlpfordt et al. (2018).

Remark 1. (Cond. probabilities, moments, and PCEs). From a stochastic control perspective, it is natural to ask how the PCE framework sketched above relates to widely used concepts such as conditional probabilities, conditional probability densities, and statistical moments. For starters, we remark that the moments are obtained as polynomial functions of the PCE coefficients (Sullivan, 2015). Due to the fact that the $\mathcal{L}^2$ framework covers a wide range of random variables, it is not immediate to give closed-form expressions of probability densities in the PCE framework. Yet, given a PCE for $Z = f(X, C)$ where $X, C \in \mathcal{L}^2(\Omega, \mathcal{F}_k, \mu; \mathbb{R}^{n_x})$ are independently distributed, conditional densities and probabilities (e.g. $P(Z \,|\, C = c)$ can be approximated via sampling of $Z = f(X, c)$ over X. While the numerical details are skipped due to space limitations, it is crucial to note that density information and conditional probability information is not lost using PCEs. $\square$

3.2 Stochastic Fundamental Lemmata

Replacing all random variables of (2) with corresponding PCE expansions with respect to the basis $\{\phi^j(\omega)\}_{j=0}^{\infty}$ and performing a Galerkin projection onto the basis functions $\phi^j(\omega)$, one obtains the dynamics of the PCE coefficients with given initial condition $\mathsf{x}^j_{\text{init}}$ for $j \in \{0, \dots, L-1\}$

$$\mathsf{x}^j_{k+1} = A\mathsf{x}^j_k + B\mathsf{u}^j_k + E\mathsf{w}^j_k, \quad \mathsf{x}^j_0 = \mathsf{x}^j_{\text{init}}, \tag{5a}$$
$$\mathsf{y}^j_{k+1} = C\mathsf{x}^j_k + D\mathsf{u}^j_k, \quad \forall j \in \{0, \dots, L-1\} \tag{5b}$$

Since (5) is a deterministic LTI system, it allows the conceptual application of the usual LTI fundamental lemma.

Lemma 2. (Fundamental lemma for PCE coefficients). Let $T, t \in \mathbb{N}^+$. For all $j \in \{0, \dots, L-1\}$ and given a trajectory tuple $(\mathsf{x}, \mathsf{u}, \mathsf{w}, \mathsf{y})^j_{[0,T-1]}$ generated by (5), suppose $(\mathsf{u}, \mathsf{w})^j_{[0,T-1]}$ is persistently exciting of order $n_x + t$

and (5) is controllable with respect to $(\mathsf{u}^j, \mathsf{w}^j)$. Then, for all $j \in \{0, \dots, L-1\}$, $(\tilde{\mathsf{x}}, \tilde{\mathsf{u}}, \tilde{\mathsf{w}}, \tilde{\mathsf{y}})^j_{[0,t-1]}$ is an element of the behavior of (5) if and only if there exists a $\mathsf{g}^j \in \mathbb{R}^{T-t+1}$ such that

$$\mathcal{H}_t(\mathsf{z}^j_{[0,T-1]})\mathsf{g}^j = \tilde{\mathsf{z}}^j_{[0,t-1]}, \quad \forall \mathsf{z} \in \{\mathsf{x}, \mathsf{u}, \mathsf{w}, \mathsf{y}\}. \qquad \square$$

The proof follows directly from the results of Willems et al. (2005). Lemma 2 as such is straightforward but of limited practical use. Consider the case that the disturbance w is i.i.d., i.e. identically and independently distributed. In terms of PCE this implies that the coefficients modelling W_k, w^j_k, are constant for all k. Hence, persistency of excitation cannot be satisfied. Moreover, it is not trivial to measure/estimate PCE coefficients of a stochastic LTI system from data.

Recently, we made an observation which allows to overcome the issue of persistency of excitation in the PCE coefficient dynamics (5) (Pan et al., 2021). Specifically, it is worth to be noted—in a model-based setting—that the realization dynamics (1), the stochastic dynamics (2), and the dynamics of the PCE coefficients (5) are all parametrized by the same matrices (A, B, C, D, E). This, in turn, implies that the subspaces spanned by available data are equivalent (provided persistency of excitation holds).

To the end of exploiting this observation, we introduce the notation $(\mathbf{z}, \mathbf{Z}) \in \{(\mathbf{x}, \mathbf{X}), (\mathbf{u}, \mathbf{U}), (\mathbf{w}, \mathbf{W}), (\mathbf{y}, \mathbf{Y})\}$ which expresses that $\mathbf{x}$ corresponds as a realization trajectory to the random-variable trajectory $\mathbf{X}$ and likewise for $(\mathbf{u}, \mathbf{U}), (\mathbf{w}, \mathbf{W}), (\mathbf{y}, \mathbf{Y})$.

Lemma 3. (Column-space equivalence). Consider system (2) and an $\mathcal{L}^2(\Omega, \mathcal{F}_k, \mu; \mathbb{R}^{n_z})$, $n_z \in \{n_x, n_u, n_x, n_y\}$ random-variable trajectory tuple $(\mathbf{X}, \mathbf{U}, \mathbf{W}, \mathbf{Y})_{[0,T-1]}$. Let the corresponding PCE coefficient trajectories $(\mathsf{u}, \mathsf{w})^j_{[0,T-1]}$, $j \in \{0, \dots, L-1\}$ and the realizations $(\mathbf{u}, \mathbf{w})_{[0,T-1]}$ be persistently exciting of order n_x+t, and let (1) be controllable with respect to (u, w).

(i) Then, for all $j \in \{0, \dots, L-1\}$ and all $(\mathbf{z}, z) \in \{(\mathbf{x}, \mathsf{x}), (\mathbf{u}, \mathsf{u}), (\mathbf{w}, \mathsf{w}), (\mathbf{y}, \mathsf{y})\}$, it holds that

$$\operatorname{colsp}\big(\mathcal{H}_t(\mathsf{z}^j_{[0,T-1]})\big) = \operatorname{colsp}\big(\mathcal{H}_t(\mathbf{z}_{[0,T-1]})\big). \qquad (6a)$$

(ii) Moreover, for all $g \in \mathbb{R}^{T-t+1}$, there exists a $G \in \mathcal{L}^2(\Omega, \mathcal{F}, \mu; \mathbb{R}^{T-t+1})$ such that

$$\mathcal{H}_t(\mathbf{Z}_{[0,T-1]})g = \mathcal{H}_t(\mathbf{z}_{[0,T-1]})G. \qquad (6b)$$

for all $(\mathbf{z}, Z) \in \{(\mathbf{x}, X), (\mathbf{u}, U), (\mathbf{w}, W), (\mathbf{y}, Y)\}$. $\square$

In slightly different form this result has appeared as Lemma 3 in Pan et al. (2021). Hence its proof is omitted.

The crucial observation is that in (6a) PCE data appears in the Hankel matrices on the left hand side, while realization data is used on the right hand side. This allows to overcome the issue of persistency of excitation for PCE coefficients by resorting to realization trajectory data instead.

Lemma 4. (Stochastic fundamental lemma).
Consider system (2) and its $\mathcal{L}^2(\Omega, \mathcal{F}_k, \mu; \mathbb{R}^{n_z})$, $n_z \in \{n_x, n_u, n_x, n_y\}$ trajectory tuples of random variables, PCE coefficients (5), and the corresponding realizations (1), which are $(\mathbf{X}, \mathbf{U}, \mathbf{W}, \mathbf{Y})_{[0,T-1]}$, $(\mathsf{x},\mathsf{u},\mathsf{w},\mathsf{y})^j_{[0,T-1]}$, $j \in \{0, \dots, L-1\}$, and $(\mathbf{x}, \mathbf{u}, \mathbf{w}, \mathbf{y})_{[0,T-1]}$. Let (1) be controllable with respect to (u, w), then following assertions hold:

(i) Let $(\mathbf{u}, \mathbf{w})_{[0,T-1]}$ be persistently exciting of order $n_x + t$. Then $(\tilde{\mathbf{X}}, \tilde{\mathbf{U}}, \tilde{\mathbf{W}}, \tilde{\mathbf{Y}})_{[0,t-1]}$ satisfies the dynamics (2) if and only if there exists $G \in \mathcal{L}^2(\Omega, \mathcal{F}, \mu; \mathbb{R}^{T-t+1})$ such that

$$\mathcal{H}_t(\mathbf{z}_{[0,T-1]})G = \tilde{\mathbf{Z}}_{[0,t-1]} \qquad (7a)$$

for all $(\mathbf{z}, \tilde{\mathbf{Z}}) \in \{(\mathbf{x}, \tilde{\mathbf{X}}), (\mathbf{u}, \tilde{\mathbf{U}}), (\mathbf{w}, \tilde{\mathbf{W}})\}$.

(ii) Let $(\mathbf{U}, \mathbf{W})_{[0,T-1]}$ satisfy

$$\mathbf{Z}_{[0,T-1]} = \sum_{j=0}^{L-1} \mathsf{z}^j \phi^j, \quad \mathbf{Z} \in \{\mathbf{U}, \mathbf{W}\}$$

with $L \in \mathbb{N}$ and all PCE trajectories $(\mathsf{u}, \mathsf{w})^j_{[0,T-1]}$ with $j \in \{0, \dots, L-1\}$ are persistently exciting of order $n_x + t$. If there exists a $g \in \mathbb{R}^{T-t+1}$ such that, for all $\mathbf{Z} \in \{\mathbf{X}, \mathbf{U}, \mathbf{W}, \mathbf{Y}\}$,

$$\mathcal{H}_t(\mathbf{Z}_{[0,T-1]})g = \tilde{\mathbf{Z}}_{[0,t-1]} \qquad (7b)$$

then $(\tilde{\mathbf{X}}, \tilde{\mathbf{U}}, \tilde{\mathbf{W}}, \tilde{\mathbf{Y}})_{[0,t-1]}$ satisfies the dynamics (2). $\square$

In slightly modified form, the proof of this result is contained in Pan et al. (2021), where the result appears as Lemma 4.

3.3 Discussion

Recall the usual form of a fundamental lemma, i.e., the columns of the Hankel matrix constructed by past variables span the full, finite-horizon system behavior of the LTI system. It is crucial to note that if the Hankel matrix is constructed directly from random variables, this usual form of the lemma does not necessarily hold in the stochastic setting, cf. Part (ii) of Lemma 4. Specifically, notice that upon applying Galerkin projection for $L \in \mathbb{N}$ PCE basis functions to (7a) and using the equivalence of $\operatorname{colsp}\big(\mathcal{H}_t(\mathsf{z}^j_{[0,T-1]})\big)$ and $\operatorname{colsp}\big(\mathcal{H}_t(\mathbf{z}_{[0,T-1]})\big)$ established in (6a), we obtain the system of linear equations to compute the vector $\mathsf{g}^{[0,L-1]}$. This linear problem reads $\big(I_L \otimes \mathcal{H}_t(\mathbf{z}_{[0,T-1]})\big)\,\mathsf{g}^{[0,L-1]} = \tilde{\mathsf{z}}^{[0,L-1]}$, where $\otimes$ denotes the Kronecker product and $\mathsf{g}^{[0,L-1]} \in \mathbb{R}^{L(T-t+1)}$ stacks the vectors g^j into one vector. In contrast, Galerkin projection of (7b) combined with column-space equivalence gives $\big(\mathbf{1}_L \otimes \mathcal{H}_t(\mathbf{z}_{[0,T-1]})\big)\,\mathsf{g} = \tilde{\mathsf{z}}^{[0,L-1]}$,where $\mathbf{1}_L$ is the $L \times 1$ vector of all 1 and g is of dimension $T-t+1$. In other words, Galerkin projection of (7b) does not give sufficient flexibility to represent all trajectories.

Example 1. (If and iff statements in Lemma 4).
We present a simple example illustrating why Part (ii) of Lemma 4 does not admit an *iff* statement. Consider the scalar stochastic system $X_{k+1} = 2X_k + U_k$ with past trajectories given in terms of their PCEs

$$\begin{aligned} X_0 &= 0\phi^0 + 0\phi^1, \quad U_0 = 0\phi^0 + 1\phi^1, \\ X_1 &= 0\phi^0 + 1\phi^1, \quad U_1 = 1\phi^0 + 0\phi^1, \\ X_2 &= 1\phi^0 + 2\phi^1, \quad U_2 = 1\phi^0 + 1\phi^1. \end{aligned}$$

Note that the PCE coefficients of $\mathbf{U}_{[0,2]}$ satisfy the persistency of excitation required by Part (ii) of Lemma 4.

We aim to find $g \in \mathbb{R}^3$ in (7b) to represent $\tilde{X}_0 = 0\phi^0 + 1\phi^1$, $\tilde{U}_0 = 0\phi^0 + 1\phi^1$. We obtain (7b) as

$$\begin{bmatrix} X_0 & X_1 & X_2 \\ U_0 & U_1 & U_2 \end{bmatrix} g = \begin{bmatrix} \tilde{X}_0 \\ \tilde{U}_0 \end{bmatrix}. \tag{8}$$

After Galerkin projection onto the basis functions and stacking the projected equations we obtain $Mg = c$ with

$$M = \left[\begin{array}{ccc} 0 & 0 & 1 \\ 0 & 1 & 1 \\ \hline 0 & 1 & 2 \\ 1 & 0 & 1 \end{array}\right] \quad c = \left[\begin{array}{c} 0 \\ 0 \\ \hline 1 \\ 1 \end{array}\right]$$

where the upper block corresponds to ϕ^0 and the lower one to ϕ^1. By the Rouché–Capelli theorem, $Mg = c$ admits a solution g if and only if $[M|c]$ has the same rank as M. Observe that $\operatorname{rank} M = 3$ and $\operatorname{rank}[M|c] = 4$. Thus, we conclude that (8) does not admit solutions $g \in \mathbb{R}^3$. □

Remark 2. (Knowlegde of past noise realizations).
From an applications point of view further comments are in order. First, observe that Lemma 4 requires knowledge of past realization of noise trajectories. Depending on the context such realization data might be accessible a posteriori through measurements—e.g., consider cases in which the disturbance W_k models volatile renewable energy production or randomly varying energy demands, cf. Bilgic et al. (2022)—or one may estimate them from available measurements. For details on the latter for the case of state feedback and $E = I$ see (Pan et al., 2021). □

Remark 3. (Data-driven stochastic control). One may wonder how to put the presented stochastic fundamental lemma to use for stochastic predictive control leveraging the lemma including numerical examples are provided by Pan et al. (2021). For tailored numerical solutions methods see (Ou et al., 2023), stability results for state feedback can be given (Pan et al., 2022). □

Remark 4. ($\mathcal{L}^2$ Equivalence). From a conceptual point of view, we remark that the PCE approach gives finite-dimensional representations of random variables only in an $\mathcal{L}^2$ equivalence sense. Hence, also the non-parametric system description via the fundamental lemma is in general to be understood in an $\mathcal{L}^2$ equivalence sense. □

4. CONCLUSIONS

This note has recalled first steps towards a fundamental lemma for stochastic LTI systems. To this end, we have recalled parts of the results of our recently submitted paper (Pan et al., 2021). The crucial insights obtained include the column-space equivalence of Hankel matrices for PCE coefficients and realizations which in turn enables the derivation of a fundamental lemma wherein the Hankel matrix contains deterministic data (of realizations or PCE coefficients) while the vector expressing linear combinations of the columns becomes a vector-valued random variable. Moreover, we have shown that the counterpart, i.e. Hankel matrices in terms of random variables and a deterministic vector expressing linear combinations, does not lead to an equivalent description.

Real hyperplane sections and linear series on algebraic curves

Daniel Plaumann *

* *Fakultät für Mathematik, Technische Universität Dortmund, D-44227 Dortmund, Germany*

Abstract: Given a real algebraic curve in projective space, we study the computational problem of deciding whether there exists a hyperplane meeting the curve in real points only. More generally, given any divisor on such a curve, we may ask whether the corresponding linear series contains an effective divisor with totally real support. This translates into a particular type of parametrized real root counting problem that we wish to solve exactly.
We will focus on examples and some general results and conjectures, based on recent work with Huu Phuoc Le and Dimitri Manevich.

Keywords: real algebraic curve, totally real hyperplane section, divisor, Hermite matrix, parametrized root counting

1. INTRODUCTION

In this talk I will survey some computational problems concerning real algebraic curves. Results will be based on a joint paper

Computing totally real hyperplane sections and linear series on algebraic curves
by Huu Phuoc Le, Dimitri Manevich, Daniel Plaumann

available from

`https://arxiv.org/abs/2106.13990`

and accepted for publication in Le Matematiche.

From the introduction:

Given a real algebraic curve X of degree d embedded into some projective space, we consider the computational problem of deciding whether there exists a real hyperplane meeting X in a prescribed number r of real points, counted with multiplicity. Of particular interest is the case $r = d$, i.e., hyperplanes meeting X in real points only. More generally, given any divisor D on X defined over $\mathbb{R}$, and thus consisting of real points and complex-conjugate pairs, we may ask whether the linear series $|D|$ contains an effective divisor with totally real support. (The first question is the special case when D is a hyperplane section of a suitably embedded curve.) A number of general results have been obtained in this direction: The answer is known to be positive for any divisor of sufficiently high degree (see Scheiderer (2000)). However, the precise degree required, relative to the genus of X, is the subject of several results and conjectures, some of which we will investigate from a computational point of view. Explicit bounds are only known if the real locus $X(\mathbb{R})$ has many connected components (so-called M-curves or $(M-1)$-curves), by results due to Huisman (2001) and Monnier (2003). On the other hand, very little is known about curves whose number of connected components is not close to maximal.

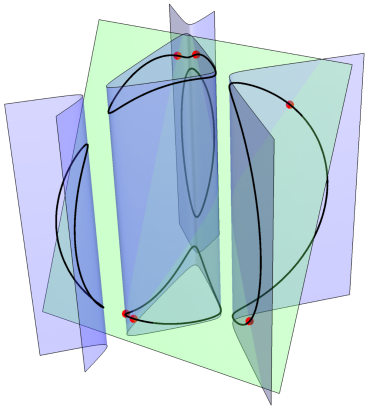

Fig. 1. A real space curve of degree 6 with a totally real hyperplane section.

Of course, the computational problem makes sense for any given curve and divisor, regardless of whether or not there is a general result covering all curves and divisors of the given kind.

It comes down to "solving" polynomial systems whose coefficients depend on parameters. More precisely, we consider the coefficients of the equation defining the hyperplane as *parameters*. One then associates a hyperplane to a point in the space of parameters. The number of real points at the intersection of the considered hyperplane with the curve may vary depending on the parameters, while the number of complex intersection points between the curve and the hyperplane is equal to the degree d for *generic* values of the parameters. (If the points are counted with intersection multiplicities and the curve is not contained in a hyperplane, this complex intersection number is equal to d for *all* values of the parameters.) Hence, from a computational point of view, we are considering a polynomial system, depending on parameters such that, when these

parameters take generic values, the solution set over the complex numbers is finite. When the input system generates a radical ideal, the algorithm we use , which is detailed in Le and Safey El Din (2020), computes a partition of a dense semi-algebraic subset of the space of parameters into open semi-algebraic sets such that the number of real *simple* solutions (i.e., without multiplicities) to the input system is invariant for any point chosen in one of these sets. To do this, we compute a symmetric matrix called the *parametric Hermite matrix*, whose entries are polynomials depending on the parameters and such that, after specialization, its signature coincides with the number of real solutions to the specialized system. This allows us to classify the possible number of real roots to the input system with respect to the parameters.

Our main findings can be summarized as follows.

1. There exist canonical curves X in $\mathbb{P}^3$ with one or two ovals which do not allow simple totally real hyperplane sections.
2. There exists a curve X in $\mathbb{P}^3$ of genus two and degree five having one oval which does not allow a simple totally real hyperplane section.
3. There are infinitely many plane quartics X with many ovals possessing a (complete) linear series of degree four which does not contain a totally real divisor.
4. For every $d \geq 3$ and every number $1 \leq s \leq g+1$ with $g = \frac{(d-1)(d-2)}{2}$, there exists a plane curve X of degree d, genus g and having s branches such that the linear series of lines $|L|$ is totally real.

Abstract: This extended abstract presents several recent results and generalizations that have been obtained in the theory of collision-freeness studied in Zerz and Herty (2019). A nonlinear ODE system $\dot{x}(t) = f(x(t))$ is called collision-free if the solution to the initial value problem with $x(0) = x^0$ has distinct components for all times t whenever the initial state x^0 has distinct components. This is an important structural property of particle systems. Here, we address the case where the state of the i-th particle has d components x_{ik}, and a collision occurs if there exists t and $i \neq j$ such that $x_{ik}(t) = x_{jk}(t)$ for all $1 \leq k \leq d$.

Keywords: Structural properties; multivariable systems; linear/polynomial/nonlinear systems.

1. PRELIMINARIES AND KNOWN RESULTS

Let $N \geq 1$ be an integer, $U \subseteq \mathbb{R}^N$ an open set, and let $f : U \to \mathbb{R}^N$ be a $\mathcal{C}^1$-function. Consider the ordinary differential equation (ODE) $\dot{x}(t) = f(x(t))$. Let $x^0 \in U$ be given. The initial value problem (IVP) $\dot{x} = f(x)$, $x(0) = x^0$ has a unique nonextendable $\mathcal{C}^1$-solution

$$\varphi(\cdot, x^0) : J(x^0) \to U,$$

where $J(x^0) \subseteq \mathbb{R}$ is an open interval containing $t_0 = 0$, called the maximal existence interval of the IVP. A subset $S \subseteq U$ is called invariant for $\dot{x} = f(x)$ if $x^0 \in S$ implies that $\varphi(t, x^0) \in S$ for all $t \in J(x^0)$. Clearly, a set S is invariant if and only if its complement $U \setminus S$ is invariant.

We are particularly interested in the case where the set S is given by polynomial equations. Given a subset $P \subseteq \mathcal{P} := \mathbb{R}[X_1, \ldots, X_N]$, we write

$$V := \mathcal{V}(P) = \{x \in \mathbb{R}^N \mid p(x) = 0 \text{ for all } p \in P\}$$

for the variety defined by P. Conversely, the set

$$\mathcal{J}(V) = \{p \in \mathcal{P} \mid p(x) = 0 \text{ for all } x \in V\}$$

is an ideal in $\mathcal{P}$. We have $\mathcal{J}(V_1 \cup V_2) = \mathcal{J}(V_1) \cap \mathcal{J}(V_2)$ and $\mathcal{V}(I_1 \cap I_2) = \mathcal{V}(I_1) \cup \mathcal{V}(I_2)$ for varieties $V_i \subseteq \mathbb{R}^N$ and ideals $I_i \subseteq \mathcal{P}$. Since $\mathcal{P}$ is Noetherian, any ideal in $\mathcal{P}$ is finitely generated.

The Lie derivative of $p \in \mathcal{P}$ along f is defined by

$$L_f(p) = \sum_{i=1}^{N} \frac{\partial p}{\partial X_i} f_i \in \mathcal{C}^1(U, \mathbb{R}).$$

⋆ This work was supported by DFG-SFB 1481 and DFG-TRR 195.

In the special case where f is a polynomial function, which will be identified with some $f \in \mathcal{P}^N$, we set $U = \mathbb{R}^N$ and we have $L_f(p) \in \mathcal{P}$ for all $p \in \mathcal{P}$.

The following two results are folklore, but we state them for the sake of self-containedness; see also Zerz and Walcher (2012) and Harms et al. (2017).

Lemma 1. Let $f \in \mathcal{P}^N$ and a variety $V \subseteq \mathbb{R}^N$ be given. Then V is invariant for $\dot{x} = f(x)$ if and only if $L_f(\mathcal{J}(V)) \subseteq \mathcal{J}(V)$.

The following basic facts from algebraic geometry can be found in standard textbooks such as Kunz (1985). A variety V is said to be irreducible if it cannot be written as a union $V = V_1 \cup V_2$ with subvarieties $V_i \subsetneq V$. A maximal irreducible subvariety of V is called an irreducible component of V. Any variety V has only finitely many irreducible components V_i, and V can be written as a union of its irreducible components such that none of the V_i is superfluous. A variety V is irreducible if and only if $\mathcal{J}(V)$ is a prime ideal. Recall that an ideal $\mathfrak{p} \subsetneq \mathcal{P}$ is called prime if $pq \in \mathfrak{p}$ implies $p \in \mathfrak{p}$ or $q \in \mathfrak{p}$.

Theorem 2. Let $f \in \mathcal{P}^N$ and a variety $V \subseteq \mathbb{R}^N$ be given. Let $V = \bigcup V_i$ be the decomposition of V into its irreducible components. Then V is invariant for $\dot{x} = f(x)$ if and only if each V_i is.

With these preparations, we now introduce the central concept of this contribution.

Definition. Let $n \geq 2$ and $d \geq 1$ be integers. A vector $x = (x_1^T, \ldots, x_n^T)^T \in \mathbb{R}^{nd}$ with $x_i = (x_{i1}, \ldots, x_{id})^T$ is said to have *d-distinct components* if the x_i are (pairwise) distinct. An ODE $\dot{x} = f(x)$ is called *d-collision-free* if for any vector x^0 with d-distinct components, the solution

$\varphi(t, x^0)$ to the IVP $\dot{x} = f(x)$, $x(0) = x^0$ has d-distinct components for all t in the maximal existence interval. A matrix $A \in \mathbb{R}^{nd\times nd}$ is called *d-collision-free* if the linear ODE $\dot{x} = Ax$ is d-collision-free.

Let $I_{ij} := \langle X_{i1} - X_{j1}, \dots, X_{id} - X_{jd}\rangle \subseteq \mathcal{P}$, where

$$\mathcal{P} = \mathbb{R}[X_{11}, \dots, X_{1d}, \dots, X_{n1}, \dots, X_{nd}]$$

is a polynomial ring in nd variables, and let

$$V_{ij} := \mathcal{V}(I_{ij}) = \{x \in \mathbb{R}^{nd} \mid p(x) = 0 \text{ for all } p \in I_{ij}\} \subset \mathbb{R}^{nd}$$

be its vanishing set. Finally, let

$$V = \bigcup_{1\le i<j\le n} V_{ij}. \tag{1}$$

Clearly $\complement V := \mathbb{R}^{nd} \setminus V$ is the set of all vectors with d-distinct components. By definition, $\dot{x} = f(x)$ is d-collision-free if and only if $U \setminus V$ is an invariant set of this ODE. Equivalently, $U \cap V$ itself is an invariant set of $\dot{x} = f(x)$.

Since (1) is the decomposition of V into irreducible components, we may conclude from Theorem 2 that $\dot{x} = f(x)$ with $f \in \mathcal{P}^{nd}$ is d-collision-free if and only if each V_{ij} is invariant, which means that $x_i^0 = x_j^0$ implies that $x_i(t) = x_j(t)$ for all t in the maximal existence interval of the solution x with $x(0) = x^0$.

2. LINEAR AND POLYNOMIAL SYSTEMS

In this section, we first analyze the d-collision-freeness of linear systems, that is, $\dot{x} = Ax$ with $A \in \mathbb{R}^{nd\times nd}$.

Notation. Let $\underline{n}$ denote the set $\{1, \dots, n\}$. For a matrix $A \in \mathbb{R}^{nd\times nd}$, we consider the partition of A into submatrices $A_{ij} \in \mathbb{R}^{d\times d}$ for $i, j \in \underline{n}$.

Theorem 3. Let $A \in \mathbb{R}^{nd\times nd}$ be given. The following are equivalent:

(i) A is d-collision-free.
(ii) The submatrices A_{ij} of A satisfy

$$A_{ik} = A_{jk} \quad \text{for all } i, j, k \in \underline{n} \text{ with } i \neq k, j \neq k \tag{2}$$

and

$$\sum_{k=1}^{n} A_{ik} = \sum_{k=1}^{n} A_{jk} \quad \text{for all } i, j \in \underline{n}. \tag{3}$$

Note that in view of (2), Equation (3) is equivalent to

$$A_{ii} + A_{ij} = A_{ji} + A_{jj} \quad \text{for all } i, j \in \underline{n}.$$

From the theorem, we derive the following insights into the structural properties of d-collision-free matrices.

Corollary 4. Let $R \subseteq \mathbb{R}^{nd\times nd}$ denote the set of all d-collision-free matrices. Then R is a subring of $\mathbb{R}^{nd\times nd}$. Any $A \in R$ is uniquely determined by $A_{11}, \dots, A_{1n}$ and A_{21}, where these matrices can be freely chosen. Thus the dimension of R as a real vector space equals $(n + 1)d^2$.

Corollary 5. Let $f \in \mathcal{P}^{nd}$ be given. Then $\dot{x} = f(x)$ is d-collision-free if and only if each $f_{ik} - f_{jk}$ is contained in I_{ij}, where $1 \le i < j \le n$ and $1 \le k \le d$.

3. GENERAL $\mathcal{C}^1$-SYSTEMS

Next, we consider the general $\mathcal{C}^1$-case.

Consider $\dot{x} = f(x)$, where $f \in \mathcal{C}^1(U, \mathbb{R}^{nd})$ for some open set $U \subseteq \mathbb{R}^{nd}$. Let $V_{ij} = \bigcap_{k=1}^{d} \mathcal{V}(X_{ik} - X_{jk})$ and $V = \bigcup_{1\le i<j\le n} V_{ij}$. Recall that $\complement V = \mathbb{R}^{nd} \setminus V$ is the set of all vectors with d-distinct components. This is an open and dense subset of $\mathbb{R}^{nd}$ and its boundary equals V.

Lemma 6. Let $f \in \mathcal{C}^1(U, \mathbb{R})$ for some open set $U \subseteq \mathbb{R}^{nd}$. Suppose that f vanishes on $U \cap \mathcal{V}(X_{11}, \dots, X_{1d})$. Then there exist functions $a_i \in \mathcal{C}^0(U, \mathbb{R})$ such that $f(x) = a_1(x)x_{11} + \ldots + a_d(x)x_{1d}$ for all $x = (x_1^T, \dots, x_n^T)^T \in U$ and $x_1 = (x_{11}, \dots, x_{1d})^T$.

Lemma 7. (a) Let $q_1, \dots, q_l \in \mathcal{P}$ be polynomials. If $U \cap \mathcal{V}(q_1, \dots, q_l)$ is an invariant set of $\dot{x} = f(x)$, then every $L_f(q_k)$, where $1 \le k \le l$, vanishes on $U \cap \mathcal{V}(q_1, \dots, q_l)$.

(b) $U \cap V_{ij}$ is an invariant set of $\dot{x} = f(x)$ if and only if every $f_{ik} - f_{jk}$, where $1 \le k \le d$, vanishes on $U \cap V_{ij}$.

Theorem 8. $U \cap V$ is an invariant set if and only if each $U \cap V_{ij}$ is an invariant set for $1 \le i < j \le n$.

Corollary 9. The ODE $\dot{x} = f(x)$, where $f \in \mathcal{C}^1(U, \mathbb{R}^{nd})$ for some open set $U \subseteq \mathbb{R}^{nd}$, is d-collision-free if and only if each $f_{ik} - f_{jk}$ vanishes on $U \cap V_{ij}$ for $1 \le i < j \le n$ and $1 \le k \le d$.

Example. Consider

$$\dot{x}_i = \sum_{k=1}^{n} \phi(x_k - x_i) \tag{4}$$

for some $\phi \in \mathcal{C}^1(\mathbb{R}^d, \mathbb{R}^d)$ and $1 \le i \le n$. This system is d-collision-free.

4. DEPENDENCE ON d AND THE ROLE OF PERMUTATION SYMMETRY

Corollary 10. Let $N = nd = n'd'$, where d is a multiple of d'. Then d'-collision-freeness of an N-dimensional system $\dot{x} = f(x)$ implies d-collision-freeness. In particular, 1-collision-freeness (as studied in Zerz and Herty (2019)) implies d-collision-freeness for all divisors d of the state space dimension N.

Let $G = \{P \otimes I_d \mid P \text{ is an } n \times n \text{ permutation matrix}\} \subseteq \mathbb{R}^{nd\times nd}$, where I_d is the $d\times d$ identity matrix and $\otimes$ denotes the Kronecker product.

Definition. A function $f \in \mathcal{C}^1(U, \mathbb{R}^{nd})$ is called *G-symmetric* if $f(Tx) = Tf(x)$ holds for all $T \in G$ and $x \in U$ with $Tx \in U$. Writing $f = (f_1, \dots, f_n)$ with $f_i \in \mathcal{C}^1(U, \mathbb{R}^d)$, this means that

$$f_{\pi(i)}(x_1, \dots, x_n) = f_i(x_{\pi(1)}, \dots, x_{\pi(n)})$$

holds for any permutation $\pi \in S_n$ of the n substates and any $x = (x_1^T, \dots, x_n^T)^T \in U$ such that both sides of the equation are well-defined.

It turns out that many common models of particle interactions, such as (4), are permutation symmetric in this sense. This reflects the assumption that the particles are identical and indiscernible.

Example. Suppose that $U = V^n$ for some open set $V \subseteq \mathbb{R}^d$. Consider

$$f_i(x) = f_i(x_1, \dots, x_n) = \chi(x_i) + \sum_{k=1, k\neq i}^{n} \psi(x_k, x_i)$$

for some $\chi \in \mathcal{C}^1(V, \mathbb{R}^d)$, $\psi \in \mathcal{C}^1(V \times V, \mathbb{R}^d)$ and $1 \leq i \leq n$. Then f is G-symmetric.

Theorem 11. If f is G-symmetric, then $\dot{x} = f(x)$ is d-collision-free.

Corollary 12. Let $A \in \mathbb{R}^{nd\times nd}$ be given and let $A_{ij} \in \mathbb{R}^{d\times d}$ for $i, j \in \underline{n}$ denote its submatrices as in Theorem 3. Then A is G-symmetric, that is, it commutes with every $T \in G$, if and only if A is both d-collision-free and block symmetric, that is, $A_{ij} = A_{ji}$ for all $i, j \in \underline{n}$.

Both conditions are equivalent to

$$A = \begin{bmatrix} C & B & \dots & B \\ B & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & B \\ B & \dots & B & C \end{bmatrix}$$

for some $B, C \in \mathbb{R}^{d\times d}$.

5. OUTLOOK AND FUTURE WORK

We expect the theory of d-collision-freeness to deepen the understanding of ODE particle systems which arise with traffic, swarm, or consensus models, for instance, see Albi et al. (2015) or Miao et al. (2016). In particular, we are interested in studying how this property carries over to the PDE model resulting in the mean-field kinetic limit considered e.g. in Herty et al. (2015); Tordeux et al. (2018).

Abstract: A port-Hamiltonian formulation of a general class of interacting particle systems and its corresponding mean-field partial-differential equation is discussed. To establish the port-Hamiltonian structure of the interacting particle systems a specific variable transformation is employed. It turns out that an appropriate retransformation of the characteristics corresponding to the mean-field partial differential equation yields again a port-Hamiltonian structure.

Keywords: Port-Hamiltonian modeling, port-Hamiltonian distributed parameter systems, interacting particle systems, mean-field limit, multi-agent systems.

1. INTRODUCTION

Port-based network modeling of complex physical systems leads to port-Hamiltonian systems (PHS). For finite-dimensional systems there is by now a well-established theory, see van der Schaft (2006); Eberard et al. (2007); Duindam et al. (2009). The port-Hamiltonian approach has been further extended to the infinite-dimensional situation in van der Schaft and Maschke (2002); Zwart et al. (2010); Villegas (2007); Jacob and Zwart (2012). This class is further closed under network interconnection. That is, coupling of port-Hamiltonian systems again leads to a port-Hamiltonian system. Furthermore, the port-Hamiltonian approach is suitable for the investigation of the qualitative solution behavior and optimization questions, as it provides an energy balance.

In this talk we model interacting particle systems as well as the corresponding mean-field partial-differential equation as port-Hamiltonian system. A recent work by Matei et al. (2019) discusses the port-Hamiltonian formulation of a Cucker-Smale dynamic involving three particles. The key idea leading the reformulation is the interpretation of the Cucker-Smale interactions as generalized spring-damper systems. The approach has several advantages: the introduction of relative positions factors out the translational invariance of the system, and, the port-Hamiltonian structure allows to identify several conserved quantities namely the Hamiltonian and the so-called Casimir functions. In future work, the novel interpretation of interacting particle dynamics as generalized spring-damper systems with PHS structure can be employed for new control-strategies of interacting particle systems.

2. MODELING

We recall the classical formulation of interacting particle systems in position and velocity coordinates before we introduce the reformulation in PHS structure.

Let us denote the space dimension d and consider $N \in \mathbb{N}$ agents, let $x_i \colon [0,T] \to \mathbb{R}^d$ and $v_i \colon [0,T] \to \mathbb{R}^d$ denote the position and velocity functions of the i-th agent, respectively. We collect the positions and the velocities of all agents in the vectors x and v with $[x]_i = x_i$ and $[v]_i = v_i$ for $i = 1, \dots, N$, respectively. Let $G \in \mathcal{C}(\mathbb{R}, \mathbb{R}_{\geq 0})$ model a generalized damper and $V \in \mathcal{C}^1(\mathbb{R}^d, \mathbb{R})$ be the potential for the binary interactions of the particles. For the forces resulting from the interactions we require

$$\nabla_{x_i} V(x_j - x_i) = -\nabla_{x_j} V(x_j - x_i). \tag{1}$$

According to Newton's second law, a general interacting particle systems can be written as

$$\frac{d}{dt} x = v, \qquad x(0) = x_0, \tag{2a}$$

$$\frac{d}{dt} v = \mathcal{G}(x)v - \nabla \mathcal{V}(x), \qquad v(0) = v_0, \tag{2b}$$

where

$$[\mathcal{G}(x)]_{ii} = -\frac{1}{N} \sum_{j \neq i} G(|x_j - x_i|)$$

$$[\mathcal{G}(x)]_{ij} = \frac{1}{N} G(|x_j - x_i|), \quad i \neq j,$$

model pairwise alignment of the agents, like for example in the model by Cucker and Smale (2007), and

$$[\nabla \mathcal{V}(x)]_{ii} = 0, \quad [\nabla \mathcal{V}(x)]_{ij} = \frac{1}{N} \nabla_{x_i} V(x_j - x_i), \quad i \neq j$$

model pairwise interactions of the particles. We remark, that the matrix $\mathcal{G}(x)$ is negative semi-definite by definition. For well-posedness the systems is supplemented with initial conditions $x(0) = x_0, v(0) = v_0$ with $[x_0]_i$ and $[v_0]_i$ drawn independently from a probability distribution $\hat{f} \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d)$.

This general class of interaction models contains the following well-known examples: Cucker and Smale (2007), Matei et al. (2019), Morse-interactions (sheep flocks, double and single milling birds) as proposed in D'Orsogna et al. (2006), or herding dynamics Burger et al. (2020).

For later use we mention the well-known mean-field PDE corresponding to (2) given by

$$\begin{aligned} \partial_t f_t + \nabla_x(v f_t) &= \nabla_v \left((G * \varrho_t) + \nabla_x V * \varrho_t) f_t \right), \qquad (3) \\ f_0(x,v) &= \hat{f}(x,v) \end{aligned}$$

for some probability measure $\hat{f} \in \mathcal{P}(\mathbb{R}^d \times \mathbb{R}^d)$, where we used $\varrho_t(x) = \int_{\mathbb{R}^d} f_t(x,v)dv$.

We note that the actual positions of the agents do not influence the dynamic but rather the relative distances $x_j - x_i$. This is exploited in the derivation of port-Hamiltonian system (PHS) reformulation proposed below. Indeed, following the approach of Matei et al. (2019) we introduce new variables $q_{ij} = x_i - x_j$ and $p_i = mv_i$, the relative positions and impulses of the agents. In the remainder we set $m = 1$ such that $p_i = v_i$ and write $z = (q,p)$ with $[q]_{ij} = q_{ij}$ and $[p]_i = p_i$. For notational convenience we fix the ordering of q as follows:
We consider the matrix Q with $[Q]_{ij} = q_{ij}$ for $i \neq j$ and $[Q]_{ii} = 0$. We "remove" the diagonal of the matrix and write the entries q_{ij} of the resulting matrix $Q_- \in (\mathbb{R}^d)^{N\times(N-1)}$ row-wise in the vector q.

Using the new variables the above dynamic can be written as

$$\frac{d}{dt} q_{ij} = p_i - p_j, \quad q_{ij}(0) = (q_0)_{ij}, \qquad (4a)$$

$$\frac{d}{dt} p = \mathcal{G}(q)p - \nabla\mathcal{V}(q), \quad p(0) = v_0, \qquad (4b)$$

where

$$\begin{aligned} [\mathcal{G}(q)]_{ii} &= -\frac{1}{N}\sum_{j\neq i} G(|q_{ij}|) \\ [\mathcal{G}(x)]_{ij} &= \frac{1}{N} G(|q_{ij}|), \quad i \neq j, \\ [\nabla\mathcal{V}(q)]_{ii} &= 0, \quad [\nabla\mathcal{V}(q)]_{ij} = \frac{1}{N}\nabla V(q_{ij}), \quad i \neq j. \end{aligned}$$

Remark 1. In order to be consistent, the initial conditions of (2) and (4) have to be chosen carefully. In case of independent uniformly distributed initial positions $\text{law}(x_i(0)) = \mathcal{U}[a,b]$ with $a,b \in \mathbb{R}, a < b$, we can exploit the fact that the probability distribution function of $x_i(0) - x_j(0)$ is given by a convolution, leading to $\text{law}(q_{ij}(0)) = \mathcal{U}[a,b] * \mathcal{U}[-b,-a]$.

As the Hamiltonian reformulation for general N is quite technical, we sketch the main ideas with the derivation of the PHS formulation for $N = 2$:

Let $z = (q_{12}, q_{21}, p_1, p_2)^\top$ and consider the Hamiltonian

$$\mathcal{H}(z) = \frac{1}{2}|p_1|^2 + \frac{1}{2}|p_2|^2 + \frac{1}{4}(V(q_{12}) + V(q_{21})).$$

The dynamics of z is defined by (4) leading to

$$\frac{d}{dt} z = \begin{pmatrix} p_1 - p_2 \\ p_2 - p_1 \\ \mathcal{G}(q)p - \nabla\mathcal{V}(q) \end{pmatrix}$$

Note that it holds

$$\frac{\partial\mathcal{H}(z)}{\partial z} = (\frac{1}{4}\nabla V(q_{12}), \frac{1}{4}\nabla V(q_{21}), p_1, p_2)^\top$$

which allows us to rewrite

$$\begin{aligned} \frac{d}{dt} z &= \begin{pmatrix} 0 & \begin{pmatrix} I & -I \\ -I & I \end{pmatrix} \\ \begin{pmatrix} -I & I \\ I & -I \end{pmatrix} & \mathcal{G}(q) \end{pmatrix} \begin{pmatrix} \frac{1}{4}\nabla V(q) \\ p \end{pmatrix} + \begin{pmatrix} 0 \\ B \end{pmatrix} u \\ &= \left[J - \begin{pmatrix} 0 & 0 \\ 0 & -\mathcal{G}(q) \end{pmatrix} \right] \frac{\partial\mathcal{H}(z)}{\partial z} \end{aligned}$$

with

$$J = \begin{pmatrix} 0 & \begin{pmatrix} I & -I \\ -I & I \end{pmatrix} \\ \begin{pmatrix} -I & I \\ I & -I \end{pmatrix} & 0 \end{pmatrix}.$$

Here I denotes the identity matrix in $\mathbb{R}^{d\times d}$. We want to emphasize that the upper-right part of J is set by the structure of q_{ij} and by the skew-symmetry of J this also sets the lower-left part of J. Therefore assumption (1) is crucial for port-Hamiltonian reformulation.

For $N \in \mathbb{N}$ the above derivation generalizes to $z = (q,p)^\top$ and

$$\mathcal{H}(z) = \frac{1}{2}p^T p + \frac{1}{2N}\sum_{i=1}^{N}\sum_{j\neq i}^{N} V(q_{ij}).$$

We then derive

$$\frac{d}{dt} z = \left[\begin{pmatrix} 0 & J \\ -J & 0 \end{pmatrix} - \begin{pmatrix} 0 & 0 \\ 0 & -\mathcal{G}(q) \end{pmatrix} \right] \frac{\partial\mathcal{H}(z)}{\partial z}$$

where $J \in (\mathbb{R}^{d\times d})^{N(N-1)\times N}$ is given by

$$J = \begin{pmatrix} J_1 \\ \vdots \\ J_N \end{pmatrix}$$

with

$J_i \in \mathbb{R}^{(N-1)\times N}$, $i = 1, \ldots, N$,

$$[J_i]_{jk} = \begin{cases} I, & k = i \\ -I, & (k = j+1 \wedge j \geq i) \vee (k = j < i) \\ 0, & \text{otherwise} \end{cases}.$$

In particular

$$J_1 = \begin{pmatrix} I & -I & 0 & 0 & \cdots & 0 \\ I & 0 & -I & 0 & \cdots & 0 \\ \vdots & & & & & \vdots \\ I & & & & & -I \end{pmatrix}$$

and

$$J_2 = \begin{pmatrix} -I & I & 0 & 0 & \cdots & 0 \\ 0 & I & -I & 0 & \cdots & 0 \\ \vdots & & & & & \vdots \\ 0 & I & & & & -I \end{pmatrix}$$

Then it is easy to verify that (4) can be written as

$$\frac{d}{dt}z = (J - R(z))\frac{\partial \mathcal{H}(z)}{\partial z}, \qquad z(0) = (q(0), p(0)).$$

At first sight we have increased the number of variables from $2Nd$ to dN^2 during the reformulation process. Note that due to the dependencies, it is enough to have the information of one particle and then the relative positions of all the other particles to recover the full information of the system. This observation together with the fact that the PHS formulation factors out the translational invariance of the system, motivates us to introduce the center of mass variable $\bar{x} = \frac{1}{N}\sum_{i=1}^{N} x_i$ and the relative positions $\xi_i = \frac{1}{N}\sum_{j=1, j\neq i}^{N} q_{ij} = x_i - \bar{x}$. System (4) can then by rewritten as

$$\frac{d}{dt}\xi_i = p_i - \frac{1}{N}\sum_{j=1}^{N} p_j, \tag{5}$$

$$\frac{d}{dt}p_i = \frac{1}{N}\sum_{j=1}^{N}\left[\mathcal{G}(\xi_i - \xi_j)p_j - \nabla\mathcal{V}(\xi_i - \xi_j)\right] \tag{6}$$

supplemented with initial conditions $\xi_i(0) = x_i(0) - \bar{x}(0)$ and $p_i(0) = v(0)$.

Remark 2. It is important to note that we loose the port-Hamiltonian structure with this reformulation. Indeed, the right-hand side of (5) sets the structure of the upper-right part of J. Nonlinearities of ∇V prevent a suitable reformulation of (6) to meet this structure. We further remark that in general the nonlinearity of ∇V prevents to reduce the number of variables q_{ij} to only N variables.

3. MEAN-FIELD LIMIT

For interacting particle systems in x-v-formulation a model hierarchy exists Carrillo et al. (2010) that ranges from the particle description, to a mesoscopic and even a hydrodynamic formulation. In the following we discuss the mean-field limit in the port-Hamiltonian formulation. We use the transformed version in (ξ, p) coordinates. It is important to note that $q_{ij} = \xi_i - \xi_j$.

Let $\delta(x, y)$ denote the Delta-distribution on $\mathbb{R}^d \times \mathbb{R}^d$ and define the empirical measure

$$f^N(t, \xi, p) = \frac{1}{N}\sum_{i=1}^{N}\delta(\xi - \xi_i, p - p_i).$$

Further, let $\varphi \in C^1(\mathbb{R}^d \times \mathbb{R}^d)$ be an arbitrary test function. To compute the evolution of f^N, we use the notation

$$\langle f^N, \varphi\rangle = \int_{\mathbb{R}^d\times\mathbb{R}^d}\varphi(\xi, p)df^N(\xi, p) = \frac{1}{N}\sum_{i=1}^{N}\varphi(\xi_i, p_i)$$

and (formally) obtain

$$\begin{aligned}
\left\langle \partial_t f^N, \varphi\right\rangle &= \frac{d}{dt}\left\langle f^N, \varphi\right\rangle \\
&= \frac{1}{N}\sum_{i=1}^{N}\left(\nabla_p\varphi(p_i, \xi_i)\cdot\frac{d}{dt}p_i + \nabla_\xi\varphi(p_i, \xi_i)\cdot\frac{d}{dt}\xi_i\right) \\
&= -\frac{1}{N}\sum_{i=1}^{N}\nabla_p\varphi(p_i, \xi_i)\cdot\left[\frac{1}{N}\sum_{j\neq i}G(\xi_i - \xi_j)p_i\right] \\
&\quad - \frac{1}{N}\sum_{i=1}^{N}\nabla_p\varphi(p_i, \xi_i)\cdot\left[\frac{1}{N}\sum_{j\neq i}\nabla V(\xi_i - \xi_j)\right] \\
&\quad + \nabla_\xi\varphi(p_i, \xi_i)\cdot\left[\frac{1}{N}\sum_{j\neq i}p_i - p_j\right] \\
&= \left\langle \nabla_p\cdot\left(\int G(\xi - \bar{\xi})p - \nabla V(\xi - \bar{\xi})\, df_t^N(\bar{p}, \bar{\xi}))\, f_t^N(p, \xi)\right)\right. \\
&\quad \left. - \nabla_\xi\cdot\left(\left[p - \int\bar{p}\, df_t^N(\bar{p}, \bar{\xi})\right] f_t^N(p, \xi)\right), \varphi\right\rangle.
\end{aligned}$$

With the help of the Variational Lemma we can identify the evolution equation for f^N as

$$\begin{aligned}
&\partial_t f_t^N + \nabla_\xi\cdot\left(\left[p - \int\bar{p}\, df_t^N(\bar{p}, \bar{\xi})\right] f_t^N(p, \xi)\right) \\
&= \nabla_p\cdot\left(\int G(\xi - \bar{\xi})p - \nabla V(\xi - \bar{\xi})\, df_t^N(\bar{p}, \bar{\xi}))f_t^N(p, \xi)\right), \\
&\qquad f_0^N(p, \xi) = \hat{f}(p, \xi).
\end{aligned}$$

Note that this computation slightly differs from the standard derivation of the mean-field equation (3) as the drift with respect to ξ is shifted by the average momentum.

Remark 3. The characteristic equations of this PDE are given by

$$\begin{aligned}
\frac{d}{dt}\xi_t &= P_t - \int P_t(\bar{v})d\hat{f}(\bar{x}, \bar{v}), \qquad \xi_0(x) = x, \\
\frac{d}{dt}P_t &= (G * \varrho_t)(\xi_t)P_t - (\nabla V * \varrho_t)(\xi_t), \qquad P_0(v) = v.
\end{aligned}$$

Note that $\hat{f}$ is the initial distribution of the particles, the evolution of f over time is in terms of the characteristics as $f_t = (p_t, \xi_t)_\# \hat{f}$, i.e., the distribution of the particles at time $t > 0$ is the push forward of the initial distribution along the characteristics.

To recover the PHS structure, we need to perform a retransformation similar to the finite dimensional case. Due to the relative positions the transformation is based on the initial conditions of two independently chosen particles $z = (x, v)$ and $\bar{z} = (\bar{x}, \bar{v})$, respectively.

Let $\mathrm{law}(z) = \mathrm{law}(\bar{z}) = \hat{f}$. As before it holds $v = p$ and $\bar{v} = \bar{p}$. The initial conditions of the characteristics are given by

$$\xi_0(x) = x,\ \xi_0(\bar{x}) = \bar{x}, \qquad P_0(p) = p,\ P_0(\bar{p}) = \bar{p}.$$

For the retransformation we set

$$Q_t(q) := \xi_t(x) - \xi_t(\bar{x}), \quad Q_0(q) = x - \bar{x} = q.$$

Then we obtain

$$\frac{d}{dt}Q_t(q) = P_t(p) - P_t(\bar{p}), \quad \frac{d}{dt}Q_t(-q) = P_t(\bar{p}) - P_t(p),$$

which implies $Q_t(-q) = -Q_t(q)$. Moreover, the characteristics of the impulses read

$$\begin{aligned}
\frac{d}{dt}P_t(p) &= G(Q_t(q))P_t(p) - \nabla V(Q_t(q)), \\
\frac{d}{dt}P_t(\bar{p}) &= G(Q_t(-q))P_t(\bar{p}) - \nabla V(Q_t(-q)).
\end{aligned}$$

Our assumptions on G and U yield

$$G(Q_t(q) = G(Q_t(-q),\ \nabla V(Q_t(q)) = -\nabla V(Q_t(-q))$$

as in the finite dimensional case.

The Hamiltonian for $Z_t(z,\bar{z}) = (Q_t(q), Q_t(-q), P_t(p), P_t(\bar{p}))$ is given by

$$\mathcal{H}(Z_t(z,\bar{z})) = \frac{1}{2}|P_t(p)|^2 + |P_t(\bar{p})| + \frac{1}{2}V(Q_t(q)) + V(Q_t(\bar{q})),$$

to obtain the Banach space valued ODE in PHS form

$$\frac{d}{dt}Z_t = (J-R)\frac{\partial \mathcal{H}}{\partial Z_t}$$

supplemented with initial condition

$$Z_0 = (q_0, -q_0, p_0, \bar{p}_0) \in \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}^d$$

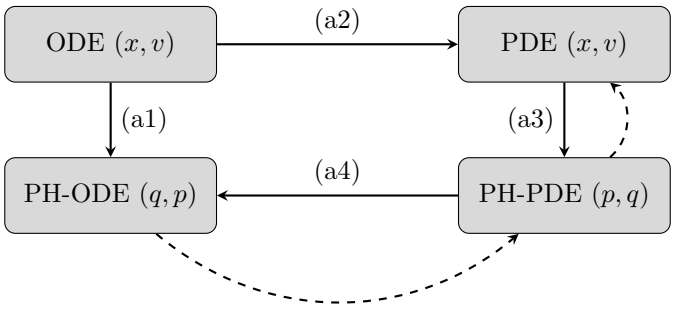
with $\text{law}(q_0) = f_q$ and $\text{law}(p_0) = \text{law}(\bar{p}_0) = f_p$. The skew-symmetric matrix J is the same as in the case $N = 2$ discussed above and

$$R = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -G(Q_t(q)) & 0 \\ 0 & 0 & 0 & -G(Q_t(-q)) \end{pmatrix}.$$

Note that the characteristic equations of the PHS systems resemble as expected. Indeed, drawing $N/2$ independent relative positions q_i and N velocities p_i and exploiting the relationships of the finite dimensional PHS allows to recover the PHS particle dynamics.

4. RELATIONSHIP OF THE DIFFERENT APPROACHES

Starting from the ODE description of interacting particle systems that is based on Newton's Second Law, we find a reformulation as finite dimensional port-Hamiltonian System (a1). This reformulation is not directly feasible for the passage to the limit $N \to \infty$, but we obtain a mean-field formulation via a shifting with respect to the center of mass of the system. This is illustrated by the dashed arrow below (a4). The classical formulation based on positions and velocities admits a the well-known mean-field equation also formulated in position and velocity variables (a2). Considering again relative positions allows us to obtain (a3). When drawing $N/2$ independent relative positions and N independent impulses and let them follow the characteristics of the mean-field PDE in PHS formulation, we recover the finite-dimensional PHS description of the interacting particle system (a4). Finally, note that all PHS formulations are based on relative positions, therefore it is only possible to recover the original (x,v) formulation on the ODE as well as on the PDE level with center of mass shifted to $0 \in \mathbb{R}^d$.



5. OUTLOOK

In future work, we plan to employ control-strategies based on the new port-Hamiltonian formulation of interacting particle systems. Moreover, the port-Hamiltonian structure will be useful in a stability analysis of general interacting particle systems.

Abstract:
We study a network design problem (NDP) where the planner aims at selecting the optimal single-link intervention in a transportation network to minimize the total congestion. Our first result is to show that the NDP may be formulated in terms of electrical quantities on a related resistor network, in particular in terms of the effective resistance between adjacent nodes. We then suggest an approach to approximate such an effective resistance by performing only local computations, and exploit this approach to design an efficient algorithm to solve the NDP, without recomputing the equilibrium flow after the intervention. We then study the optimality of the proposed procedure for recurrent networks, and provide simulations over relevant networks. *

1. INTRODUCTION

Congestion of transportation networks leads to massive waste of time and money (European Union (2021)). To mitigate such a problem, one approach is to optimize the underlying network (e.g., add lanes to existing roads or construct new roads) given a certain budget. This class of problems, known as *network design problem* (NDP), has been first defined in LeBlanc (1975). For a complete survey we refer to Farahani et al. (2013). NDPs are typically computationally hard. In this work we focus on a specific NDP where one link only can be improved, and show how to approximate its solution in a tractable way when the link delay functions are affine functions of the flow. Our contribution is twofold. First, we derive an alternative formulation of the problem in terms of electrical quantities, in particular the effective resistance between adjacent nodes. Then, we propose a method to locally approximate such a quantity, and based on this method we propose an efficient algorithm to find an approximated solution of the original problem. Our work is related to Steinberg and Zangwill (1983) and Dafermos and Nagurney (1984), where the travel time variation after the addition of a new route is studied with similar assumptions as ours. The main objective of those works is to investigate the sign of the travel time variation, i.e., the emergence of Braess' paradox. We instead study the problem from an optimization perspective, and quantify the travel time variation corresponding to a single link intervention. Another related problem is the optimal toll design (see, e.g., Hoefer et al. (2008) and Jelinek et al. (2014)). However, the NDP and toll design differ in the fact that tolling schemes modify the equilibrium flows on the network, but the performance of the tolls is evaluated with respect to the original delay functions. Instead, in NDP the intervention modifies both the equilibrium flows and the delay functions according to which the performance of the NDP is evaluated.

2. MODEL AND PROBLEM STATEMENT

2.1 Notation and setting

We model the transportation network as a directed multi-graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$ with a single origin o and destination d, where $\mathcal{N}$ and $\mathcal{E}$ denote respectively the node and the link sets. We let $\xi(e)$ and $\theta(e)$ denote respectively the head and the tail of the link e. Let $\mathcal{R}$ denote the set of the routes from o to d. Let τ denote the throughput of non-atomic agents moving from the origin o to the destination d, and $\nu = \tau(\delta_{\mathrm{o}} - \delta_{\mathrm{d}}) \in \mathbb{R}^{\mathcal{N}}$ denote the net inflow to the network, where δ_i indicates the vector with 1 in position i and 0 in the other positions. An admissible route flow is a vector $z \in \mathbb{R}^{\mathcal{R}}_+$ satisfying the constraint $z^T\mathbf{1} = \tau$. A route flow z induces a unique link flow $f \in \mathbb{R}^{\mathcal{E}}_+$ via the relation

$$f_e = \sum_{r \in \mathcal{R}: e \in r} z_r, \tag{1}$$

i.e., the flow on link e is the sum of the flow over the routes including link e. We endow each link with a delay

function, which is assumed affine, non-negative and strictly increasing, i.e., in the form

$$d_e(f_e) = a_e f_e + b_e, \quad a_e > 0, \quad b_e \geq 0, \quad \forall e \in \mathcal{E},$$

and define the cost of the route r under flow f as

$$c_r(f) = \sum_{e \in \mathcal{E}: e \in r} d_e(f_e), \tag{2}$$

which is the sum of the delay functions of the links belonging to the route.

Definition 1. An *affine routing game* is a quadruple $(\mathcal{G}, a, b, \nu)$.

A Wardrop equilibrium is a flow distribution such that no one has incentive in changing route.

Definition 2. (Wardrop equilibrium). A feasible route flow z^*, with associated link flow f^* obtained via (1), is a Wardrop equilibrium if for every route r

$$z_r^* > 0 \implies c_r(f^*) \leq c_q(f^*), \quad \forall q \in \mathcal{R}.$$

Let $B \in \mathbb{R}^{\mathcal{N} \times \mathcal{E}}$ denote the node-link incidence matrix, with entries $B_{ne} = 1$ if $n = \xi(e)$, $B_{ne} = -1$ if $n = \theta(e)$, or $B_{ne} = 0$ otherwise. It is known that a link flow f^* is a Wardrop equilibrium of a routing game if and only if it is solution of the following convex program:

$$f^* \in \underset{f \in \mathbb{R}_+^{\mathcal{E}}: Bf = \nu}{\arg\min} \quad \sum_{e \in \mathcal{E}} \int_0^{f_e} d_e(s) ds, \tag{3}$$

where $Bf = \nu$ is the projection of $z^T \mathbf{1} = \tau$ in the space of link flows. Since the delay functions are assumed strictly increasing, the objective function is strictly convex and the Wardrop equilibrium f^* is unique (Beckmann et al. (1956)). We now define the social cost, which is the total travel time at the equilibrium.

Definition 3. (Social cost). Let f^* be the unique Wardrop equilibrium of an affine routing game. The social cost is

$$C(f^*) = \sum_{e \in \mathcal{E}} f_e^* d_e(f_e^*).$$

The social cost can be interpreted as a measure of performance of the transportation network by a planner that aims at minimizing the overall congestion of the network.

2.2 Problem statement

We consider a NDP where the planner can rescale the slopes of the delay functions, from a_e to $\tilde{a}_e = a_e/(\kappa_e + 1)$, with $\kappa_e \geq 0$. We let $h_e : [0, +\infty) \to [0, +\infty)$ denote the cost associated to the intervention on link e. For every link e, we assume that h_e is non-decreasing and convex in κ_e, with $h_e(0) = 0$. The goal of the planner is to minimize a combination of the social cost and the intervention cost, where $\alpha \geq 0$ is the trade-off parameter. Specifically, by letting $f^*(\kappa)$ denote the Wardrop equilibrium corresponding to intervention κ, the NDP reads

$$\kappa^* \in \underset{\kappa \geq \mathbf{0}}{\arg\min} \sum_{e \in \mathcal{E}} \frac{a_e}{1 + \kappa_e} \left(f_e^*(\kappa)\right)^2 + b_e f_e^*(\kappa) + \alpha \sum_{e \in \mathcal{E}} h_e(\kappa_e),$$

with

$$f^*(\kappa) = \underset{f \in \mathbb{R}_+^{\mathcal{E}}: Bf = \nu}{\arg\min} \quad \sum_{e \in \mathcal{E}} \frac{a_e}{2(1 + \kappa_e)} f_e^2 + b_e f_e \tag{4}$$

This problem is in general non-convex, and hard to solve because of its bi-level nature, in the sense that the planner optimizes the network intervention κ, but the cost function depends on κ also via the Wardrop equilibrium $f^*(\kappa)$, which in turn is solution of the optimization problem (4), whose objective function depends on the intervention κ itself. For these reasons, we restrict our analysis to the case where the planner can intervene on a single link. For this special class of interventions, we are able to rephrase the problem into a single-level optimization problem and to provide an electrical interpretation of the problem. We express interventions as pairs $(e, \kappa) \in \mathcal{I}$, where κ is now a scalar value and $\mathcal{I}$ denotes the set of the feasible interventions. Let $(\mathcal{G}, a(e, \kappa), b, \nu)$ and $f^*(e, \kappa)$ denote the modified routing game and the corresponding Wardrop equilibrium respectively, and $\Delta C(e, \kappa) = C(f^*) - C_{e,\kappa}(f^*(e, \kappa))$ denote the corresponding social cost gain. Our goal is to identify the optimal intervention (e^*, κ^*). The problem can be expressed as follows.

Problem 1. Let $(\mathcal{G}, a, b, \nu)$ be an affine routing game and $\alpha \geq 0$ a trade-off parameter. Find

$$(e^*, \kappa^*) \in \underset{(e,\kappa) \in \mathcal{I}}{\arg\max} \quad \Delta C(e, \kappa) - \alpha h_e(\kappa).$$

3. RESULTS

3.1 Electrical formulation

As anticipated, the social cost variation in the transportation network may be formulated in terms of electrical quantities on a related resistor network. Let us define how to construct such a resistor network $\mathcal{G}_R$.

Definition 4. Given the transportation network $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, we construct the *associated resistor network* $\mathcal{G}_R = (\mathcal{N}, \mathcal{L}, W)$ as follows:

- the node set $\mathcal{N}$ is equivalent.
- $W \in \mathbb{R}^{\mathcal{N} \times \mathcal{N}}$ is the conductance matrix, which reads

$$W_{ij} := \begin{cases} \displaystyle\sum_{\substack{e \in \mathcal{E}: \\ \xi(e)=i, \theta(e)=j, \text{ or} \\ \xi(e)=j, \theta(e)=i}} \frac{1}{a_e} & \text{if } i \neq j \\ 0 & \text{if } i = j. \end{cases} \tag{5}$$

  Note that W is symmetric, thus $\mathcal{G}_R$ is undirected. The element W_{ij} indicates the conductance between nodes i and j.
- Multiple links from the same pair of nodes are not allowed, so that every link $l \in \mathcal{L}$ can be identified by an unordered pair of nodes $\{i, j\}$, and the set $\mathcal{L}$ is univocally determined by non-zero elements of W. We define a mapping $M : \mathcal{E} \to \mathcal{L}$ that associates to every link $e \in \mathcal{E}$ of the transportation network the corresponding link $l = M(e) = \{\xi(e), \theta(e)\}$ of the resistor network.

Definition 5. (Effective resistance). Consider a resistor network $(\mathcal{N}, \mathcal{L}, W)$ and an arbitrary link $l = \{i, j\} \in \mathcal{L}$. We define the effective resistance r_l of the link l as the effective resistance between i and j, i.e.,

$$r_l = \overline{v}_i - \overline{v}_j,$$

where $\overline{v}$ is the voltage vector when unitary current from i to j is injected, i.e.,

$$\sum_k W_{hk}(\overline{v}_h - \overline{v}_k) = \delta_i - \delta_j \qquad \forall h \in \mathcal{N}. \tag{6}$$

The next theorem establishes a relation between the social cost variation corresponding to a single-link interventions on the transportation network and the associated resistor network. The result holds under the following regularity assumption, which states that all the feasible interventions do not modify the support of the Wardrop equilibrium.

Assumption 1. Let $\mathcal{E}_+(e,\kappa)$ be the set of links $j \in \mathcal{E}$ such that $f_j^*(e,\kappa) > 0$ in the Wardrop equilibrium of $(\mathcal{G}, a(e,\kappa), b, \nu)$. We assume that $\mathcal{E}_+(e,\kappa) = \mathcal{E}$ for every $(e,\kappa) \in \mathcal{I}$.

Theorem 1. Let $(\mathcal{G}, a, b, \nu)$ be a routing game, and suppose Assumption 1 holds. Then,

$$\Delta C(e,\kappa) = \iota \frac{f_e^*(v_{\xi(e)} - v_{\theta(e)})}{\frac{1}{\kappa} + \frac{r_{M(e)}}{a_e}}, \tag{7}$$

where v is the voltage vector over the associated resistor network when a unitary current from o to d is injected, $r_{M(e)}$ is the effective resistance of the link $M(e)$, and ι is a positive constant.

The idea behind the proof is that with affine delay function the Wardrop equilibrium is the result of a quadratic program with constraints, whose KKT conditions are linear. Moreover, it is possible to relate the social cost variation to Lagrangian multipliers. Since Assumption 1 guarantees that interventions are rank-1 perturbation of such linear system, we exploit Sherman-Morrison relation to compute the Lagrangian multiplier variation, and then relate it to electrical quantities by using some electrical circuits theory. Observe that the social cost variation is expressed in terms of quantities that do not depend on the intervention, and does not require the computation of the new Wardrop equilibrium. In particular, f^* can be computed by solving the convex program (3), and the voltage v by solving a sparse linear system analogous to (6). Also the constant ι can be easily computed. The computational bottleneck is given by the computation of all the link effective resistances, which require to solve $|\mathcal{L}|$ sparse linear systems. In the next section we propose a method to approximate r_l that does not scale with the size of the network. Before doing that, we discuss Assumption 1. The assumption is not new in NDP literature (Steinberg and Zangwill (1983) and Dafermos and Nagurney (1984)). Moreover, the next lemma shows that it is without loss of generality on series-parallel graphs, provided that the throughput is sufficiently large.

Lemma 1. Let $(\mathcal{G}, a, b, \nu)$ be a routing game, and assume that $\mathcal{G}$ is series-parallel. Then, there exists $\overline{\tau}$ such that for every $\tau \geq \overline{\tau}$ the set of links such that $f_e^* > 0$ does not depend on a.

The result above follows from the fact that along all routes of series-parallel networks the nodes are ordered in such a way that the Lagrangian multipliers corresponding to relation $Bf = \nu$ in (3) are always decreasing from the origin to the destination.

3.2 Our algorithm

In this section we propose an algorithm to solve in approximation Problem 1. Our algorithm relies on Theorem 1, and on the idea that the effective resistance of a link can be approximated by looking at a local portion of the network. Let us introduce the following operations.

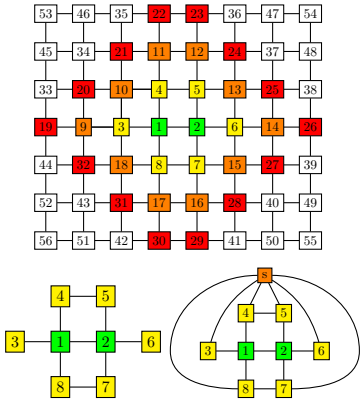

Fig. 1. Square grid. *Above*: the yellow, orange and red nodes are at distance 1, 2 and 3, respectively from the green nodes. *Bottom left*: cut at distance 1. *Bottom right*: shorted at distance 1.

Definition 6. A resistor network $\mathcal{G}_R$ is cut at distance d with respect to a link $l = \{i,j\} \in \mathcal{L}$ if every node at distance greater than d from link l, i.e., from both i and j, is removed, and every link having at least one endpoint in the set of the removed nodes is removed. Let $\mathcal{G}_l^{U_d}$ and $r_l^{U_d}$ denote such a network and the effective resistance of link l on it, respectively.

Definition 7. A resistor network $\mathcal{G}_R$ is shorted at distance d with respect to a link $l \in \mathcal{L}$ if all the nodes at distance greater than d from the link l are shorted together, i.e., an infinite conductance is added between each pair of such nodes. Let $\mathcal{G}_l^{L_d}$ and $r_l^{L_d}$ denote such a network and the effective resistance of link l on it, respectively.

We refer to Fig. 1 for an example of cut and shorted regular grid. The next proposition states that cutting and shorting a network provide respectively upper and lower bounds for the effective resistance of a link. Moreover, the tightness of the bounds is a monotone function of the distance d.

Proposition 1. Let $\mathcal{G}_R$ be a resistor network. Then, for every link $l = \{i,j\} \in \mathcal{L}$,

$$r_l^{U_{d_1}} \geq r_l^{U_{d_2}} \geq r_l \geq r_l^{L_{d_2}} \geq r_l^{L_{d_1}}, \quad \forall\ d_2 > d_1 \geq 1.$$

The following algorithm provides an approximated solution of Problem 1 based on Proposition 1.

Theorem 2. Let $\Delta C(e,\kappa)$ be the cost variation corresponding to intervention (e,κ) as given in Theorem 1, and

$$\Delta C_d(e,\kappa) = \iota \frac{f_e^*(v_{\xi(e)} - v_{\theta(e)})}{\frac{1}{\kappa} + \frac{r_{M(e)}^{U_d} + r_{M(e)}^{L_d}}{2a_e}}$$

be the cost variation estimated by Algorithm 1 for a given distance $d \geq 1$. Then,

$$\left| \frac{\Delta C(e,\kappa) - \Delta C_d(e,\kappa)}{\Delta C(e,\kappa)} \right| \leq \frac{\epsilon_{ed}}{2\left(\frac{1}{\kappa} + \frac{r_{M(e)}^{U_d} + r_{M(e)}^{L_d}}{2a_e}\right)}$$

where

$$\epsilon_{ed} := \frac{r_{M(e)}^{U_d} - r_{M(e)}^{L_d}}{a_e}.$$

Furthermore,

$$\Delta C(e,\kappa) \geq \iota \frac{f_e^*(v_{\xi(e)} - v_{\theta(e)})}{\frac{1}{\kappa} + \frac{r_{M(e)}^{U_d}}{a_e}}. \tag{8}$$

Algorithm 1:

Input: The affine routing game $(\mathcal{G}, a, b, \nu)$, the cost functions $\{h_e\}_{e\in\mathcal{E}}$, and the distance $d \geq 1$ used to approximate the effective resistance.
Output: The optimal intervention $(e,\kappa)^{*d} \in \mathcal{I}$.
Construct the associated resistor network $\mathcal{G}_R$.
Compute v by solving the sparse linear system

$$\sum_k W_{hk}(v_h - v_k) = \delta_o - \delta_d \qquad \forall h \in \mathcal{N}.$$

for *each* $l \in \mathcal{L}$ **do**
  Construct $\mathcal{G}_l^{U_d}$ and $\mathcal{G}_l^{L_d}$;
  Compute $r_l^{U_d}$ on $\mathcal{G}_l^{U_d}$, and $r_l^{L_d}$ on $\mathcal{G}_l^{L_d}$.
end
for *each* $e \in \mathcal{E}$ **do**
  Select κ_e^{*d} such that

$$\kappa_e^{*d} \in \arg\max_{\kappa:(e,\kappa)\in\mathcal{I}} \quad \iota \frac{f_e^*(v_{\xi(e)} - v_{\theta(e)})}{\frac{1}{\kappa} + \frac{r_{M(e)}^{U_d} + r_{M(e)}^{L_d}}{2a_e}} - \alpha h_e(\kappa).$$

end
Select $(e,\kappa)^{*d}$ such that

$$(e,\kappa)^{*d} \in \arg\max_{(e,\kappa_e^{*d})} \quad \iota \frac{f_e^*(v_{\xi(e)} - v_{\theta(e)})}{\frac{1}{\kappa} + \frac{r_{M(e)}^{U_d} + r_{M(e)}^{L_d}}{2a_e}} - \alpha h_e(\kappa).$$

Remark 1. Observe that the upper and lower bounds of the effective resistance of a link depend only on the local structure of the network. If we assume that the local structure of the transportation network does not depend on its size (which is a reasonable assumption, think for instance of bidimensional grids), both the tightness of the bounds and their computational complexity do not scale with the size of the network. Thus, the complexity for computing all the links effective resistance scale linearly with the number of links (or nodes) of the network.

In the final part of the section we provide a sufficient condition on the network topology under which the gap between the upper and the lower bound of the effective resistances, and therefore ϵ_{ed} defined in Theorem 2, vanishes in the limit of infinite distance. To this end, we interpret the conductance matrix W of a resistor network as the transition rates matrix of a continuous-time random walk, and define the class of recurrent networks.

Definition 8. A network $\mathcal{G}_R = (\mathcal{N}, \mathcal{L}, W)$ is *recurrent* if the random walk with transition rates W visits its starting node infinitely often with probability one.

The next theorem states that the gap between the upper and the lower bound vanishes asymptotically on recurrent networks, provided that the degree of every node is bounded.

Theorem 3. Let $\mathcal{G}_R = (\mathcal{N}, \mathcal{L}, W)$ be an infinite recurrent resistor network, and let the weighted degree of every node be finite. Then, for every link $l \in \mathcal{L}$,

$$\lim_{d\to+\infty} (r_l^{U_d} - r_l^{L_d}) = 0.$$

Theorem 3 is a consequence of the relation between effective resistance and random walks over networks. The result states that the gap between the bounds vanish asymptotically if the associated resistor network is recurrent. In the next subsection we provide numerical results on an infinite square grid, showing that gap between the bounds is quite small even for small distances d.

3.3 Simulations on infinite grids

Grids are a significant test for our algorithm, since they are a good proxy for the transportation network of many cities. In Table 1 the performances of the upper and lower bounds for a infinite square grid are shown. Despite the grid being infinite, we get a good approximation even for small distance. The simulations show that for every link l

$$r_l^{U_d} - r_l = r_l - r_l^{L_d} = O(1/d^2).$$

The tightness of the bounds scales similarly in all the regular grids.

Table 1. Table of upper and lower bound in infinite square grid.

	$d=1$	$d=2$	$d=3$	$d=4$	$d=5$
$(r_l^{U_d} - r_l)/r_l$	1/5	0.0804	0.0426	0.0262	0.0178
$(r_l - r_l^{L_d})/r_l$	1/5	0.0804	0.0426	0.0262	0.0178

4. CONCLUSION

In this work we reformulate a network design problem in terms of electrical quantities. We then propose a method to approximate the effective resistance between two adjacent nodes, and exploit this method to construct an efficient algorithm that finds in approximation the optimal intervention on the transportation network. Future research lines include the relaxation of some restrictive assumptions, as well as studying the case of multiple interventions.

Abstract: Recently, volumetric displays based on acoustic levitation have demonstrated the capability to produce mid-air content using the Persistence of Vision (PoV) effect. In these displays, acoustic traps are used to rapidly move a small levitated particle along a prescribed path. This note is based on our recent work *OptiTrap* (Paneva et al., 2022), the first structured numerical approach for computing trap positions and timings via optimal control to produce feasible and (nearly) time-optimal trajectories that reveal generic levitated graphics. While previously, feasible trap trajectories needed to be tuned manually for each shape and levitator, relying on trial and error, *OptiTrap* automates this process by allowing for a systematic exploration of the range of contents that a given levitation display can render. This represents a crucial milestone for future content authoring tools for acoustic levitation displays and advances volumetric displays closer toward real-world applications.

Keywords: Ultrasonic levitation, Minimum time problems, Path following, Optimal control

1. INTRODUCTION

Acoustic levitation displays use ultrasonic waves to trap small particles in mid-air, acting as volumetric pixels (voxels). Several practical aspects have been investigated around these displays, such as low-latency particle manipulation (Bachynskyi et al., 2018), and content detection and initialisation (Fender et al., 2021).

The ability to move single (Hirayama et al., 2019) or multiple (Plasencia et al., 2020) levitated particles at very high speeds was instrumental for achieving dynamic and free-form volumetric content. However, this was nonetheless limited to relatively small sizes and simple vector graphics (Fushimi et al., 2020). Little effort was made towards optimising the levitated visual content while considering the system dynamics of such displays, particularly for challenging content such as the one created by levitated particles moving at PoV speeds. Paneva et al. (2020) proposed an interactive simulation of a levitation interface, using a model of the particle movement in such a display. The application operates in a feed-forward manner, simulating the dynamics of the particle given a specific path for the traps, however, it does not address the inverse problem.

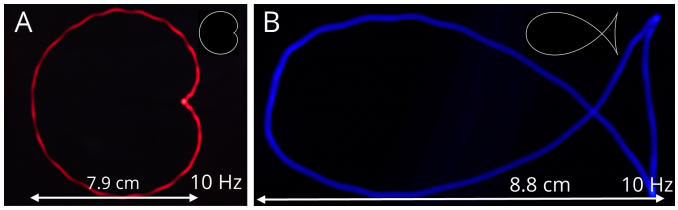

Fig. 1. Shapes involving sharp edges and significant changes in curvature demonstrated using acoustic levitation.

OptiTrap (Paneva et al., 2022) is the first algorithm allowing the definition of generic PoV content, requiring only a geometric definition (i.e., shape to present, no timing information) and optimising it according to the capabilities of the device and the dynamics of the trap-particle system. *OptiTrap* automates the definition of levitated PoV content, computing physically feasible and nearly time-optimal trap trajectories given only a reference path. This allows for larger shapes than previously demonstrated, as well as shapes featuring significant changes in curvature and/or sharp corners (Figure 1).

2. OPTIMAL CONTROL FOR LEVITATION DISPLAYS

2.1 Hardware Setup

Our setup, illustrated in Figure 2, consists of two arrays of 16×16 transducers facing each other, controlled by an FPGA, and an OptiTrack [1] tracking system - Prime 13 motion capture cameras operating at a frequency of 240Hz.

[1] www.optitrack.com

With an update rate of up to 10kHz, the device can create a single twin-trap within the levitation volume using the method from Hirayama et al. (2019). We experimentally determined the vertical and horizontal forces exerted on the particle and found that the vertical force is double the horizontal. This difference needs to be reflected by the model that is introduced in the next section.

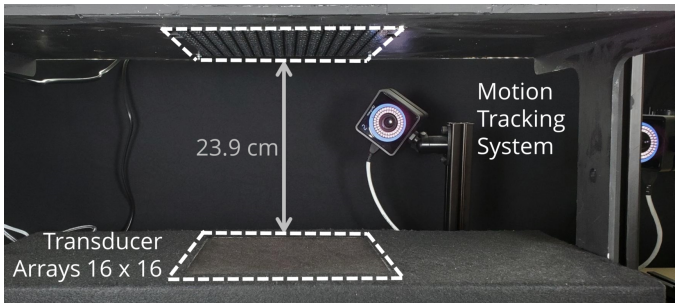

Fig. 2. Overview of the components of our levitation display.

2.2 Modelling the Trap-Particle Dynamics

To model the trap-particle dynamics, we use simple Newtonian mechanics, i.e.,

$$m\ddot{\mathbf{p}}(t) = F(\mathbf{p}(t), \dot{\mathbf{p}}(t), \mathbf{u}(t)), \tag{1}$$

where $\mathbf{p}(t) = (p_x(t), p_y(t), p_z(t))^\top \in \mathbb{R}^3$ represents the particle position in Cartesian (x, y, z) coordinates at time $t \in \mathbb{R}_0^+$, m is the particle mass, $\mathbf{u}(t) = (u_x(t), u_y(t), u_z(t))^\top \in \mathbb{R}^3$ is the control input specifying the position of the acoustic trap, and F is the net force acting on the particle. Following Hirayama et al. (2019), we neglect drag and gravitational forces due to the dominating acoustic radiation forces.

In many cases, the acoustic force can be described by the gradient of the Gor'kov potential (Bruus, 2012). Our specific setup (top-bottom transducer placement and vertical twin traps) and objective (find where to place the acoustic trap to produce a specific force) allows to consider only a region around the peak forces. In this region, the forces in our setup distribute mostly axis-symmetrically. Hence, we approximate the force as

$$F(\mathbf{p}, \mathbf{u}) = \begin{pmatrix} F_x(\mathbf{p}, \mathbf{u}) \\ F_y(\mathbf{p}, \mathbf{u}) \\ F_z(\mathbf{p}, \mathbf{u}) \end{pmatrix} := \begin{pmatrix} F_r(\mathbf{p}, \mathbf{u}) \cos\phi \\ F_r(\mathbf{p}, \mathbf{u}) \sin\phi \\ F_z(\mathbf{p}, \mathbf{u}) \end{pmatrix}, \tag{2}$$

where

$$F_r(\mathbf{p}, \mathbf{u}) := \mathcal{A}_r \cdot \cos\left(\mathcal{V}_z \cdot (u_z - p_z)\right) \cdot \sin\left(\mathcal{V}_{xr} \cdot \sqrt{(u_x - p_x)^2 + (u_y - p_y)^2}\right), \tag{3a}$$

$$F_z(\mathbf{p}, \mathbf{u}) := \mathcal{A}_z \cdot \sin\left(\mathcal{V}_z \cdot (u_z - p_z)\right) \cdot \cos\left(\mathcal{V}_{zr} \cdot \sqrt{(u_x - p_x)^2 + (u_y - p_y)^2}\right), \tag{3b}$$

$$\phi = \arctan\left(\frac{u_y - p_y}{u_x - p_x}\right),$$

and where $\mathcal{A}_r, \mathcal{A}_z$ denote the peak forces along the radial and vertical directions of the trap, respectively, and $\mathcal{V}_z$, $\mathcal{V}_{xr}$, $\mathcal{V}_{zr}$ are the characteristic frequencies of the sinusoidals describing how the forces evolve around the trap. For more details on this approximation procedure we refer to the original paper (Paneva et al., 2022).

2.3 Rendering Content via Path Following

The task at hand is to render, as fast as possible, arbitrary complex objects, formulated as an explicitly parameterised curve

$$Q := \{\xi \in \mathbb{R}^3 \mid \theta \in [\theta_0, \theta_f] \mapsto \mathbf{q}(\theta)\}, \tag{4}$$

where we require $\mathbf{q} \in C^2(\mathbb{R}; \mathbb{R}^3)$. The path parameter θ models the progress on the path from the starting point $\mathbf{q}(\theta_0)$ to the end point $\mathbf{q}(\theta_f)$. To create the PoV effect, we consider periodic paths, for which $\mathbf{q}(\theta_0) = \mathbf{q}(\theta_f)$ and $\dot{\mathbf{q}}(\theta_0) = \dot{\mathbf{q}}(\theta_f)$ hold. For example, consider the shape of the cardioid in Figure 1 (left), which can be described by $\mathbf{q}(\theta) = (0, r\sin(\theta)(1+\cos(\theta)), -r\cos(\theta)(1+\cos(\theta)) + r)^\top$, where $\theta \in [0, 2\pi]$ and $r > 0$.

Since Q comes without any preassigned time information, we need to determine the timing $t \mapsto \theta(t)$. Following Faulwasser (2012); Faulwasser et al. (2017), we assume the particle follows the path Q exactly at all times, i.e., $\mathbf{p}(t) - \mathbf{q}(\theta(t)) \equiv 0$. This leads to

$$\mathbf{p}(t) = \mathbf{q}(\theta(t)), \tag{5a}$$

$$\dot{\mathbf{p}}(t) = \dot{\mathbf{q}}(\theta(t)) = \frac{\partial \mathbf{q}}{\partial \theta}\dot{\theta}(t), \tag{5b}$$

$$\ddot{\mathbf{p}}(t) = \ddot{\mathbf{q}}(\theta(t)) = \frac{\partial^2 \mathbf{q}}{\partial \theta^2}\dot{\theta}(t)^2 + \frac{\partial \mathbf{q}}{\partial \theta}\ddot{\theta}(t). \tag{5c}$$

Using a virtual function $v(t) \in \mathbb{R}$ to control the progress of the particle along Q, the timing law is modelled as a double integrator

$$\ddot{\theta}(t) = v(t) \tag{6}$$

to avoid large jumps in the acceleration. To keep the periodic nature, we impose

$$\theta(0) = \theta_0, \quad \theta(T) = \theta_f, \quad \dot{\theta}(0) = \dot{\theta}(T), \tag{7}$$

where the traversal time T will be an optimisation variable in the latter optimal control problem (12). Using

$$\mathbf{z}(t) := (\theta(t), \dot{\theta}(t))^\top$$

we rewrite (6)-(7) as

$$\dot{\mathbf{z}}(t) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \mathbf{z}(t) + \begin{pmatrix} 0 \\ 1 \end{pmatrix} v(t), \ \mathbf{z}(0) = \mathbf{z}_0, \ \mathbf{z}(T) = \mathbf{z}_T, \tag{8}$$

solvable with standard Runge-Kutta methods (Butcher, 2016).

2.4 Coupling Path Following with Trap-Particle Dynamics

To render content on the levitator, we couple the path-following approach from Section 2.3 with the trap-particle dynamics (1)-(3) from Section 2.2. The usual approach of rewriting (1) as

$$M(\ddot{\mathbf{p}}(t), \mathbf{p}(t), \mathbf{u}(t)) := m\ddot{\mathbf{p}}(t) - F(\mathbf{p}(t), \mathbf{u}(t)) = 0 \tag{9}$$

and finding a local inversion $\mathbf{u}(t) = M^{-1}(\ddot{\mathbf{p}}(t), \mathbf{p}(t))$ is not straightforward for (3). Hence, we tackle this task via numerical optimisation by introducing auxiliary variables

$$\zeta_1 := \sin(\mathcal{V}_{xr}\sqrt{(u_x - q_x(\theta))^2 + (u_y - q_y(\theta))^2}), \quad (10a)$$
$$\zeta_2 := \cos \mathcal{V}_z \cdot (u_z - q_z(\theta)), \quad (10b)$$
$$\zeta_3 := \sin \mathcal{V}_z \cdot (u_z - q_z(\theta)), \quad (10c)$$
$$\zeta_4 := \cos \mathcal{V}_{zr}\sqrt{(u_x - q_x(\theta))^2 + (u_y - q_y(\theta))^2}), \quad (10d)$$
$$\zeta_5 := \sin \phi, \quad (10e)$$
$$\zeta_6 := \cos \phi, \quad (10f)$$

for each trigonometric term in (3), where p_i is replaced by $q_i(\theta)$, $i \in \{x, y, z\}$. This allows us to formally express (2) in terms of $\zeta := (\zeta_1, ..., \zeta_6)$:

$$\tilde{F}(\zeta) := \begin{pmatrix} \mathcal{A}_r \zeta_1 \zeta_2 \zeta_6 \\ \mathcal{A}_r \zeta_1 \zeta_2 \zeta_5 \\ \mathcal{A}_z \zeta_4 \zeta_3 \end{pmatrix}.$$

Similar to (9), along the path Q we define

$$\widetilde{M}(\mathbf{z}(t), v(t), \zeta(t)) := m\ddot{\mathbf{q}}(\theta(t)) - \tilde{F}(\zeta(t)) = 0. \quad (11)$$

With this approach, we will need to extract the trap positions $\mathbf{u}(t)$ by solving (10) numerically. To counter numerical instabilities that could occur in particular for ζ_i approaching ± 1, we introduce additional constraints

$$\mathcal{Z} := \left\{\zeta \in [\varepsilon - 1, 1 - \varepsilon]^6 \mid \zeta_2^2 + \zeta_3^2 = 1,\ \zeta_5^2 + \zeta_6^2 = 1\right\},$$

with a user-chosen back-off parameter $\varepsilon \in]0, 1[$ that captures the trade-off between numerically "stable" solutions for $\mathbf{u}(t)$ and exploiting the maximum forces of the device.

The final OCP is then given by

$$\begin{aligned} \min_{v,T,\zeta}\ & T + \gamma \int_0^T v(t)^2 \mathrm{d}t \\ \text{subject to } & (8), \\ & \widetilde{M}(\mathbf{z}(t), v(t), \zeta(t)) = 0, \\ & \zeta(t) \in \mathcal{Z}. \end{aligned} \quad (12)$$

Lastly, we discretised the final OCP and solved the resulting nonlinear programming problem using Ipopt (Andersson et al., 2018). The function evaluations and the computation of the derivatives were performed with CasADi (Wächter and Biegler, 2006).

3. EVALUATION

Next we compare our *OptiTrap* approach against a *Baseline*, where the path parameter is homogeneously sampled and the traps are placed directly on the reference path of the particle. The evaluation was conducted on four test shapes: circle, cardioid, squircle and fish, as shown in Figures 3 and 4. The particle motion shown in these figures comes not from simulations, but from actual experimental results, captured using the OptiTrack tracking system.

In the first part of the evaluation, we investigate the maximum shape size that can be rendered in PoV time (0.1s) with each approach. We see in Figure 3 that the most striking difference was obtained for the squircle, where with *OptiTrap* 1.9 meters of content per second was rendered, and with the *Baseline* only 0.29. The increase in size was similar for both the cardioid (2.80m of content per s with *OptiTrap*, 2.48 with the *Baseline*) and the fish (2.75m of content per s with *OptiTrap*, 2.42 with the *Baseline*), while there was not significant difference for the circle. This is not surprising, as the circle is the simplest and most homogeneous shape in the test parkour.

In the second part of the evaluation, we investigate the maximum possible rendering frequency with *OptiTrap* and the *Baseline*, while keeping the size of the test shape constant. The results are illustrated in Figure 4. As expected,

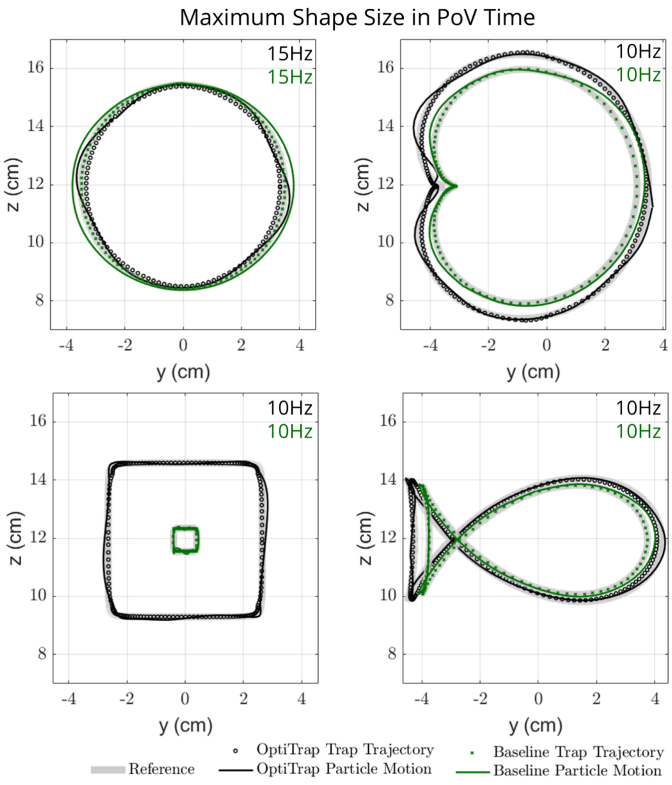

Fig. 3. Maximum shape size of *OptiTrap* vs. the Baseline.

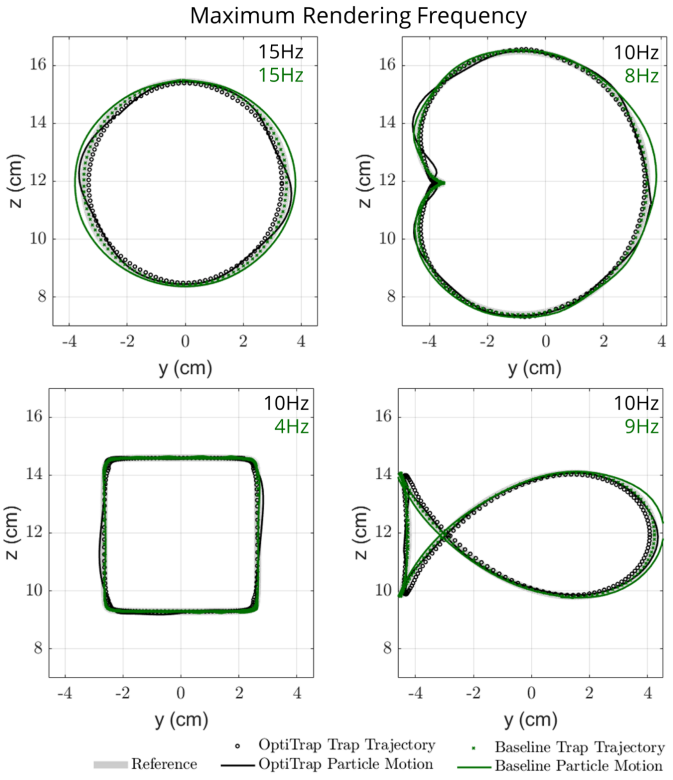

Fig. 4. Maximum rendering frequency of *OptiTrap* vs. the Baseline.

the same rendering frequency was obtained for the circle using both methods. However, the cardioid was rendered at 10Hz using *OptiTrap*, and 8Hz with the *Baseline* (25% increase). The rendering frequency for the fish increased by 11% using *OptiTrap*, i.e., from 9 to 10Hz, and lastly, we obtain an increase of 150% for the squircle.

For a more extensive and detailed evaluation of *OptiTrap*, also including a comparison to a more sophisticated baseline, please refer to Paneva et al. (2022).

4. CONCLUSION

We briefly discussed *OptiTrap* – a structured numerical approach to compute trap trajectories for acoustic levitation displays. *OptiTrap* automatically computes physically feasible and nearly time-optimal trap trajectories to reveal generic levitated content in mid-air, assuming only a reference path. This is a particularly important step for the adoption of PoV levitation displays, as it allows the content designers to focus on the shapes to be rendered, with feasible solutions taking into account the capabilities of the specific device, being computed automatically by the algorithm. As such, *OptiTrap* has the potential to become an instrumental tool in helping to further explore and develop these displays. In the future, this method can be extended to include visual content composed of multiple levitated particles, it can be applied to other domains, such as photophoretic displays or containerless matter transportation for applications in pharmacy and biochemistry, or can be used as a base for developing more complex learning-based approaches.

Sparsity Enforcing Convex Relaxation of D-Optimal Sensor Selection for Parameter Estimation of Distributed Parameter Systems

Dariusz Uciński

Institute of Control and Computation Engineering
University of Zielona Góra, Zielona Góra, Poland
(e-mail: d.ucinski@issi.uz.zgora.pl)

Abstract: Owing to the wide availability of efficient convex optimization algorithms, convex relaxation of optimum sensor selection problems has gained in popularity. Generally, however, there is a performance gap between the optimal solution of the original combinatorial problem and the heuristic solution of the respective relaxed continuous problem. This gap can be small in many cases, but there is no guarantee that this is always the case. That is why the D-optimality criterion is often extended by addition of some kind of sparsity-enforcing penalty term. Unfortunately, the problem convexity is then lost and the question of how to control the influence of this penalty so as not to excessively deteriorate the optimal relaxed solution remains open. This work proposes an alternative problem formulation, in which the sparsity-promoting term is directly minimized subject to the constraint that the D-efficiency of the sensor selection is no less than a given threshold. This offers direct control of the degree of optimality of the produced solution. An efficient computational scheme based on the majorization-minimization algorithm is proposed, which reduces to solving a sequence of low-dimensional convex optimization problems via generalized simplicial decomposition. A numerical example illustrating the effectiveness of the proposed approach is also reported.

Keywords: system identification, distributed parameter systems, sensor location, convex relaxation, sparsification.

MSC 2010: 62K05, 35Q93, 90C25.

1. INTRODUCTION

Distributed parameter systems (DPSs) constitute a class of dynamic systems whose states depend not only on time, but also on the spatial variable. Their adequate description are partial differential equations (PDEs). In most cases, not all physical parameters underlying such models can be directly measured and they have to be estimated via calibration yielding the best fit of the model output to the observations of the actual system which are provided by measurement sensors. But the number of sensors is usually limited and practitioners face the problem of where to locate them so as to collect the most valuable information about the parameters.

The traditional approach to optimal sensor location consists in formulating it in terms of an optimization problem employing various design criteria defined on the Fisher information matrix (FIM) associated with the estimated parameters. Comprehensive overviews of the works published in this area are contained in the monographs by Uciński (2005), Patan (2012) and Rafajłowicz (2022).

In the past two decades, the interest in this problem has increased rapidly due to the growing popularity of sensor networks. More and more complex scenarios have been investigated to accomodate to more and more demanding practical settings. They have primarily been concentrated around properly addressing the ill-posedness inherent in problems with large (or even infinite) dimensions of the parameter space, see works by Alexanderian (2021), Alexanderian et al. (2014), Gejadze and Shutyaev (2012) and Haber et al. (2010).

The number of sensors is usually fixed and imposed by the available experimental budget. Most techniques come down to the selection of optimal sensor locations from a finite (but possibly very large) set of candidate locations. Note that the problem of assigning sensors to specific spatial locations can equivalently be interpreted in terms of activating an optimal subset of all the available sensors deployed in the spatial area (the non-activated sensors remain dormant). This framework is typical of the measurement regime in modern sensor networks.

A grave difficulty in selecting an optimal subset of gauged sites from among a given set of candidate sites is the combinatorial nature of this optimization problem. As the cardinalities of those sets increase, the exhaustive search of the search space quickly becomes computationally intractable. This stimulated attempts to solve this problem in a more constructive manner. For problems with low or moderate

dimensionalities, Uciński and Patan (2007) set forth a branch-and-bound method, which most often drastically reduces the search space and produces an optimal integral solution. In turn, for large-scale observation networks, the existing approaches replace the original NP-hard combinatorial problem with its convex relaxation in the form of a convex programming problem. This paves the way for application of interior-point methods, see the works by Joshi and Boyd (2009) and Chepuri and Leus (2015), or polyhedral approximation methods, cf. Uciński and Patan (2007), Herzog et al. (2018) and Uciński (2020b).

A major drawback of convex relaxation is the necessity of transforming the optimal relaxed solution into an acceptable solution of the original combinatorial problem. This is by no mean trivial and, when done carelessly, may make the performance gap between both the solutions quite wide. In recent years, handling the problem with various sparsity-enforcing penalty terms have won popularity. Although as a result of their addition to the original design criteria the problem convexity is lost, this property can be easily retrieved by resorting to iterations of the majorization-minimization scheme, cf. Sun et al. (2017). Unfortunately, it is not clear how to control the impact of this penalty so as not to depart from the relaxed solution too much.

The main contribution of this work consists in establishing an alternative approach which explicitly controls the quality of the sparsified solution in terms of the original design criterion. It focuses on directly minimizing the sparsity-enforcing penalty within the set of relaxed solutions which are allowed to deteriorate the optimal relaxed solution in terms of the original design criterion by no more than an arbitrarily set threshold. The technique reduces to a sequence of nonlinearly constrained convex optimization problems which are solved using an extremely fast generalized simplicial decomposition. As a result, a relatively simple and efficient technique of postprocessing relaxed solutions is proposed.

2. D-OPTIMUM SENSOR LOCATION AND ITS CONVEX RELAXATION

Consider a spatiotemporal system whose scalar state is given by the solution y to a deterministic partial differential equation (PDE) accompanied by the appropriate boundary and initial conditions. The PDE is defined on a bounded spatial domain $\Omega \subset \mathbb{R}^d$ $(d \leq 3)$ with a boundary $\partial\Omega$ and a bounded time interval $T = (0, t_f]$. It is specified up to $\boldsymbol{\theta} \in \mathbb{R}^m$, a vector of unknown parameters which are to be estimated from noisy observations of the state. These observations are going to be made by n pointwise sensors at given time instants $t_1, \ldots, t_K \in T$.

The sensor locations are to be selected from among $N > n$ candidate sites $\boldsymbol{x}^1, \ldots, \boldsymbol{x}^N \in \bar{\Omega} := \Omega \cup \partial\Omega$. Their measurements are modelled as

$$z_j = y(\boldsymbol{x}^{i_j}, t_k; \bar{\boldsymbol{\theta}}) + \varepsilon_{i_j,k} \tag{1}$$

for $j = 1, \ldots, n$ and $k = 1, \ldots, K$, where $y(\boldsymbol{x}, t; \boldsymbol{\theta})$ stands for the state at a spatial point $\boldsymbol{x} \in \bar{\Omega}$ and a time instant $t \in \bar{T} := [0, t_f]$, evaluated for a given parameter $\boldsymbol{\theta}$. Here $\bar{\boldsymbol{\theta}}$ signifies the vector of 'true' values of the unknown parameters, $i_1, \ldots, i_n \in \{1, \ldots, N\}$ are the indices of the gauged sites, and the $\varepsilon_{i_j,k}$'s are independent normally-distributed random errors with zero mean and constant variance σ^2.

Depending on whether or not prior background information about $\bar{\boldsymbol{\theta}}$ is accessible, Bayesian (e.g., maximum a posteriori estimation) or frequentionist (maximum-likelihood estimation, possibly combined with the Tikhonov-Phillips regularization) approaches can be used to produce an estimate $\hat{\boldsymbol{\theta}}$ of $\bar{\boldsymbol{\theta}}$. Its accuracy is characterized by the Fisher information matrix (FIM), cf. Atkinson et al. (2007)

$$\boldsymbol{M}(\boldsymbol{v}) = \boldsymbol{M}_0 + \sum_{i=1}^{N} v_i \boldsymbol{M}_i, \tag{2}$$

in which

$$\boldsymbol{M}_i = \frac{1}{\sigma^2} \sum_{k=1}^{K} \boldsymbol{g}(\boldsymbol{x}^i, t_k) \boldsymbol{g}^\top(\boldsymbol{x}^i, t_k), \quad i = 1, \ldots, n, \tag{3}$$

with $\boldsymbol{g}(\boldsymbol{x}, t) = \nabla_{\boldsymbol{\theta}}\, y(\boldsymbol{x}, t; \boldsymbol{\theta})\big|_{\boldsymbol{\theta}=\boldsymbol{\theta}^0}$ stands for the sensitivity vector evaluated at a prior estimate $\boldsymbol{\theta}^0$ of the 'true' vector $\bar{\boldsymbol{\theta}}$. Furthermore, $\boldsymbol{v} = (v_1, \ldots, v_N)$ and v_i is the binary indicator variable equal to 1 or 0 depending on whether or not a sensor resides at site $\boldsymbol{x}^i$.

In the Bayesian setting, the inverse of $\boldsymbol{M}_0$ is the known covariance matrix of the prior density of $\boldsymbol{\theta}$ and then $\boldsymbol{M}^{-1}(\boldsymbol{v})$ approximates the covariance matrix of the posterior density of $\boldsymbol{\theta}$. In the frequentionist setting when no background information is available, $\boldsymbol{M}_0$ is set as zero, and then $\boldsymbol{M}^{-1}(\boldsymbol{v})$ approximates the covariance matrix of the maximum-likelihood estimator of $\bar{\boldsymbol{\theta}}$.

The 'goodness' of a sensor location represented as $\boldsymbol{v}$ is quantified by a design criterion related to the confidence ellipsoid, i.e., a highest probability regions for the parameters. The most common option is the D-optimality criterion

$$\Phi_{\mathrm{D}}(\boldsymbol{M}) = \det{}^{1/m}(\boldsymbol{M}), \tag{4}$$

maximization of which is equivalent to minimizing the volume of the confidence ellipsoid. Thus the spread of the estimates of the unknown parameters around their mean values is minimized (and on some not particularly restricted assumptions, these means are at least approximately equal to the 'true' values of the unknown parameters).

Consequently, we can formulate the following problem:

Problem 1. Find $\boldsymbol{v}^\star_{\mathrm{bin}} \in \mathcal{V}_{\mathrm{bin}} := \{\boldsymbol{v} \in \{0,1\}^N : \boldsymbol{1}^\top \boldsymbol{v} = n\}$ to maximize $\Phi_{\mathrm{D}}(\boldsymbol{M}(\boldsymbol{v}))$ Each minimizer $\boldsymbol{v}^\star_{\mathrm{bin}}$ is called a D-optimum *exact* design.

Unfortunately, the search for $\boldsymbol{v}^\star_{\mathrm{bin}}$ through evaluating $\Phi_{\mathrm{D}}(\boldsymbol{M}(\boldsymbol{v}))$ for each of $\binom{N}{n}$ possible choices of gauged sites quickly becomes computationally intractable with an increase in N. Therefore, following the customary procedure adopted in OED, we relax the nonconvex 0–1 constraints on the design variables, thereby allowing them to take any real values in the interval $[0, 1]$. Thus we get the following much more convenient formulation:

Problem 2. Find $\boldsymbol{v}^\star_{\mathrm{D}} \in \mathcal{V} := \{\boldsymbol{v} \in [0,1]^N : \boldsymbol{1}^\top \boldsymbol{v} = n\}$ to maximize $\Phi_{\mathrm{D}}(\boldsymbol{M}(\boldsymbol{v}))$ Each minimizer $\boldsymbol{v}^\star_{\mathrm{D}}$ is called a D-optimum *relaxed* design.

3. SPARSITY-PROMOTING POSTPROCESSING OF RELAXED DESIGNS

Obviously, the relaxed design $\boldsymbol{v}_{\mathrm{D}}^{\star}$ may have many fractional components. On the one hand, there is an acute need to convert it to a design desirably with binary weights. Mathematically, the transformed design ought to be characterized by minimal support, i.e., a minimal number of nonzero components. On the other hand, however, the loss in the attained extreme value of the D-optimality criterion should be as small as possible.

For any design $\boldsymbol{v} \in \mathcal{V}$ define its D-efficiency

$$\mathcal{E}_{\mathrm{D}}(\boldsymbol{v}) = \frac{\det^{1/m}(\boldsymbol{M}(\boldsymbol{v}))}{\det^{1/m}(\boldsymbol{M}(\boldsymbol{v}_{\mathrm{D}}^{\star}))}, \tag{5}$$

cf. Atkinson et al. (2007). It quantifies the degree of D-optimality of $\boldsymbol{v}$ with respect to $\boldsymbol{v}_{\mathrm{D}}^{\star}$. Note that $0 \leq \mathcal{E}_{\mathrm{D}}(\boldsymbol{v}) \leq 1 = \mathcal{E}_{\mathrm{D}}(\boldsymbol{v}_{\mathrm{D}}^{\star})$.

Let us also denote by $\|\boldsymbol{v}\|_0$ the number of nonzero components of the vector $\boldsymbol{v}$, i.e., $\|\boldsymbol{v}\|_0 = |\mathrm{supp}(\boldsymbol{v})|$, $\mathrm{supp}(\boldsymbol{v}) = \big\{j \in \{1,\ldots,N\} : v_j \neq 0\big\}$,

The following formulation can address the above dilemma:

Problem 3. Find $\boldsymbol{v}_{\mathrm{D},0}^{\star} \in \mathcal{V} := \big\{\boldsymbol{v} \in [0,1]^N : \boldsymbol{1}^{\top}\boldsymbol{v} = n\big\}$ to minimize $\|\boldsymbol{v}\|_0$ subject to

$$\mathcal{E}_{\mathrm{D}}(\boldsymbol{v}) \geq \eta, \tag{6}$$

where η signifies a given minimal acceptable value of D-efficiency. Each minimizer $\boldsymbol{v}_{\mathrm{D},0}^{\star}$ is called a minimum-support *relaxed* design with guaranteed D-efficiency η.

The constraint (6) endows Problem 3 with the following meaningful interpretation: Having obtained a D-optimum design $\boldsymbol{v}_{\mathrm{D}}^{\star}$, we sacrifice some (possibly high) degree of D-optimality, which is controlled by η, for minimization of the support of the relaxed design.

In the literature, $\|\cdot\|_0$ is termed the ℓ_0-norm, although it is not a norm, as it does not satisfies the condition of absolute homogeneity. Its direct minimization is extremely hard, which is why we replace the ℓ_0-'norm' by the ℓ_q-'norm'

$$\|\boldsymbol{w}\|_q = \Big(\sum_{j=1}^{r} |w_j|^q\Big)^{\frac{1}{q}}, \tag{7}$$

which is justified by the property $\|\boldsymbol{w}\|_0 = \lim_{q \downarrow 0} \|\boldsymbol{w}\|_q$ valid for each fixed $\boldsymbol{w}$. Observe that given $0 < q < 1$, $\|\cdot\|_q$ it is not a norm, either, as it does not satisfy the triangle inequality.

Problem 3 is then replaced by its counterpart for a fixed $q \in (0,1)$:

Problem 4. Find a vector $\boldsymbol{v}_{\mathrm{D},q}^{\star} \in \mathbb{R}^N$ minimizing

$$J(\boldsymbol{v}) = \|\boldsymbol{v}\|_q^q = \sum_{j=1}^{N} w_j^q \tag{8}$$

over the feasible set $\mathcal{W} := \{\boldsymbol{v} \in \mathcal{V} : \mathcal{E}_{\mathrm{D}}(\boldsymbol{v}) \geq \eta\}$.

3.1 Majorization-minimization algorithm

At first sight the concavity of the design criterion J seems to make the attendant optimization problems prohibitively difficult. However, on close examination the majorization-minimization (MM) algorithm, cf. Sun et al. (2017), turns out a simple remedy to this problem.

For J the MM algorithm is going to generate a sequence of feasible vectors $\big\{\boldsymbol{v}^{(\kappa)}\big\}_{\kappa=0}^{\infty}$ starting from an arbitrary feasible initial point $\boldsymbol{v}^{(0)}$ by minimizing in each iteration a surrogate function $\boldsymbol{v} \mapsto \Psi(\boldsymbol{v}|\boldsymbol{v}^{(\kappa)})$. This function should be a convex tangent majorant of $J(\boldsymbol{v})$ at $\boldsymbol{v}^{(\kappa)}$. Observe that here, in view of the concavity of J, we have

$$\begin{aligned} J(\boldsymbol{v}) &\leq J(\boldsymbol{v}^{(\kappa)}) + (\boldsymbol{v} - \boldsymbol{v}^{(\kappa)})^{\top}\nabla J(\boldsymbol{v}^{(\kappa)}) \\ &:= \Psi(\boldsymbol{v}|\boldsymbol{v}^{(\kappa)}), \quad \forall \boldsymbol{v} \in \mathcal{W}, \end{aligned} \tag{9}$$

and its right-hand side satisfies all the requirements for the surrogate function in question.

The consecutive iterates of the MM algorithm are then defined as

$$\boldsymbol{v}^{(\kappa+1)} = \arg\min_{\boldsymbol{v} \in \mathcal{W}} \Psi(\boldsymbol{v}|\boldsymbol{v}^{(\kappa)}). \tag{10}$$

A characteristic feature of the MM algorithm is that the sequence $\big\{J(\boldsymbol{v}^{(\kappa)})\big\}$ is strictly decreasing until a minimizer is attained. What is more, any limit point $\boldsymbol{v}^{\star}$ of $\big\{\boldsymbol{v}^{(\kappa)}\big\}$ is a stationary point of J. Note, however, that the function J may have multiple local minima and only one of them can be attained.

4. GENERALIZED SIMPLICIAL DECOMPOSTION TO MINIMIZE THE SURROGATE FUNCTION

The linearity of the surrogate objective function $\Psi(\,\cdot\,|\boldsymbol{v}^{(\kappa)})$, the polyhedral form of the set $\mathcal{V}$ and the convexity of the constraint (6) make the optimization problem (10) ideal for the use of generalized simplicial decomposition (GSD) to quickly solve it and drastically reduce the problem dimensionality, cf. Bertsekas and Yu (2011) and applications in Uciński (2020a) and Uciński (2022). The essence of the dimensionality reduction involved by GSD is that at each iteration the polyhedral set $\mathcal{V}$ in $\mathbb{R}^N$ is approximated with the convex hull of an ever expanding set $\mathcal{V}^{(\tau)}$ that consists of extreme points of $\mathcal{V}$. The method alternates between minimization of $\Psi(\boldsymbol{v}|\boldsymbol{v}^{(\kappa)})$ over $\mathrm{conv}(\mathcal{V}^{(\tau)})$, subject to the additional side constraint (6), and finding a new extreme point $\boldsymbol{v}_{\mathrm{xtrm}}^{(\tau)} \in \mathcal{V}$ to be added to $\mathcal{V}^{(\tau)}$. (These tasks are called the restricted master problem, or RMP, and the column generation problem, or CGP, respectively.) The polyhedron $\mathrm{conv}(\mathcal{V}^{(\tau)})$ can be treated as a subset of $\mathbb{R}^{\tau+2}$ and for a typical run of GSD we have $\tau \ll N$. This is where a substantial dimensionality reduction emerges.

The low-dimensional RMP can be solved by any solver for constrained nonlinear optimization which returns, as a by-product, the values of the Lagrange multipliers (this is usually the case when fast Newton-like methods, such as SQP, are used).

5. NUMERICAL RESULTS

Consider the setting of the moving source identification investigated in the paper by Uciński (2022). There are seven unknown parameters characterizing the diffusion coefficient and the moving source. The parameters are going to be estimated using $n = 150$ sensors selected from a total of $N = 780$ sensor network nodes residing

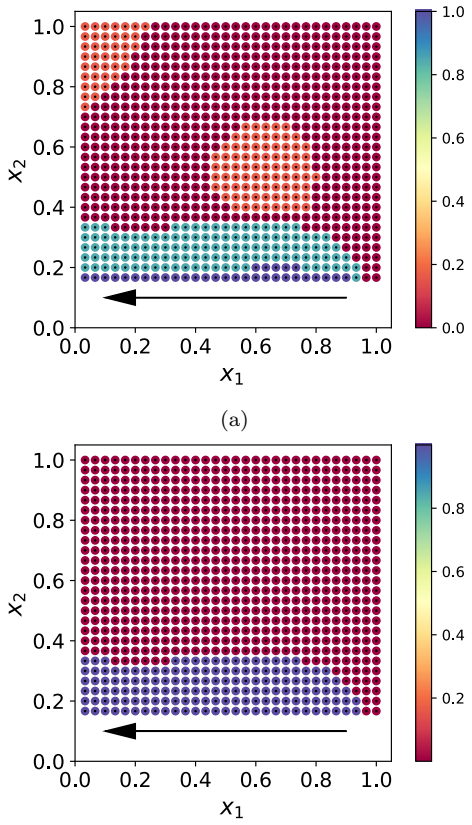

Fig. 1. Optimum sensor configurations: relaxed D-optimum design with some nonnegligible weights in the centre and top-left subregions (a), sparse solution with a guaranteed D-efficiency of $\eta = 0.95$ (b). Black points denote candidate sites and the colours of the discs around them represent the weight values. The arrow represents the movement of the pollution source.

in a unit square. Figure 1 shows the original relaxed D-optimum design weights and the same weights post-processed with the proposed algorithm for the minimal acceptable D-efficiency level set at 0.95 and $q = 0.2$. Only two iterations of the MM scheme were needed. Overall, the postprocessing took no more than 1 second on a mediocre PC computer and an implementation in Python.

Structure of Feedback-Loops through Positive Real Odd Functions

Izchak Lewkowicz *

* *School of Electrical and Computer Engineering, Ben-Gurion University, Beer-Sheba, Israel (e-mail: izchak@bgu.ac.il)*

The family of (matrix-valued) Positive real Odd, $\mathcal{PO}$, functions $F(s)$ may be described as,

$$\mathcal{PO} := \{F(s) \ : \ F(s) = -\left(F(-s^*)\right)^* \quad \forall s \in \mathbb{C} \ \}.$$

Resorting to the framework of the Quadratic Matrix Inequality one can explicitly describe $\mathcal{PO}$ functions as,

$$\mathcal{PO} = \left\{ F(s) : \begin{bmatrix} F(s) \\ I_m \end{bmatrix}^* \begin{bmatrix} 0 & I_m \\ I_m & 0 \end{bmatrix} \begin{bmatrix} F(s) \\ I_m \end{bmatrix} \begin{matrix} \preccurlyeq 0 & \forall s \in \mathbb{C}_L \\ = 0 & \forall s \in i\mathbb{R} \\ \succcurlyeq 0 & \forall s \in \mathbb{C}_R \end{matrix} \right\}. \quad (1)$$

The subset of rational functions within this family (a.k.a. Lossless or Foster) corresponds to electrical circuits with reactive elements (i.e. $L - C$) and no resistance, see e.g. Figures 1, 2 and 5, below.

In Figure 1 the elements sC and sL on the left-hand side, are substituted, on the right, by an admittance network Y_F and an impedance network Z_G, respectively. In contrast, in Figure 2 the elements sC and sL on the left-hand side are substituted, on the right, by an admittance network Y_G and an impedance network Z_F, respectively.

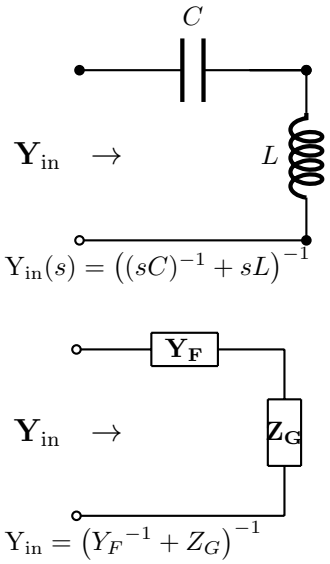

Fig. 1. Driving point admittance of a series circuit of degree 2

For instance, the elements sC and sL, on the left-hand side of Figure 1 are substituted, on the right-hand side, by admittance network Y_F and impedance network Z_G, respectively. In contrast, in Figure 2 sC and sL, on the left-hand side, are substituted, on the right-hand side, by the admittance network Y_G and impedance network Z_F, respectively.

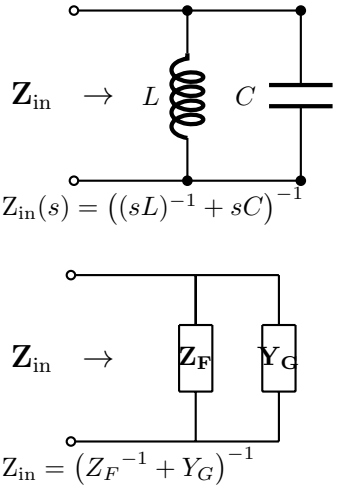

Fig. 2. Driving point impedance of a parallel circuit of degree 2

It is now appropriate to introduce the notation,

$$\phi(X, Y) := \left(X^{-1} + Y\right)^{-1}, \quad (2)$$

where X, Y are square variables so that X and $(X^{-1}+Y)$ are non-singular.

As a first application, one can write,

Figure 1	Figure 2
$Y_{in}(s)=\phi(sC \ , \ sL)$	$Z_{in}(s)=\phi(sL \ , \ sC)$
$Y_{in}(s)=\phi(Y_F \ , \ Z_G)$	$Z_{in}(s)=\phi(Z_F, \ Y_G).$

The rest of this section is devoted to showing that the role of the function ϕ in Eq. (2), goes beyond an exercise in circuits.

Following the spirit of the description of $\mathcal{PO}$ functions in Eq. (1), ϕ is a $\mathcal{PO}$ function in the sense that,

$$(X+X^*) \ \text{ and } \ (Y+Y^*) \begin{matrix} \preccurlyeq 0 \\ = 0 \\ \succcurlyeq 0 \end{matrix} \implies \Phi+\Phi^* \begin{matrix} \preccurlyeq 0 \\ = 0 \\ \succcurlyeq 0 \end{matrix} \quad (3)$$

Note also that whenever in addition Y and $(Y^{-1}+X)$ are non-singular then,

$$\phi(Y, X) := \left(Y^{-1} + X\right)^{-1} = \phi(X^{-1}, Y^{-1}). \quad (4)$$

Thus, one can conclude that ϕ is a $\mathcal{PO}$ function of two non-commuting variables.

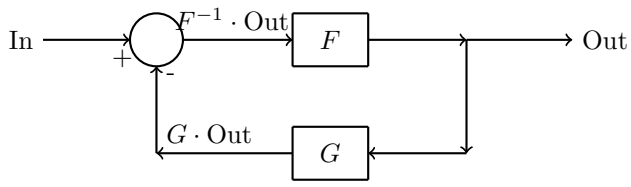

Fig. 3. Out $= \left(F^{-1}+G\right)^{-1}\cdot \text{In} = \phi(F,\ G)\cdot \text{In}$

In analogy to Figures 1 and 2, one may view Figure 4 as a complement to Figure 3.

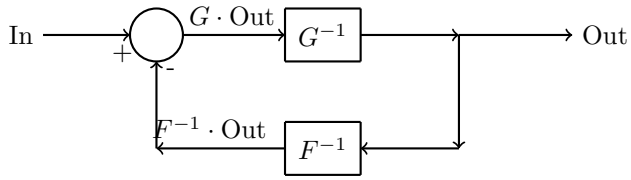

Fig. 4. Out $= \left(F^{-1}+G\right)^{-1}\cdot \text{In} = \phi(G^{-1},\ F^{-1})\cdot \text{In}$

Let F and G are $m\times m$-valued rational functions. Assuming in Figure 3 that F and $(F^{-1}+G)$ are invertible, or assuming in Figure 4 that in addition G is invertible, one has that in both cases,

$$\begin{aligned}\text{In}-G\cdot\text{Out}=F^{-1}\cdot\text{Out} \quad &\Longrightarrow \quad \text{In}=\left(F^{-1}+G\right)\cdot\text{Out}\\ &\Longrightarrow \quad \text{Out}=\phi(F,G)\cdot\text{In}.\end{aligned}$$

In each of the Figures 1 and 2 the circuit was comprised of a pair reactive element, i.e. a rational positive real odd function of degree two. The circuit in Figure 5 is comprised of four reactive elements.

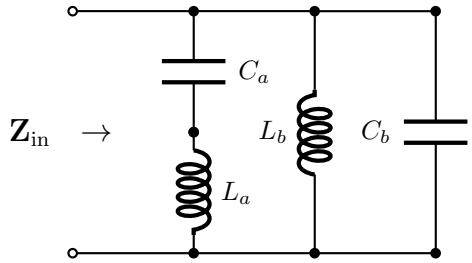

Fig. 5. $\text{Z}_{\text{in}}(s) = \left(\left((sC_a)^{-1}+sL_a\right)^{-1}+(sL_b)^{-1}+sC_b\right)^{-1}$.

The driving point impedance in Figure 5 can also be written as,

$$\begin{aligned}\text{Z}_{\text{in}}(s) &= \Big(\overbrace{\left((sC_a)^{-1}+sL_a\right)^{-1}}^{\phi(sC_a\ ,\ sL_a)}+\overbrace{{sL_b}^{-1}+sC_b}^{(\phi(sL_b\ ,\ sC_b))^{-1}}\Big)^{-1} \qquad (5)\\ &= \phi\left(\ \phi(sL_b\ ,\ sC_b),\ \phi(sC_a\ ,\ sL_a)\ \right).\end{aligned}$$

As before, in analogy to the $L-C$ circuit in Figure 5, we have the multiple feedback loops in Figure 6.

As before one can re-write the input-output relation in Figure 6 as,

$$\begin{aligned}\text{Out} &= \left(\left({F_b}^{-1}+G_b\right)^{-1}+{F_a}^{-1}+G_a\right)^{-1}\text{In}\\ &= \phi(\ \phi(F_a\ ,\ G_a)\ ,\ \phi(F_b\ ,\ G_b)\ )\text{In}.\end{aligned} \qquad (6)$$

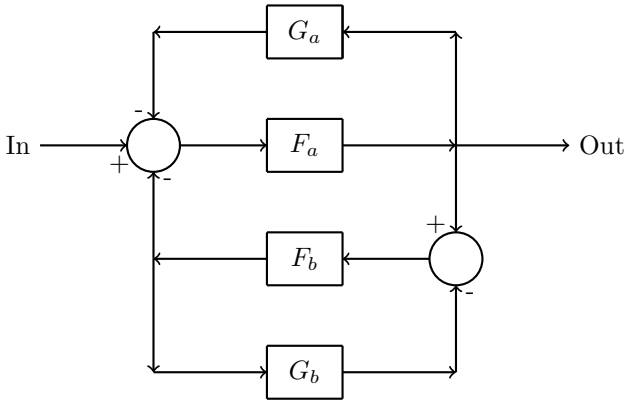

Fig. 6. Out $= \left(\left({F_b}^{-1}+G_b\right)^{-1}+{F_a}^{-1}+G_a\right)^{-1}$ In

Now, comparing Eq. (5) with Eq. (6), one can formally identify the elements sC_a, sL_a, sC_b, sL_b, in Figure 5 with the blocks $F_a(s)$, $G_a(s)$, $F_c(s)$, $F_d(s)$ in Figure 6.

This calls for adapting one of the classical construction schemes of $R-L-C$ circuits, e.g. Brune, Bott-Duffin, Darlington, Foster, Cauer, etc., to introducing a design tool for networks of feedback-loops, more elaborate than that in Figure 6 (and as mentioned, the building blocks need not be positive real).

A word of caution: The passage from one-port circuit design to that of feedback-loops networks can not be straightforward: Typically blocks like $F_a(s)$, $G_a(s)$, $F_c(s)$, $F_d(s)$ are *non-commutative*. Hence, one needs to formally extend the notion of $\mathcal{PO}$ functions to real rational functions of say k *non-commuting* variables. See e.g. ϕ in Eqs. (2) (3)

As a hint to the potential of the propsed approach, the feedback loop network from Figure 6 is extended in Figure 7, to having two inputs and two outputs.

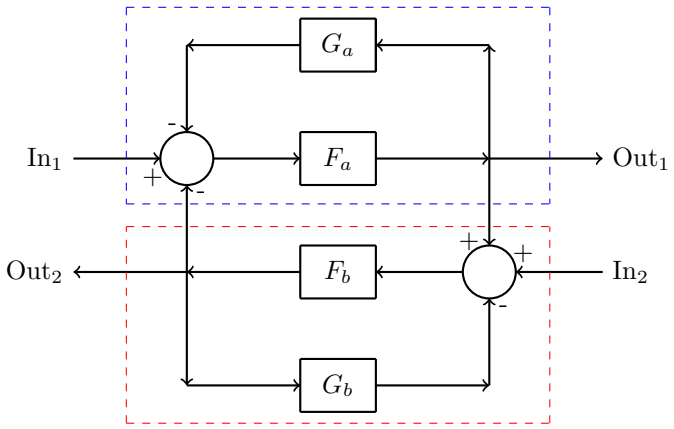

Fig. 7. Multiple Feedback Loops

$$\begin{aligned}\begin{bmatrix}\text{Out}_1\\ \text{Out}_2\end{bmatrix} &= \begin{bmatrix}\left(F_c+G_c^{-1}\right)^{-1} & -\left(F_c+G_c^{-1}\right)^{-1}G_c^{-1}\\ G_c^{-1}\left(F_c+G_c^{-1}\right)^{-1} & \left(F_c^{-1}+G_c\right)^{-1}\end{bmatrix}\begin{bmatrix}\text{In}_1\\ \text{In}_2\end{bmatrix}\\ &= \begin{bmatrix}\left(F_c+G_c^{-1}\right)^{-1} & -F_c^{-1}\left(F_c^{-1}+G_c\right)^{-1}\\ \left(F_c^{-1}+G_c\right)^{-1} & F_c^{-1}\left(F_c^{-1}+G_c\right)^{-1}\end{bmatrix}\begin{bmatrix}\text{In}_1\\ \text{In}_2\end{bmatrix}\end{aligned} \qquad (7)$$

where

$$F_c := F_a^{-1} + G_a \qquad G_c := F_b^{-1} + G_b \ .$$

Realizations of Passive Systems are Inter-related

Izchak Lewkowicz

School of Electrical and Computer Engineering

E-mail: izchak@bgu.ac.il

Passive Rational Functions

Passivity is a physical property of dynamical systems. Recently, it was shown that, at least in the linear time-invariant framework, it is equivalent to an explicit mathematical structure. See **?**, **?**.

As it is well known, physically the set of $m \times m$-valued positive real rational functions represents linear time-invariant passive systems.

In fact, there are four variants. To describe them we shall adopt the following notation. $\mathbb{C}_R$ will be the open right half of the complex plane, and $\overline{\mathbb{D}}^c = \{c \in \mathbb{C} \ : \ |c| > 1 \ \}$, i.e. the exterior of the closed unit disk.
Consider $m \times m$-valued real rational functions $F(z)$ (m is a parameter).

$\mathcal{P}$ Positive-Real (continuous-time) $\mathrm{Re}\,(x^*F(s)x) \geq 0 \ \ \forall x \in \mathbb{C}^m \ \ \forall s \in \mathbb{C}_R$

$\mathcal{B}$ Bounded-Real, (continuous-time) $1 \geq \|F(s)\|_2 \ \ \forall s \in \mathbb{C}_R$.

$\mathcal{DP}$ Discrete-Time-Positive-Real $\mathrm{Re}\,(x^*F(s)x) \geq 0 \ \ \forall x \in \mathbb{C}^m \ \ \forall s \in \overline{\mathbb{D}}^c$

$\mathcal{DB}$ Discrete-Time-Bounded-Real $1 \geq \|F(s)\|_2 \ \ \forall s \in \overline{\mathbb{D}}^c$

The above four families, are common in Engineering circles, in particular $\mathcal{P}$ can be viewed as the Laplace transform of a continuous-time, stable, linear time-invariant system, described by a differential equation, while $\mathcal{DB}$ may be the Z-transform of a discrete-time, stable, linear time-invariant system, described by a difference equation.

As already mentioned, in **?**, **?** the above two better known families were characterized through their structure.

Theorem 1
Consider two families of functions.

$\mathcal{P}$ *This set is a maximal matrix-convex cone of matrix-valued real rational functions, closed under inversion, which are analytic in* $\mathbb{C}_R$.

Conversely, a maximal matrix-convex cone of matrix-valued rational functions, closed under inversion, which are analytic in $\mathbb{C}_R$ *and containing the zero degree function* $F_o(s) \equiv I$*, is the set* $\mathcal{P}$.

$\mathcal{DB}$ *Let* $\mathcal{F}$ *be a family of square matrix-valued (of various dimensions) real rational functions* $F(s)$*. For all* s *outside the closed unit disk, each* $F(s)$ *is analytic.*

If as a family, $\mathcal{F}$ *is matrix-convex, and a maximal set closed under products of its elements (whenever dimensions are suitable), this is the set* $\mathcal{DB}$ *of Discrete-time Bounded real rational functions.*

The converse is true as well.

By definition each of the pairs $\mathcal{P}$, $\mathcal{B}$ along with $\mathcal{DP}$, $\mathcal{DB}$, shares the same domain. In contrast, each of the pairs $\mathcal{P}$, $\mathcal{DP}$ along with $\mathcal{B}$, $\mathcal{DB}$ shares the same range. To be more specific, we recall the following: Assume that the Cayley transform of $F(s)$ is, almost everywhere, well defined, i.e.

$$\mathcal{C}(F) = (I_m - F)(I_m + F)^{-1} \qquad \det\left(F(s) + I_m\right) \not\equiv 0. \quad (1)$$

Then above four variants of passive functions satisfy the following relations,

$$\mathcal{B} = \mathcal{C}\left(\mathcal{P}\right) \qquad \mathcal{DB} = \mathcal{C}\left(\mathcal{DP}\right)$$

$$F(s) \in \mathcal{P} \iff F\left(\tfrac{1+s}{1-s}\right) \in \mathcal{DP} \quad (2)$$

$$F(s) \in \mathcal{B} \iff F\left(\tfrac{1+s}{1-s}\right) \in \mathcal{DB}.$$

Namely the sets $\mathcal{P}$, $\mathcal{B}$, $\mathcal{DP}$ and $\mathcal{DB}$ are inter-related as *rational functions.*

Here we proceed in the direction of exploring structure of *families* passive systems, and now focus on state-space *realizations*. Specifically, we show that realizations of the above four families, are inter-related through *Linear Fractional Transformation*. Specifically, starting with any of the families ($\mathcal{P}$, $\mathcal{B}$, $\mathcal{DP}$ or $\mathcal{DB}$) all other three can be obtained.

Here are the details. Recall that with an arbitrary $m \times m$-valued rational function $F(s)$, with no pole at infinity, i.e.

$$\exists \lim_{s \longrightarrow \infty} F(s),$$

one can associate a corresponding $(n+m) \times (n+m)$ state-space realization array, R_F i.e.

$$F(s) = C(sI_n - A)^{-1}B + D \qquad R_F = \left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right]. \quad (3)$$

The realization R_F in Eq. (3) is called *minimal*, if n is the McMillan degree of $F(s)$.

We can now state the main result of this presentation.

Theorem 2
For $l = \mathcal{P}$, $\mathcal{B}$, $\mathcal{DP}$ and $\mathcal{DB}$, let $\mathcal{F}_l$ be families of rational functions. Let R_{F_l} be a corresponding state space realization (assuming there is no pole at infinity). Then (whenever inverses exit) the following is true.

$$(\mathcal{P}) \quad R_{F_\mathcal{P}} = \begin{bmatrix} A_{\mathcal{DB}}-I_n & B_{\mathcal{DB}} \\ -C_{\mathcal{DB}} & -D_{\mathcal{DB}}+I_m \end{bmatrix} \begin{bmatrix} A_{\mathcal{DB}}+I_n & B_{\mathcal{DB}} \\ C_{\mathcal{DB}} & D_{\mathcal{DB}}+I_m \end{bmatrix}^{-1}$$

$$(\mathcal{B}) \quad R_{F_\mathcal{B}} = \begin{bmatrix} A_\mathcal{P}-B_\mathcal{P}(I_m+D_\mathcal{P})^{-1}C_\mathcal{P} & -\sqrt{2}B_\mathcal{P}(I_m+D_\mathcal{P})^{-1} \\ \sqrt{2}(I_m+D_\mathcal{P})^{-1}C & (I_m-D_\mathcal{P})(I_m+D_\mathcal{P})^{-1} \end{bmatrix}$$

$$(\mathcal{DP}) \quad R_{F_\mathcal{DP}} = \begin{bmatrix} A_\mathcal{B}+I_n & B_\mathcal{B} \\ C_\mathcal{B} & D_\mathcal{B}-I_m \end{bmatrix} \begin{bmatrix} A_\mathcal{B}-I_n & B_\mathcal{B} \\ -C_\mathcal{B} & -D_\mathcal{B}-I_m \end{bmatrix}^{-1}$$

$$(\mathcal{DB}) \quad R_{F_\mathcal{DB}} = \begin{bmatrix} A_\mathcal{DP}-B_\mathcal{DP}(I_m+D_\mathcal{DP})^{-1}C_\mathcal{DP} & -\sqrt{2}B_\mathcal{DP}(I_m+D_\mathcal{DP})^{-1} \\ \sqrt{2}(I_m+D_\mathcal{DP})^{-1}C & (I_m-D_\mathcal{DP})(I_m+D_\mathcal{DP})^{-1} \end{bmatrix}.$$

Roughly speaking, one can conclude that K-Y-P type results for $\mathcal{P}$, $\mathcal{B}$, $\mathcal{DP}$ or $\mathcal{DB}$, are all equivalent, up to linear fractional transformation.

Although derived independently, one can relate Eq. (2) to Theorem 2.

Remarks
a. Having the "matrix" R_F non-singular, and the realization array R_F minimal, are two independent properties.

b. Recall in the realization of a Cayley transform of a rational function: Let $F(s)$ be a square matrix-valued rational function along with its realization as in Eq. (3). Then a realization of $\mathcal{C}(F)$ is given by,

$$R_{\mathcal{C}(F)} = \left[\begin{array}{c|c} A-B(I_m+D)^{-1}C & \mp\sqrt{2}B(I_m+D)^{-1} \\ \hline \pm\sqrt{2}(I_m+D)^{-1}C & (I_m-D)(I_m+D)^{-1} \end{array}\right]. \quad (4)$$

This conforms with items $(\mathcal{B})$ and $(\mathcal{DB})$ in Theoremi 2.

c. From Eq. (3) one has that $F(s) \in \mathcal{C}(\mathcal{P}) \iff F\left(\frac{1+s}{1-s}\right) \in \mathcal{DB}$.
Using Theorem **??**, let $R_{F_\mathcal{P}} = \left[\begin{array}{c|c} A_\mathcal{P} & B_\mathcal{P} \\ \hline C_\mathcal{P} & D_\mathcal{P} \end{array}\right]$ and $R_{F_\mathcal{DB}} = \left[\begin{array}{c|c} A_\mathcal{DB} & B_\mathcal{DB} \\ \hline C_\mathcal{DB} & D_\mathcal{DB} \end{array}\right]$ be realizations of $\mathcal{P}$ and $\mathcal{DB}$ functions, respectively. Then whenever inverses exit, $R_{F_\mathcal{P}} = -\mathcal{C}\left(R_{(F_\mathcal{DB})^{-1}}\right)$.

Abstract: In recent years, network synthesis theory has been successfully applied to vibration absorber design, to identify optimum mechanical networks providing performance improvements. These identified mechanical networks consist of ideal linear modelling elements, such as springs, dampers and inerters. For real-life applications, the essential next step is to transfer these linear mechanical networks into physical absorber designs. There are two major challenges for this step: firstly, in order to achieve practical physical realisations, multidomain physical components (mechanical, hydraulic, pneumatic and electrical) need to be considered; and secondly, nonlinearities and other parasitic properties of physical components must be taken into consideration or potentially be made full use of. To this end, this paper, using a nonlinear mechanical network-based model for a bespoke mechanical-hydraulic device, demonstrates the feasibility of resolving both challenges.

Keywords: Vibration absorber design; nonlinearity; force control; mechanical network; physical models

1. INTRODUCTION

For vibration absorber design, different from the traditional approach focusing on modifying the specific designs, network synthesis theory has been applied in recent years, allowing a wide range of absorber networks to be explored systematically (Smith, 2002; Chen and Smith, 2009; Yamamoto and Smith, 2015; Zhang et al., 2017b, 2019a; Hughes, 2020). These networks consist of ideal linear modelling properties, such as stiffness, damping and inertance (Smith, 2002) and have demonstrated their advantages for various engineering structures (Smith and Wang, 2004; Jiang et al., 2012; Zhang et al., 2017a, 2019b; Lewis et al., 2019). To achieve the real-life benefits, the next step is to transfer these networks into physical absorber design.

Not only focusing on mechanical domain, the physical realisation needs to consider the components from multiple domains (mechanical, hydraulic, pneumatic and electrical) allowing numerous design possibilities and functionalities to be explored. There are challenges to be addressed for this step. The first challenge is to achieve the ideal mechanical network topology, which depends on how to choose the multidomain components and coupling mechanisms. The basic modelling elements from each domain have been summarised in the table of Fig. 1 and the physical component would need single or multiple basic elements to represent, such as a hydraulic orifice as a single resistance while a hydraulic tube as hydraulic inertance and resistance in parallel (Liu et al., 2018, 2019). In order to achieve the desirable force-velocity properties, suitable coupling mechanisms need to be considered, such as the piston-cylinder coupling (Liu et al., 2019), rubber-fluid coupling (Li et al., 2019) and electrical transducers (Wang and Chan, 2011). These mechanisms will determine how the non-mechanical components and implementation are mapped into equivalent mechanical components and topological connections.

Once the desirable network topology is realised using multidomain components, the next challenge will be how to realise the network modelling properties (stiffness, damping and inertance) and the difficulty lies in that the physical component nonlinearities and parasitic effects need to be characterised. The approach proposed by Liu et al. (2019) which develops a generalisable model for a physical device with key design parameters will be used to address this challenge. This generalisable model will not only help to develop an accurate dynamic model but also allow the key physical parameters to be optimum designed maximising the performance benefits.

To address the aforementioned two challenges, a nonlinear mechanical network-based model is needed, to transfer the multidomain components into an equivalent mechanical network and enable the component nonlinearity to be characterised or potentially made use of. In this work, a feasibility of resolving these two challenges will be

⋆ Research is supported by the Engineering and Physical Sciences Research Council (EPSRC) (Grant Reference: EP/P013546/1).

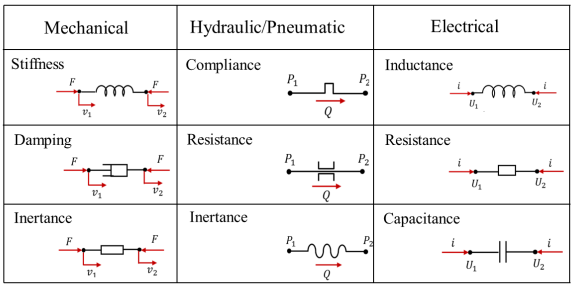

Fig. 1. A mechanical-hydraulic-electrical analogy (Schönfeld, 1954)

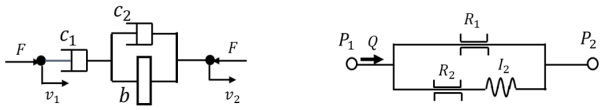
demonstrated using nonlinear mechanical network-based model for a bespoke mechanical-hydraulic device.

2. A FEASIBILITY STUDY USING A MECHANICAL-HYDRAULIC DEVICE

In this feasibility study, a mechanical-hydraulic device which could realise a specific linear mechanical network topology is first presented in Section 2.1. Based on this physical device, the component-level nonlinearites and parasitic effects are identified experimentally in Section 2.2. By integrating such component nonlinearities and parasitic effects into the mechanical network topology, the final nonlinear mechanical network-based model, where the properties are represented by physical design parameters, is developed in Section 2.3. Readers could refer to Liu et al. (2019) for more details.

2.1 Mutlidomain Realisation of A Linear Network

A linear mechanical network shown in Fig. 2(a) is assumed to be realised in this feasibility study.



(a) (b)

Fig. 2. (a) The linear mechanical network which needs to be realised; (b) The equivalent linear hydraulic network using the piston-cylinder coupling.

Considering a mechanical-hydraulic device and piston-cylinder coupling mechanism, the physical device force F and the relative terminal velocity Δv can be transferred to hydraulic pressure difference Δp and flow rate Q due to the piston movement, using the relationships:

$$F = A_P \Delta p, \tag{1}$$

$$\Delta v = \frac{Q}{A_P}, \tag{2}$$

where A_P is the piston area. Using these coupling equations, the mechanical through variable F is linked with the hydraulic cross variable Δp while the mechanical cross variable Δv with the hydraulic through one Q. Therefore, the equivalent hydraulic network is dual to the mechanical network, as shown in Fig. 2(b). For ideal linear modelling elements, the corresponding transformation between hydraulic and mechanical elements are

$$c_1 = {A_P}^2 R_1 \tag{3}$$

$$c_2 = {A_P}^2 R_2 \tag{4}$$

$$b = {A_P}^2 I_2. \tag{5}$$

A schematic plot of a mechanical-hydraulic device in Fig. 3, is proposed to realise the ideal hydraulic network topology in Fig. 2(b). As shown in Fig. 3, the two cylinder chambers are connected with a helical tube, which provides the hydraulic inertance and resistance, and there are valves in the piston providing the resistance. When the piston is moving relatively to the cylinder, two main flow paths, where one is through the helical tube and the other through the valves on the piston, are considered and hydraulically parallel. Note that the physical component nonlinearity and parasitic effects will be introduced in Section 2.2.

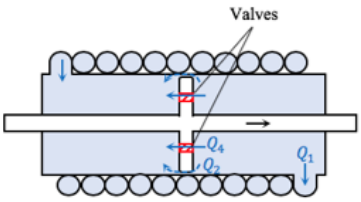


Fig. 3. A schematic plot of a mechanical-hydraulic device which can realise the network in Fig. 2 (Liu et al., 2019).

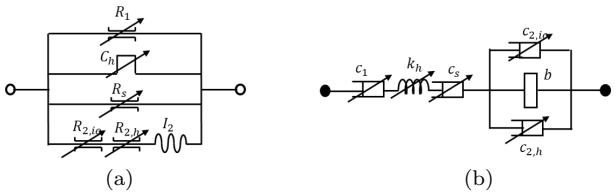
2.2 Experimental Identification of Component Nonlinearities and Parasitic Effects

As introduced in the previous section, based on the linear assumptions, the mechanical-hydraulic device can realise the linear mechanical network topology shown in Fig. 2(a). In order to achieve the desirable network element properties or making use of them, component nonlinearities and parasitic effects need to be modelled. Note that due to the introduction of nonlinearities, the linear transformation between hydraulic and mechanical elements, such as equations (3), (4) and (5), will not hold. However, the mechanical coupling equations between force and pressure difference, relative velocity and flow rate (equations (1) and (2)), still hold, hence the topological connection of the nonlinear equivalent mechanical network is the same as that of the linear equivalent one.



(a) (b)

Fig. 4. (a) The nonlinear hydraulic network of the mechanical-hydraulic device, (b) the equivalent nonlinear mechanical network of the mechanical-hydraulic device (Liu et al., 2019)

.

Fig. 4(a) shows the nonlinear hydraulic network of the mechanical-hydraulic device, where R_1 is nonlinear orifice

damping, C_h is the hydraulic compliance due to fluid compressibility, R_s is the nonlinear leakage damping, $R_{2,io}$ is the inlet/outlet damping of the helical tube, $R_{2,h}$ is the damping due to surface friction in the tube and I_2 is the tube inertance. Using the mechanical-hydraulic coupling equations (equations (1) and (2)), the nonlinear equivalent mechanical network is presented in Fig. 4(b). Those nonlinear element properties can be identified in separate subsets using designated tests (Liu et al., 2019), which is named as a generalisable model developing approach in Liu et al. (2019).

2.3 Final Nonlinear Mechanical Network-based Model

By implementing all the component nonlinearities and parasitic effects, the final nonlinear mechanical network-based model has been developed, as shown in Fig. 5. In this network model, it has been found that the effects of piston leakage c_s and tube inlet/outlet damping $c_{2,io}$ are negligible. Extra effects, such as the friction force f, coupler stiffness k_s and backlash p are experimentally identified to obtain accurate terminal behaviour. The key element properties (c_1, $c_{2,h}$ and b) in this nonlinear model are expressed by formulae with key design parameters, such as the valve size, tube length and cross-section area (see Table 6 of Liu et al. (2019)). The validity of this nonlinear model has been verified using different design parameter settings.

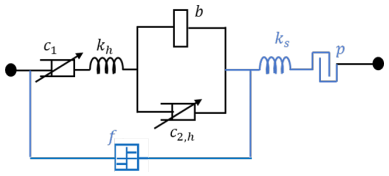


Fig. 5. A schematic plot of a mechanical-hydraulic device which can realise the network in Fig. 2 (Liu et al., 2019).

3. CONCLUSION

Using the feasibility study, a nonlinear mechanical network-based model has been developed for a force-controlling device which could realise the linear mechanical network using nonlinear multidomain components. This modelling approach is applicable for different networks and realisation across different domains.

** *Technische Universität Dresden, Dresden, D-01062 Germany (e-mail: mario.kummer@tu-dresden.de).*

Abstract: We present recent results joint with Mario Kummer (TU Dresden) on convex hulls of curves. We see a large family of examples where these convex hulls turn out to be hyperbolicity cones. For convex hulls of elliptic curves, we are able to show that these hyperbolicity cones are spectrahedra, generalizing previous results by Henrion and Scheiderer.

Keywords: spectrahedra, convex hull, algebraic curves, hyperbolic polynomial

1. INTRODUCTION

Hyperbolic polynomials and the associated algebraic hypersurfaces are at the intersection of algebraic geometry, optimization, combinatorics, and computer science. Historically, they go back to partial differential equations in the work of Peter Lax and have started a new life in convex programming since the advent of interior point methods. In real algebraic geometry, (smooth) hyperbolic hypersurfaces are an extremal topological type, namely the most nested.

In this paper, we provide a geometric construction of highly singular hyperbolic hypersurfaces, which is interesting from several perspectives. The hyperbolicity of secant varieties of M-curves is closely linked to a property of linear systems on real algebraic curves that we call *vastly real*. This is a common generalization of Ahlfors's circle maps, i.e. real fibered (also called separating or totally real) morphisms to the projective line, and Mikhalkin and Orevkov's maximally writhed links. Vastly real linear systems on curves are an extremal real embedding into projective spaces of almost any odd dimension.

From the point of view of optimization, highly singular hyperbolicity cones are necessary to even have a chance to construct expressive hierarchies analogous to sum-of-squares and moment methods widely used in semidefinite programming (as shown in the work of Saunderson Saunderson (2020) building on Averkov (2019)). Our geometric construction provides such examples. It can be used to write certain convex hulls of connected components of real curves as projections of hyperbolicity cones. The hyperbolic secant hypersurfaces for curves of genus at least 2 are a promising testing ground for the Generalized Lax-Conjecture, which claims that they admit definite determinantal representations up to a cofactor with controlled hyperbolicity cone. Vinnikov (2012). We construct examples of hyperbolic polynomials with a highly singular hyperbolicity cone so that these cones have an interesting facial structure. Our construction also generalizes the Hankel spectrahedron for binary forms to the convex hull of (a connected component) of an M-curve of genus greater than 1. We also show that the hyperbolicity cones constructed in this way are simplicial and therefore do not admit small SDP-lifts. In general, we do not know, if these hyperbolicity cones are spectrahedral.

In classical algebraic geometry, an attractive class of examples of hyperbolic hypersurfaces are definite symmetroids: hypersurfaces whose defining polynomials are the determinant of real symmetric matrix pencils that contain a definite matrix. We show the existence of such determinantal representations for secant varieties of elliptic normal M-curves.

2. CONCLUSION

This work provides many examples of highly singular hyperbolic polynomials. Singularities are necessary for an interesting facial structure and therefore for expressive powers of possible hyperbolic hierarchies. So these examples might lead to interesting applications later. Moreover, they are a testing ground for the generalized Lax conjecture. In genus 1, however, the hyperbolicity cones in question are spectrahedral in the easiest possible way, generalizing previous results by Henrion Henrion (2011) and Scheiderer Scheiderer (2011).

On computing the H_2 norm using the polynomial Diophantine equation

Timothy H. Hughes and Gareth H. Willetts *

* *University of Exeter, Penryn Campus, Cornwall, U.K. (e-mail: T.H.Hughes@exeter.ac.uk, G.H.Willetts@exeter.ac.uk).*

Abstract: An explicit algorithm will be presented for computing the H_2 norm of a single input single output system from the coefficients in its transfer function. The algorithm follows directly from Cauchy's residue theorem, and the most computationally intensive step involves solving a polynomial Diophantine equation. This can be efficiently solved using subresultant sequences in a fraction-free variant of the extended Euclidean algorithm. The coefficients in these subresultant sequences correspond to the Hurwitz determinants, whereby a stability test can be obtained alongside computing the H_2 norm with little additional computational effort. Implementations of the algorithm symbolically, in exact arithmetic, and in floating-point arithmetic will be presented. The accompanying talk will demonstrate an example application on the design of passive train suspension systems that optimise passenger comfort. The example will demonstrate the algorithm's greater robustness and computational efficiency relative to H_2 norm algorithms requiring the computation of the controllability or observability Gramians. The more general application of the techniques to the realisation of optimal lumped-parameter networks will also be discussed.

Keywords: H_2 optimal control; Mechanical systems; Symbolic computation; Real algebraic geometry; Linear systems; Subresultant sequences.

1. INTRODUCTION

The H_2 norm is a widely used metric for characterising system performance, corresponding to the square root of the power spectral density of the system's output in response to zero mean white noise input of unit power spectral density. It is a natural measure of system performance for the design of mechanical networks, such as vehicle suspension systems; for example, it is commonly used to characterise passenger comfort as a vehicle traverses a rough surface (see, e.g., Wang et al., 2009). The design of the famous Linear Quadratic Gaussian controller also corresponds to a H_2 norm minimisation problem. There is therefore a need for efficient algorithms for the computation of the H_2 norm of a given system. In safety critical applications, or when numerical robustness is a consideration, it can be desirable to compute the H_2 norm using exact arithmetic. Moreover, in the design of lumped-parameter systems, it can be desirable to obtain symbolic expressions for the H_2 norm in terms of the system's parameters. For example, this is useful in the design of optimal mechanical networks, or in other structured H_2 norm optimisation problems, where it is necessary to choose one or more system parameters to optimise a H_2 norm performance measure.

In this paper, an algorithm will be presented for the computation of the H_2 norm of a single input single output system from the coefficients in its transfer function. The most computationally demanding step in the algorithm corresponds to solving a polynomial Diophantine equation. This equation arises from the application of Cauchy's residue theorem to evaluate the frequency domain integral formula (obtained from Parseval's theorem) for the H_2 norm. It will be shown how this equation can be solved efficiently by a fraction-free variant of the extended Euclidean algorithm, which corresponds to the computation of subresultant and remainder polynomials generated from the even and odd part of the denominator polynomial in the system's transfer function. Moreover, the coefficients in these subresultant polynomials correspond to Hurwitz determinants, whereby the stability of the system can be determined alongside the H_2 norm computation. Examples will be presented to demonstrate the robustness and computational efficiency of the algorithm as compared to H_2 norm algorithms that involve computation of the controllability or observability Gramians. The algorithm is broadly applicable to the design of optimal lumped-parameter networks (such as the aforementioned vehicle suspension systems), and more general structured H_2 norm optimisation problems.

The notation employed is as follows. $\mathbb{R}$ denotes the real numbers; $\mathbb{R}^{m\times n}$ the real matrices with m rows and n columns; and $\mathbb{R}[s]$ and $\mathbb{R}(s)$ the univariate polynomials and rational variables in the indeterminate s, respectively. If $p \in \mathbb{R}[s]$, then $\deg(p(s))$ denotes its degree, and $\mathrm{LC}(p(s))$ its leading coefficient. If $G \in \mathbb{R}(s)$, then $\|G\|_2$ denotes its H_2 norm. For a complex number z, its conjugate is denoted z^*, and j denotes the imaginary unit $\sqrt{-1}$. Finally, if $x \in \mathbb{R}$, then $\lceil x \rceil$ rounds $x \in \mathbb{R}$ up to the next integer, and $\lfloor x \rfloor$ rounds $x \in \mathbb{R}$ down to the previous integer; and if x is an integer then $x\%2$ denotes the remainder of x upon division by 2.

2. COMPUTING THE H_2 NORM USING THE POLYNOMIAL DIOPHANTINE EQUATION

The H_2 norm of a linear system has a number of well known equivalent characterisations. From the perspective of system performance, it is most naturally characterised as the power spectral density of the system's output when the input is zero-mean white noise whose power spectral density is equal to the identity matrix. For the purposes of computation, there are three alternative characterisations, corresponding to the system's impulse response, frequency response, and the controllability or observability Gramian. For the case of a (rational and strictly proper) single input single output system with impulse response $g(t)$, frequency response $G(s) \in \mathbb{R}(s)$ (the Laplace transform of $g(t)$), and state-space realization (A, B, C) (i.e., $A \in \mathbb{R}^{n\times n}, B \in \mathbb{R}^{n\times 1}$ and $C \in \mathbb{R}^{1\times n}$ satisfy $G(s) = C(sI - A)^{-1}B$), these three alternative characterisations are as described next. It should be noted that the H_2 norm as defined below requires the system to be asymptotically stable, and accordingly this will be assumed to be the case throughout. The algorithm proposed in this paper for its computation contains a test for stability and can flag when this condition is not met.

Firstly, the H_2 norm is the 2-norm of the impulse response, i.e., $\|G\|_2^2 = \int_{-\infty}^{\infty} g(t)^2 \mathrm{d}t$.

Secondly, using Parseval's theorem, this can be evaluated using the frequency response $G(j\omega)$ as follows:

$$\|G\|_2^2 = \frac{1}{2\pi}\int_{-\infty}^{\infty} G(j\omega)^* G(j\omega)\mathrm{d}\omega. \tag{1}$$

Thirdly, $\|G\|_2^2 = B^T L_o B = C L_c C^T$, where L_o and L_c are the observability and controllability Gramians, which are the solutions to the Lyapunov equations $A^T L_o + L_o A + C^T C = 0$ and $A L_c + L_c A^T + B B^T = 0$, respectively.

Similar characterisations to the above also hold for multi-input multi-output systems (see, e.g., Zhou et al., 1996, pp. 112–113).

Owing to the abundance of efficient computational methods for solving Lyapunov equations, such as those characterising the observability and controllability Gramians, then algorithms for computing the H_2 norm typically employ the third of the aforementioned characterisations. While the Lyapunov equations themselves are linear in the entries in the observability and controllability Gramians, the size of such equations are considerably greater than the state dimension, and the solutions depend in a complicated manner on the entries in the matrices A, B and C. In contrast, in this paper, an algorithm will be presented based on the second of the aforementioned characterisations for the H_2 norm. The most computationally demanding step in the calculation corresponds to solving a structured linear equation of dimension equal to the state dimension. Moreover, the structural properties of this equation can be handled in a computationally efficient manner via a fraction-free variant of the extended Euclidean algorithm.

The algorithm for the computation of the H_2 norm will be stated in terms of the coefficients in the numerator and denominator polynomials of the transfer function:

$$G(s) = \frac{c(s)}{a(s)} = \frac{c_{n-1}s^{n-1} + c_{n-2}s^{n-2} + \ldots + c_1 s + c_0}{a_n s^n + a_{n-1}s^{n-1} + \ldots + a_1 s + a_0}, \tag{2}$$

where, without loss of generality, we let $a_n > 0$, and we assume that $c(s)$ and $a(s)$ have no common roots in the closed right half plane (whereupon G is asymptotically stable if and only if the roots of $a(s)$ are all in the open left half plane). Following Ablowitz (2003, pp. 220–221), it follows that the integral in equation (1) is equal to $\oint_D G(-s)G(s)\mathrm{d}s/(2\pi j)$, where D is a contour that traverses the imaginary axis from a point $s = -jR$ to the point $s = jR$, then follows a semicircular arc of radius R into the left half plane, for any given $R > 0$ such that this contour encloses all of the poles of $G(s)$ (see also Zhou et al., 1996).

Since the roots of $a(s)$ are all in the open left half plane, then $a(s)$ and $a(-s)$ have no roots in common, whereupon there exists a unique solution to the polynomial Diophantine equation $c(-s)c(s) = a(s)x(s)+a(-s)y(s)$ for which the degrees of $x(s)$ and $y(s)$ are strictly less than n. Moreover, it can be noted that if the pair $(x(s), y(s))$ satisfies the aforementioned equation, then so too does the pair $(y(-s), x(-s))$, and it follows that $x(s) = y(-s)$. In other words, $y(s)$ is the unique polynomial whose degree is strictly less than n that solves the equation

$$c(-s)c(s) = a(s)y(-s) + a(-s)y(s). \tag{3}$$

Rearranging (3) and substituting it into the previous contour integral yields

$$2\pi j\|G\|_2^2 = \oint_D \frac{c(s)c(-s)}{a(s)a(-s)}\mathrm{d}s = \oint_D \frac{y(-s)}{a(-s)}\mathrm{d}s + \oint_D \frac{y(s)}{a(s)}\mathrm{d}s.$$

Since the roots of $a(s)$ are all in the open left half plane, then D contains all of the poles of $y(s)/a(s)$ and none of the poles of $y(-s)/a(-s)$, whereupon by Cauchy's residue theorem it follows that

$$\|G\|_2^2 = \frac{1}{2\pi j}\oint_D \frac{y(s)}{a(s)}\mathrm{d}s.$$

Since D contains all of the poles of $y(s)/a(s)$, then the above contour integral can be evaluated using the concept of the *residue at infinity* (see Ablowitz, 2003, pp. 211–212). Specifically, from (Ablowitz, 2003, equations (4.1.13) and (4.1.14)), it follows that

$$\|G\|_2^2 = \lim_{s\to\infty}\left(\frac{sy(s)}{a(s)}\right) = \frac{y_{n-1}}{a_n},$$

where y_{n-1} denotes the coefficient of s^{n-1} in $y(s)$. In summary, the computation of the H_2 norm of the system whose transfer function is as in (2) amounts to the determination of the coefficient y_{n-1} from the polynomial solution $y(s)$ (of degree $n-1$ or less) to equation (3).

Now, let

$$\begin{aligned} c^e(s) &= c_0 + c_2 s + \ldots + c_{2\lfloor\frac{n-1}{2}\rfloor} s^{\lfloor\frac{n-1}{2}\rfloor}, \\ c^o(s) &= c_1 + c_3 s + \ldots + c_{2\lceil\frac{n-3}{2}\rceil+1} s^{\lceil\frac{n-3}{2}\rceil}, \\ \text{and } z_0(s) &= (c^e(s))^2 - s(c^o(s))^2, \end{aligned} \tag{4}$$

whereupon $c(s) = c^e(s^2) + sc^o(s^2)$ and

$$c(-s)c(s) = (c^e(s^2) - sc^o(s^2))(c^e(s^2) + sc^o(s^2)) = z(s^2).$$

Further, let

$$\begin{aligned} a^e(s) &= a_0 + a_2 s + \ldots + a_{2\lfloor\frac{n}{2}\rfloor} s^{\lfloor\frac{n}{2}\rfloor}, \\ \text{and } a^o(s) &= a_1 s + a_3 s^2 + \ldots + a_{2\lceil\frac{n}{2}\rceil-1} s^{\lceil\frac{n}{2}\rceil}, \end{aligned} \tag{5}$$

whereupon $a(s) = a^e(s^2) + \frac{1}{s}a^o(s^2)$. It can be shown that $a^e(s)$ and $a^o(s)$ do not share any common roots since the

roots of $a(s)$ are all in the open left half plane, and it follows that there exist unique polynomials $f(s)$ and $g(s)$ such that the degree of $f(s)$ (resp. $g(s)$) is strictly less than the degree of $a^o(s)$ (resp. $a_e(s)$) and

$$a^e(s)f(s) + a^o(s)g(s) = z_0(s). \tag{6}$$

Then, with the notation

$$y(s) = \tfrac{1}{2}(f(s^2) - sg(s^2)), \tag{7}$$

it is easily shown that the degree of y is strictly less than n, and that $a(s)y(-s) + a(-s)y(s) = c(-s)c(s)$. In other words, $y(s)$ in equation (7) is the unique solution to equation (3) for which the degree of $y(s)$ is strictly less than n, whereupon the coefficient y_{n-1} of s^{n-1} in the polynomial $y(s)$ is determined from the solutions $f(s)$ and $g(s)$ to the polynomial Diophantine equation (6).

3. EFFICIENT COMPUTATION OF THE SOLUTION TO THE POLYNOMIAL DIOPHANTINE EQUATION

It has been shown that the H_2 norm of the system whose transfer function is as in (2) is equal to y_{n-1}/a_n, where y_{n-1} is the coefficient of s^{n-1} in the polynomial $y(s)$ in (7), where $f(s)$ and $g(s)$ are the solutions to the polynomial Diophantine equation (6). Here, $a_e(s)$, $a_o(s)$ and $z_0(s)$ are directly determined from the coefficients $c_0, c_1, \ldots c_{n-1}$ and $a_0, a_1, \ldots, a_n$ in the transfer function $G(s)$ using equations (4) and (5). In this and the next section, efficient algorithms for the computation of the solution to this Diophantine equation will be presented.

First, by equating coefficients of s in equation (6), it follows that the coefficients in the polynomials $f(s)$ and $g(s)$ can be obtained by finding the solution x to the linear equation

$$H^T x = b, \tag{8}$$

where H is the $n \times n$ Hurwitz matrix

$$H = \begin{bmatrix} a_{n-1} & a_{n-3} & a_{n-5} & \cdots \\ a_n & a_{n-2} & a_{n-4} & \cdots \\ 0 & a_{n-1} & a_{n-3} & \cdots \\ 0 & a_n & a_{n-2} & \cdots \\ & & & \ddots \end{bmatrix}, \tag{9}$$

and $b^T = [z_{0,n-1}\ z_{0,n-2}\ \cdots\ z_{0,1}\ z_{0,0}]$ where $z_0(s) = z_{0,n-1}s^{n-1} + z_{0,n-2}s^{n-2} + \ldots + z_{0,1}s + z_{0,0}$. Here, if n is odd (resp., even), then the odd (resp., even) entries in the solution x to equation (8) correspond to the coefficients in $f(s)$ in equation (6), and the even (resp., odd) entries correspond to the coefficients in $g(s)$, in descending degree. In either case, it follows that $y_{n-1} = (-1)^{n+1}x_1/2$, where x_1 denotes the first entry in the solution x to equation (8).

The preceding characterisation of the H_2 norm is similar to the approach taken by Betser et al. (1995) to characterise the solution P to the Lyapunov equation $-PA - A^TP = Q$ in the case that A is a companion matrix. In contrast to the preceding derivation, the result of Betser et al. (1995) used the theory of matrix polynomials. A similar approach was followed by Hughes (2016), where an alternative characterisation was also obtained in terms of the Bezoutian of the polynomials $a^o(s)$ and $a^e(s)$, which allows one to exploit the algorithms of Bini and Gemignani (1998) for efficient triangularisation of Bezoutians.

This solution method via the polynomial Diophantine equation (6) also lends itself to both exact computation over the integers and to symbolic computation. This is of particular interest in safety critical applications, and in structured H_2 norm optimisation problems. In these cases, the solution can be efficiently obtained via the algorithm to be described in the next section.

4. EXACT OR SYMBOLIC COMPUTATION USING SUBRESULTANT SEQUENCES

In this section, an algorithm for solving the polynomial Diophantine equation (6) will be provided that is particularly suitable for exact or symbolic computation. The algorithm amounts to the computation of subresultant and remainder sequences in a generalised version of the extended Euclidean algorithm (see, e.g., Basu et al., 2006, Section 8.3). The coefficients of these subresultant and remainder sequences correspond to subdeterminants of the Hurwitz matrix, and so a stability test can be performed with little added computational cost. The method is also fraction-free (i.e. at each stage of the computation, the results are integers whenever the coefficients in the originating transfer function are integers), which allows for efficient exact or symbolic computation. The algorithm and its properties are presented in this section. The proof will follow in a journal paper currently in preparation.

First, note that the definitions for the polynomials change depending on whether the degree of the transfer function, n, is odd or even. Owing to space constraints, we consider only the case where n is odd in the following. Define

$$p_1(s) = a^o(s) = a_1 s + a_3 s^2 + \ldots + a_{2\lceil \frac{n}{2} \rceil - 1} s^{\lceil \frac{n}{2} \rceil},$$
$$p_2(s) = a^e(s) = a_0 + a_2 s + \ldots + a_{2\lfloor \frac{n}{2} \rfloor} s^{\lfloor \frac{n}{2} \rfloor},$$

and recall the definition of $z_0(s)$ in terms of the coefficients in the numerator polynomial of the transfer function $G(s)$ from equation (4). To calculate the H_2 norm, we recursively compute polynomials $z_1, \ldots, z_{n-1}$ and $p_3, \ldots, p_{n+1}$ as follows. Firstly, the polynomials $z_1(s)$ and $p_3(s)$ are obtained thus:

$$z_1(s) = \mathbb{LC}(p_1)z_0(s) - s^{\lceil \frac{n-2}{2} \rceil} z_{0,n-1}p_1(s),$$
$$p_3(s) = \mathbb{LC}(p_2)p_1(s) - s^{n\%2}\mathbb{LC}(p_1)p_2(s).$$

Here, and hereafter, $z_{i-1,n-i}$ denotes the coefficient of degree $n-i$ in the polynomial $z_{i-1}(s)$, which could equal 0 ($i = 1, 2, \ldots, n$). Next, the polynomials $z_2(s)$ and $p_4(s)$ are obtained thus:

$$z_2(s) = \mathbb{LC}(p_2)z_1(s) - s^{\lceil \frac{n-3}{2} \rceil} z_{1,n-2}p_2(s),$$
$$p_4(s) = \mathbb{LC}(p_3)p_2(s) - s^{(n-1)\%2}\mathbb{LC}(p_2)p_3(s).$$

Then, given polynomials $p_i(s), p_{i+1}(s)$ and $z_{i-1}(s)$, the polynomials $p_{i+2}(s)$ and $z_i(s)$ are obtained thus:

$$z_i(s) = \frac{\mathbb{LC}(p_i)}{\mathbb{LC}(p_{i-1})} z_{i-1}(s) - s^{\lceil \frac{n-i-1}{2} \rceil} \frac{z_{i-1,n-i}}{\mathbb{LC}(p_{i-1})} p_i(s),$$
$$p_{i+2}(s) = \frac{\mathbb{LC}(p_{i+1})}{\mathbb{LC}(p_{i-1})} p_i(s) - s^{(n-i+1)\%2} \frac{\mathbb{LC}(p_i)}{\mathbb{LC}(p_{i-1})} p_{i+1}(s),$$

for $i = 3, 4, \ldots, n-1$. The coefficients $\mathbb{LC}(p_k)$ correspond to principal subdeterminants of the Hurwitz matrix, whereby $\mathbb{LC}(p_k) > 0$ for all $k = 0, \ldots, n+1$ due to $G(s) = c(s)/a(s)$ being asymptotically stable (Gantmacher, 1980, p. 194). Moreover, if any one of these coefficients is non-positive, then the algorithm can terminate with notifica-

tion that the roots of $a(s)$ are not all in the open left-half plane and thus the H_2 norm is ill-posed. Asymptotic stability is also sufficient to guarantee that the degrees of the polynomials satisfy $\deg(p_{i+2}(s)) = \deg(p_i(s)) - 1$ for $i = 1, 2, \ldots, n-1$, and it is clear that $\deg(z_i(s)) < \deg(z_{i-1}(s))$ for $i = 1, 2, \ldots, n-1$, whereupon it follows that $z_{n-1}(s)$ and $p_{n+1}(s)$ are scalar constants.

Having computed this sequence of polynomials, the H_2 norm is then obtained as

$$\frac{z_{n-1}}{2a_n p_{n+1}}.$$

It can be shown that the coefficients of the polynomials $p_{i+2}(s)$ and $z_i(s)$ will be integers whenever the coefficients of the originating polynomials p_1, p_2 and z_0 are integers, for $i = 1, 2, \ldots, n-1$. In this case, all quantities can be calculated exactly and efficiently using integer arithmetic. This property also facilitates efficient symbolic computation when the coefficients are parametric, for example when considering lumped parameter networks such as mechanical suspension systems.

The performance of this algorithm has been compared to the `norm` command in MATLAB 2021b and is of the order of 100 times faster for transfer functions of degrees in the range from 5 to 21. MATLAB tends to take longer to execute code when running code for the first time, while it loads required functions and allocates memory for variables. This is illustrated in Figure 1; it is particularly prominent over the first 10 runs, but there are still spikes in execution time during the first 1000. These spikes in execution time still exist in runs after the first 1000 but are less prominent.

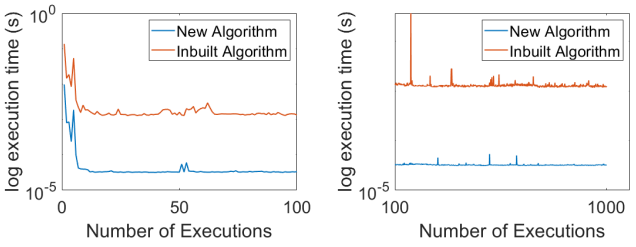

Fig. 1. Execution times plotted for the first 100 and following 1000 executions, respectively, for a transfer function with degree $n = 21$.

The following table presents the executation times for this algorithm in comparison with the `norm` command. Owing to the speed up in performance, these results represent the average execution time between the 1000th and 10000th run. A similar order of magnitude improvement in execution time is also observed for the first run and the first 1000 runs. These metrics were obtained on an Intel i7-12700K, and are reported in microseconds to 3 significant figures. Transfer functions were constructed as follows: $c(s) = \sum_{i=0}^{n-1} s^i$, $a(s) = \sum_{i=0}^{n} \binom{n}{i} s^i$.

n	MATLAB (inbuilt)	MATLAB (New Algorithm)
5	707	9.09
7	742	14.6
9	784	14.9
21	1200	32.3

Furthermore, the command `isstable`, used to test the stability of a transfer function in MATLAB 2021b, adds a further 205 microseconds to the computation time for $n = 21$, in comparison to checking the leading coefficient of $p_i > 0$, which has negligible effect on computation time.

In addition, direct solution to equation (8) was tested, using the backslash operator in MATLAB. This was roughly 3 times slower than the method outlined in this paper, yet still significantly faster than MATLAB's inbuilt function, averaging at 98.3 microseconds between the 1000th and 10000th runs for $n = 21$.

The algorithm has particular value in terms of optimisation of lumped-parameter networks, such as mechanical networks. For example, many vehicle suspension design problems can be characterised in terms of optimising the network parameters (such as the spring stiffnesses, damping rates and inertias) in order to optimise the H_2 norm of some driving-point or transfer admittance (see, e.g., Wang et al., 2009). The driving-point or transfer admittance will be functions of these design parameters whose coefficients can be obtained directly using graph theoretic methodologies (see, e.g., Percival, 1953). Optimisation of the H_2 norm can be implemented efficiently with the new algorithm, either numerically or symbolically. The symbolic approach also enables computation of the gradient vector and Hessian matrix to allow application of efficient interior-point or similar methodologies for optimisation.

Abstract: Traditional linear passive vibration-absorber networks, such as the tuned mass damper (TMD), often contain springs, dampers and masses. Recently there has been a growing trend to supplement or replace the masses with inerters. When considering the absorbers without a mass, a structure-immittance approach was proposed to identify possible configurations consisting of springs, dampers and inerters. This approach can characterise the full class of network layouts with pre-determined numbers of each element type, and also prescribe the allowed value range for each element. More recently, a mass-included passive absorber, the tuned-mass-damper-inerter, was introduced, showing significant performance benefits on vibration suppression. With the aim to further explore the potential of numerous mass-included passive absorber layouts, a more generalised methodology was developed. Using this methodology, a full class of absorber layouts with a mass and a pre-determined number of inerters, dampers and springs connected in series and parallel can be systematically investigated. A 3-storey building model is used to demonstrate the advantages of the proposed approaches for the cases without and with a mass, where the performance improvements can be up to 21.6% and 65.6%, respectively, compared to the TMD.

Keywords: Passive vibration damper, Network topologies, inerter, systematic methodology, reaction mass.

1. INTRODUCTION

Tuned mass dampers (TMDs), in which a reaction mass is attached to a structural system via a spring–parallel–damper connection, are commonly used in a wide range of applications to suppress deleterious vibrations. The inerter was introdued by Smith (2002), which allows electrical networks to be translated over to mechanical ones in a completely analogous way, with the mechanical elements springs, dampers and inerters corresponding to the electrical elements inductors, resistors and capacitors. Hence, any positive-real functions can be synthesised by passive mechanical networks consisting of dampers, inerters and springs using the theorem proposed by Bott and Duffin (1949). When considering of possible configurations with these elements broadly, two approaches are normally used: one structure-based and one immittance-based. Both approaches have their advantages and disadvantages. Later, a new approach was proposed by Zhang et al. (2017) – the structure–immittance approach. Using this approach, a full set of possible series–parallel networks with predetermined numbers of inerters, dampers and springs can be represented by structural immittances, obtained via a proposed general formulation process. Using the structural immittances, both the ability to investigate a class of absorber possibilities together (advantage of the immittance-based approach), and the ability to control the complexity, topology and element values (advantages of the structure-based approach) are provided.

Recently, by adding an inerter into the TMD and employing two structural attachment points, Marian and Giaralis (2014) proposed a new vibration suppression device, the tuned-mass-damper-inerter (TMDI), with significant benefits obtained. It demonstrates the potential advantages of passive vibration absorbers including the mass and the two-terminal mechanical elements springs, dampers and inerters. However, there are countless topological connection possibilities with these elements included, some of which can potentially provide much more advantageous performance. Therefore, an approach was proposed by Zhang et al. (2019) to systematically characterise a full set of passive vibration absorbers with series–parallel connections of a mass and a pre-determined number of springs, dampers and inerters.

⋆ This is a resubmission of the MTNS2020 extended abstract.

In this extended abstract, the structure-immittance and mass-included synthesis approaches are introduced in Sections 2&3, respectively, to demonstrate the construction of the generic networks and their corresponding mathematical representations. Examples containing one spring, one damper and one inerter (termed as 1k1c1b) are demonstrated accordingly. Finally, a three-storey building model is used in Section 4 to show the advantages of the proposed two approaches on identifying beneficial 1k1c1b mechanical networks with and without a mass element.

2. STRUCTURE-IMMITTANCE APPROACH

The structure-immittance approach is based on the force-current analogy where two-terminal networks are considered. Therefore, three elements p, q, r are considered. They can represent in any order either inerters, dampers and springs in the mechanical domain or capacitors, inductors and resistors in the electrical one. Assume the numbers of p, q and r elements are P, Q and R, respectively and $P \leq Q \leq R$ is satisfied by selecting the p, q and r elements appropriately. By using the structure-immittance approach, generic networks which contain explicit information of all topology possibilities for a given number of each component are first constructed. The formulation of a generic network representing P p, Q q and R r elements requires a series of steps, summarised as a flow chart in Figure 1. Detailed steps to obtain the generic networks can be found in the paper by Zhang et al. (2017).

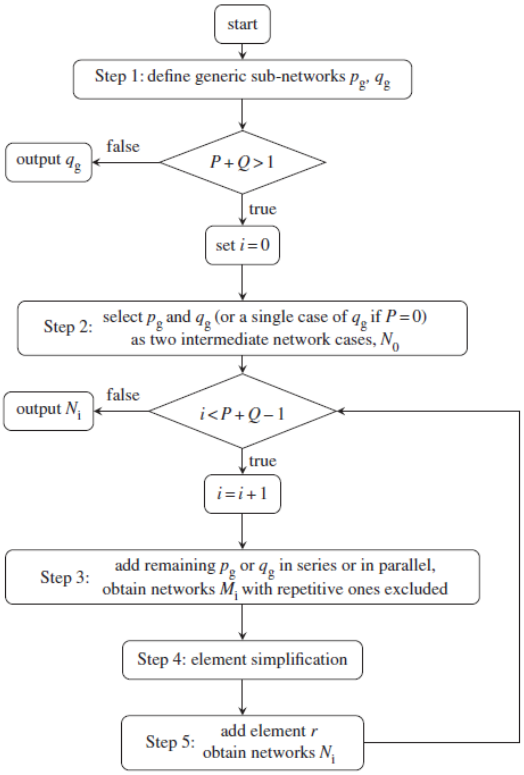

Fig. 1. Flow chart summarising the steps to obtain generic networks done by Zhang et al. (2017) for P p, Q q and R r case where $P \leq Q \leq R$.

One mechanical network example with one spring, one damper and one inerter (i.e. 1k1c1b case) are constructed based on the procedures shown in Figure 1. Two generic networks, termed Q_1 and Q_2, can be obtained as shown in Figure 2. Here we choose the damper and inerter as the base element for the sub-networks and the spring is appointed as the added element. Totally 8 layouts are included by these two generic networks which contain all the possible layouts for the 1k1c1b case.

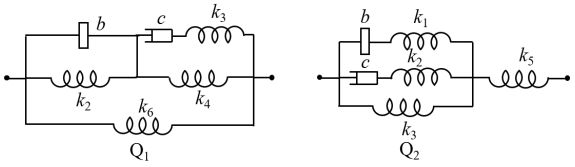

Fig. 2. The generic networks obtained for the 1k1c1b case where only one spring is actually present in each of the generic networks.

After obtaining the generic networks, their corresponding structural-immittances can be derived, which are defined as the transfer functions of generic networks from force to velocity, i.e.

$$Y(s) = \frac{F(s)}{V(s)} \tag{1}$$

$F(s)$ and $V(s)$ are the force and relative velocity across the two terminals in the Laplace domain, respectively. s is the complex frequency parameter of the Laplace transform. Here, for the 1k1c1b case, the structural-immittances of generic networks Q_1 and Q_2 are represented as:

$$\begin{aligned} Y_1(s) &= \frac{bcs^2 + b(k_4+k_6)s + c(k_2+k_6)}{bc(1/k_3)s^3 + bs^2 + cs + k_2 + k_4}, \\ Y_2(s) &= \frac{bc(1/k_1+1/k_2)s^3 + bs^2 + cs + k_3}{b(1/k_1+1/k_5)s^3 + c(1/k_2+1/k_5)s^2 + s} \end{aligned} \tag{2}$$

Note that, for $Y_1(s)$, only one of k_2, $1/k_3$, k_4 and k_6 is positive and all the others are equal to zero. Similarly, for $Y_2(s)$, only one of $1/k_1$, $1/k_2$, k_3 and $1/k_5$ is positive and all the others are equal to zero. These transfer functions can be used, along with the specific constraints on the number of spring elements, to find the optimum mechanical network for a given system and objective functions.

3. MASS-INCLUDED SYNTHESIS APPROACH

The structure-immittance approach, which employed network synthesis theory, made use of the fact that the inerters, dampers and springs all have two terminals. When a reaction mass is included into the networks, a systematic approach becomes much more challenging, as the reaction mass is always regarded as a one-terminal element. In order for network synthesis to be directly applicable to the systematic enumeration of vibration absorbers with a reaction mass, it is necessary to treat the mass as a special two-terminal element, with one terminal notionally connected to the ground, denoted as a notional-ground (NG). Accordingly, terminals connected to physical attachments are denoted as physical-terminals (PTs).

Considering the fact that most vibration suppression devices have no more than two attachment points, investigation of the mass-included synthesis approach focuses on 1PT1NG and 2PT1NG networks. The 1PT1NG network, represented by its force–velocity transfer function $H(s) = F_1(s)/V_1(s)$, is shown in Figure 3(a). At the PT1, the force f_1 ($F_1(s)$ in the Laplace domain) is applied

and results in a velocity v_1 ($V_1(s)$). Figure 3(b) shows a 2PT1NG network, with forces f_1, f_2 and velocities v_1, v_2 at two PTs. Note that because of the presence of a reaction mass, in contrast to the 2PT network (whose immittance function is $Y(s) = F(s)/(V_1(s) - V_2(s))$, see Figure 3(c)), the forces f_1, f_2 of the 2PT1NG network are not equal and opposite. In the following parts, constructions of 1PT1NG and 2PT1NG networks are briefly introduced, and generic networks of an example mechanical network containing a mass and 1k1c1b are demonstrated. Details can be found in the work done by Zhang et al. (2019).

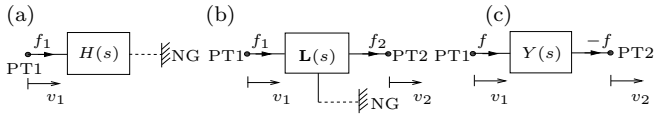

Fig. 3. (a) 1PT1NG network, (b) 2PT1NG network and (c) 2PT network (by Zhang et al. (2019)).

3.1 1PT1NG network layout enumeration

To construct the 1PT1NG networks, we consider joining a 2PT network with a 1PT1NG Immittance-Function-Network (IF-Network), where an IF-Network refers to a network layout with its 2PT sub-networks represented by Immittance-Function-Blocks (IF-Blocks). In order to formulate series-parallel 1PT1NG IF-Networks, a collection of finite numbers of IF-Blocks combined with a mass is considered. A non-unique connection sequence is proposed, with which all possible 1PT1NG IF-Networks can be obtained. Start with a single IF-Block, it can be connected in series or in parallel with other IF-Blocks, however, these always reduce to a single IF-Block. At a certain step, the resulting IF-Block is connected to the mass, where only a series connection is possible, resulting in a new 1PT1NG network. Further addition of IF-Blocks can only be connected in series with this 1PT1NG network, as a parallel connection would necessitate a NG being connected with a PT. Hence, all the IF-Networks can be represented by the generic IF-Network shown in Figure 4 with a single IF-Block $Y(s)$.

Fig. 4. The generic 1PT1NG IF-Network got by Zhang et al. (2019).

For the 1PT1NG network layouts with one reaction mass and 1k1c1b elements, all network possibilities can be obtained using the generic IF-Network in Figure 4, by enumerating the full class of 2PT network possibilities consisting of 3 elements in $Y(s)$. To this end, the structure-immittance approach can be directly applied to obtain the structural immittance $Y(s)$, which is shown in Eq. 2 for the 1k1c1b case. The transfer function of the generic IF-Network can be obtained as:

$$H(s) = Y(s)ms/(ms + Y(s)) \tag{3}$$

With $H(s)$, the optimum 1PT1NG vibration absorber can be identified for a given vibration suppression problem.

3.2 2PT1NG network layout enumeration

In order to formulate 2PT1NG IF-Networks, a sequence of steps is introduced based on the work by Nishizeki and Saito (1974), as shown in Figure 5. The construction of a three-terminal series-parallel network begins with an empty graph as shown in Step 1. We first consider joining the two terminals, PT1 and NG. Using the generic 1PT1NG IF-Network obtained in the previous section (Figure 4), a network shown in Step 2 is obtained. Then a single IF-Block $Y_2(s)$ is added to the network, resulting in Step 3 via a parallel connection. Consider adding the next IF-Block, $Y_3(s)$, resulting in the new IF-Network shown in Step 4 using the series connection. Note that all the other connection possibilities between Step 3 and the IF-Block $Y_3(s)$ can all be simplified to Step 3. At this point, only a parallel IF-Block can be added, with the resulting IF-Network shown in Step 5, since series IF-Blocks can be reduced to the network of Step 4. Following this parallel addition, only series additions modify the network. Note that series connections at both PT terminals need to be considered, and we define connecting to PT2 as Step 6. An additional IF-Block is then added in series at PT1 – the resultant network is shown in Step 7. Consequent steps will be adding IF-Blocks in parallel then in series by repeating Steps 5-7, until all IF-Blocks in the original collection are used.

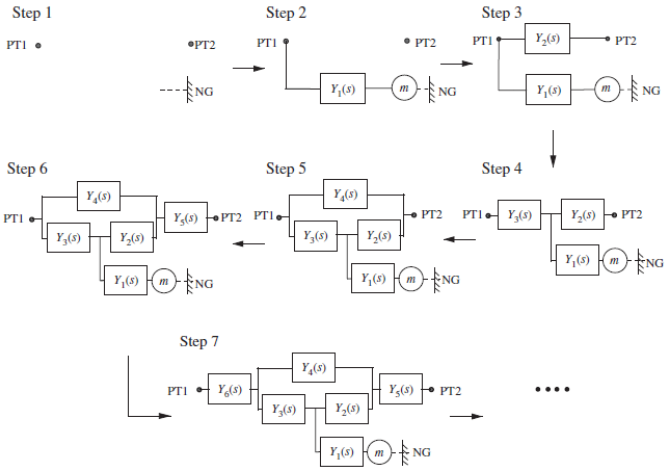

Fig. 5. A procedure summarised by Zhang et al. (2019) to form all possible series-parallel 2PT1NG IF-Networks with a mass and a pre-determined number of IF-Blocks .

Based on the obtained series-parallel 2PT1NG IF-Networks, the rest part focuses on generating generic 2PT1NG IF-Networks. Different from 1PT1NG networks, where one generic IF-Network is sufficient (Figure 4), for 2PT1NG networks, different generic IF-Networks are needed depending on the number, R, of IF-Blocks which are present. In this extended abstract, 1k1c1b case is considered for the possible 2PT1NG generic IF-Networks where at most 3 IF-Blocks exist. Therefore, three generic IF-Networks for R =1, 2, 3 are obtained as shown in Figure 6.

To describe the relations between the velocities and the forces of the 2PT1NG generic IF-Networks in the Laplace domain, an Immittance-Function-Matrix (IF-Matrix), de-

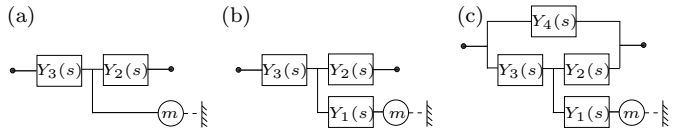

Fig. 6. Generic IF-Networks of 2PT1NG networks containing one spring, one damper and one inerter where the present IF-Blocks (a) $R = 1$, (b) $R = 2$ and (c) $R = 3$.

noted as $\mathbf{L}(s)$, is required, where the velocities and the forces are related in Laplace domain, as:

$$\begin{bmatrix} F_1 \\ F_2 \end{bmatrix} = \mathbf{L}(s) \begin{bmatrix} V_1 \\ V_2 \end{bmatrix}, \tag{4}$$

$\mathbf{L}(s)$ is a 2×2 matrix. For generic IF-Networks of 1k1c1b 2PT1NG networks as shown in Figure 6. Their IF-Matrices can be found in the paper by Zhang et al. (2019). With the obtained IF Matrices, the optimum 2PT1NG network containing 1k1c1b with a reaction mass can be identified for a given vibration suppression problem.

4. NUMERICAL APPLICATION ON THE EXAMPLE STRUCTURE

In order to demonstrate the vibration suppression abilities of the mechanical networks identified by the above introduced systematic approaches for cases with and without a mass element, a three degrees-of-freedom (DOFs) structure model is introduced, with floor masses $m_s = 10000$ kg and inter-storey stiffness $k_s = 15000$ kN/m. The structural damping is taken to be zero as it is typically negligible compared with that introduced by absorbers. The absorber is connected between the second and third floors with the reaction mass m =1000 kg if applicable. A brace stiffness $k_b = 0.2k_s$ in series with the absorber and connecting to the lower floor is included. In this example, the inter-storey drift displacement is taken as the performance measure. Therefore the objective function is defined as:

$$J_d = \max_{(\text{over } i)} \left(\max_{(\text{over } \omega)} |T_{s^2 X_0 \to X_{d_i}}| \right), \quad (i = \text{I, II, III}), \tag{5}$$

where $T_{s^2 X_0 \to X_{d_i}}$ denotes the transfer function from the earthquake acceleration to the inter-storey drift displacements and $\text{Max}|T_{s^2 X_0 \to X_{d_i}}|$ is the maximum magnitude of $T_{s^2 X_0 \to X_{d_i}}$.

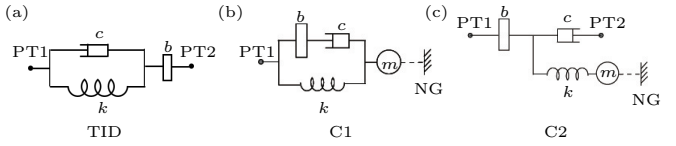

Fig. 7. Optimal mechanical layouts containing one mass and 1k1c1b for the (a) 2PT network (TID), (b) 1PT1NG network (C1) and (c) 2PT1NG network (C2).

When considering 2PT networks, the structure-immittance approach is employed, where the optimum mechanical absorber is the tuned inerter damper (TID) as shown in Figure 7(a), with the parameter values in Table 1. For the 1PT1NG and 2PT1NG networks, generic networks in Figure 4 and Figure 6, respectively, are employed, and the optimum layout is shown in Figure 7 as C1 and C2. Their corresponding parameter values are shown in Table 1. It can be obtained that the performance improvements can be up to 21.6%, 34.8% and 65.6% for the identified mechanical networks of 2PT, 1PT1NG and 2PT1NG cases. Their corresponding frequency domain responses are illustrated in Figure 8.

Table 1. Optimisation results for the optimum 2PT, 1PT1NG and 2PT1NG layouts with $m =$ 1000 kg where applicable.

Network type	TMD	TID	C1	C2
J_d ($\times 10^{-3}$ s^2)	25.0	19.6	16.3	8.60
Percentage Imp. (%)	(–)	(21.6%)	(34.8%)	(65.6%)
Stiffness (kN/m)	2.75×10^2	4.35×10^3	4.92×10^2	2.13×10^2
Damping (kNs/m)	11.7	7.50×10^2	30.5	3.26×10^2
Inertance (kg)	–	7.94×10^3	1.05×10^3	8.10×10^3

Abstract: The resource allocation problem consists in the optimal distribution of a budget between a group of agents. We consider a version of this optimization problem in open systems where agents can be replaced, resulting in variations of the budget and the total cost function to be minimized. We analyze the performance of the Random Coordinate Descent algorithm (RCD) in that setting using natural performance indexes which are related to those used in online optimization. We show that, in a simple setting, both the accumulated error obtained from using the RCD as compared to the optimal solution and the accumulated gain obtained from using the RCD instead of not collaborating grow linearly with the number of iterations considered for the computation, so that in expectation an error cannot be avoided, but remains bounded.

1. INTRODUCTION

We consider the optimal resource allocation problem, where a fixed amount of resource must be distributed among n agents while minimizing some separable cost function f. Such problems arise in different fields of research, such as actuator networks (Teixeira et al., 2013) or energy resources (Dominguez-Garcia et al., 2012). In some of their formulations, each agent i holds a quantity d_i (which we call here the "demand" of agent i), so that the total amount of resource to be distributed is $\sum_{i=1}^n d_i$; the problem can then be written as

$$\min_{x\in\mathbb{R}^{np}} f(x) = \sum_{i=1}^n f_i(x_i) \quad \text{s.t.} \quad \sum_{i=1}^n x_i = \sum_{i=1}^n d_i, \qquad (1)$$

where each function $f_i : \mathbb{R}^p \to \mathbb{R}$ is α-strongly convex and β-smooth, and represents the local cost held by agent i.

Problems of this type have received a lot of attention in the last years, see *e.g.*, (Yi et al., 2016). Yet, most of these works assume that the composition of the system remains the same during the whole process. We extend such analyses to *open multi-agent systems* where agents can join or leave the network at a time-scale comparable to that of the process. Those are motivated by the growing size of the systems that tends to slow down the process as compared to the time-scale of potential arrivals and departures of agents. More generally, systems naturally allowing agents to join and leave are becoming common, such as *e.g.* multi-vehicle systems or with the Plug and Play implementation. In the case of (1), it results in the system size n_t, the local cost functions f_i^t, and the local demands d_i^t becoming time-varying. As a consequence, the solution of (1), denoted $x^{*,t}$, changes with the time as well, preventing classical convergence.

In this work, we analyze the behavior and performance of the Random Coordinate Descent algorithm (RCD), introduced in (Necoara, 2013), in open systems. The RCD algorithm solves (1) by using pairwise interactions, where at each step two randomly selected agents follow each other's local gradient to update their estimates, which is more appropriate for open systems, in particular where the number of agents can be large as it results in a low computational complexity. The convergence of this algorithm in open systems in terms of the distance to the minimizer in expectation was studied in (Monnoyer de Galland et al., 2021). In this work, we aim at analyzing the RCD algorithm from another perspective, following the assumption that the cost function must be paid at each iteration, so that a natural choice is to evaluate the performance accumulated over the iterations. Hence, we use metrics related to those used in online optimization, which commonly studies optimization with dynamical cost functions using a similar approach. In particular, we compare

⋆ C. Monnoyer de Galland and R. Vizuete equally contributed to this work. C. Monnoyer de Galland is a FRIA fellow (F.R.S.-FNRS). This work is supported by the "RevealFlight" ARC at UCLouvain, by the *Incentive Grant for Scientific Research (MIS)* "Learning from Pairwise Data" of the F.R.S.-FNRS and in part by the Agence Nationale de la Recherche (ANR) via grant "Hybrid And Networked Dynamical sYstems" (HANDY), number ANR-18-CE40-0010.

the performance of the RCD algorithm with that of the *optimal solution* $x^{*,t}$ and of the *selfish strategy*, denoted $x^{s,t}$, which consists in the total absence of collaboration between the agents (*i.e.*, $x_i^{s,t} = d_i^t$ at all times) and which is expected to yield less good performance. A representation of the behavior of these strategies is presented in Fig. 1.

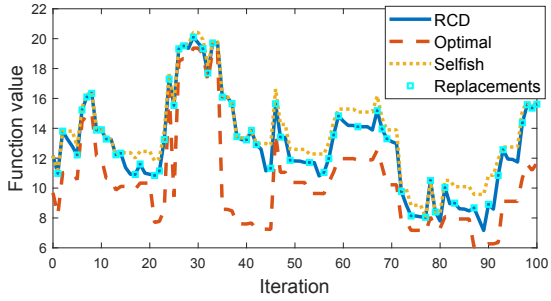

Fig. 1. Evolution of the function value f^t evaluated with the RCD algorithm, the optimal solution $x^{*,t}$, and the selfish strategy $x^{s,t}$, in a system subject to replacements of agents (*i.e.*, simultaneous departures and arrivals) happening as frequently as RCD steps.

2. PROBLEM FORMULATION

We consider the resource allocation problem defined in (1), where the local functions satisfy the following assumption.

Assumption 1. (Local cost function). At any time t, the local function f_i^t of any agent i is

- continuous differentiable;
- α-strongly convex: $f_i^t(x) - \frac{\alpha}{2}\|x\|^2$ is convex $\forall x$;
- β-smooth: $\|\nabla f_i^t(x) - \nabla f_i^t(y)\| \leq \beta\|x-y\|, \forall x, y$;
- satisfies $\arg\min_{x\in\mathbb{R}^d} f_i^t(x) = 0$ and $f_i^t(0) = 0$.

As a consequence of Assumption 1, the global cost function f^t is α-strongly convex and β-smooth as well at all time t. Assumption 1 also implies that the cost function of an agent i is zero only when $x_i = 0$, *i.e.*, when this agent does not contribute to satisfying the total demand.

In this preliminary work, we restrict our analysis to the specific setting described by the following assumptions.

Assumption 2. The local cost function of any agent i at any time t is one-dimensional: $f_i^t : \mathbb{R} \to \mathbb{R}$.

Assumption 3. (Homogeneous demand). The demand associated with any agent i at any time t is $d_i^t = 1$.

2.1 Random Coordinate Descent algorithm

We consider that agents interact through a graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{1, \dots, n\}$ is the set of agents and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is the set of edges. To solve (1), the agents perform the Random Coordinate Descent (RCD) algorithm introduced in (Necoara, 2013), such that at each iteration of the algorithm a pair of agents $(i, j) \in \mathcal{E}$ is uniformly randomly selected and i and j update their states according to

$$x_i^+ = x_i - \frac{1}{\beta}\left(f_i'(x_i) - f_j'(x_j)\right);$$
$$x_j^+ = x_j - \frac{1}{\beta}\left(f_j'(x_j) - f_i'(x_i)\right),$$

where we denote the derivative of the cost functions f_i with f_i' by simplicity because they are 1-dimensional. At the network level, the update rule can be expressed as:

$$x^+ = x - \frac{1}{\beta} Q^{ij} \nabla f(x), \tag{2}$$

where Q^{ij} is a $n \times n$ matrix filled with zeroes except for the following four entries:

$$\left[Q^{ij}\right]_{i,i} = \left[Q^{ij}\right]_{j,j} = \frac{1}{2}; \quad \left[Q^{ij}\right]_{i,j} = \left[Q^{ij}\right]_{j,i} = -\frac{1}{2}.$$

For this preliminary work we also make the following assumption, which means that pairwise interactions as defined in (2) can potentially take place between any pair of agents (i, j) in the systems.

Assumption 4. The graph $G = (\mathcal{V}, \mathcal{E})$ is complete.

2.2 Open system

We consider an *open* system, which is thus subject to arrivals and departures of agents. Those are modelled as follows, where we use respectively the subscripts *out* and *in* to refer to the leaving and joining agent:

(1) Departure: the agent *out* is uniformly randomly selected among the n agents in the system, and sends a last message to all its neighbours (*i.e.* the complete graph), such that for all $i \neq out$ there holds

$$x_i^+ = x_i + \frac{x_{out} - x_i}{n} = \left(1 - \frac{1}{n}\right) x_i + \frac{1}{n} x_{out}. \tag{3}$$

(2) Arrival: The agent *in* joins the system with its demand as initial value: $x_{in}^+ = d_{in} = 1$.

In this preliminary work, we restrict our analysis to open systems when only replacements take place (*i.e.* the simultaneous occurrence of a departure and of an arrival), so that the system size is fixed: for all t there holds $n_t = n$. We can then define the set of events possibly happening in the system as

$$\Xi := R \cup U = \left(\bigcup\nolimits_{i\in\mathcal{V}} R_i\right) \cup \left(\bigcup\nolimits_{(i,j)\in\mathcal{E}} U_{ij}\right), \tag{4}$$

where R_i denotes the replacement of agent i and U_{ij} a pairwise interaction between agents i and j leading to an update of their estimates according to (2).

We assume that two distinct events never occur simultaneously, so that we consider a discrete evolution of the time, where each time-step corresponds to an event $\xi \in \Xi$ happening in the system. Hence we can define the history of the process until a given time-step k as

$$\omega^k := \{(1, \xi_1), \dots, (k, \xi_k)\}, \tag{5}$$

where $\xi_i \in \Xi$ for all $i = 1, \dots, k$.

Assumption 5. The events ξ_i constituting a sequence ω^k happen independently of each other and of all past information, so that at each time-step either an update (*i.e.*, an event U) happens with fixed probability p or a replacement (*i.e.*, an event R) with fixed probability $1 - p$.

One can show that the definitions of arrivals, departures and of the RCD algorithm guarantee that at the occurrence of any event $\xi \in \Xi$, the estimate x^t remains feasible, *i.e.*, such that $x_i^t \geq 0$ for all i, and $\sum_{i=1}^N x_i^t = \sum_{i=1}^N d_i^t = n$, as long as the initial estimate x^0 is feasible as well.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

We can now reformulate original problem (1) in our particular setting as

$$\min_{x\in\mathbb{R}^n} f^t(x) = \sum_{i=1}^{n} f_i^t(x_i) \qquad \text{s.t.} \qquad \sum_{i=1}^{n} x_i = n. \tag{6}$$

Since the local cost functions satisfy Assumption 1, one can show that there exist $L_f, U_f \geq 0$ with $L_f \leq U_f$ such that $\forall t$ there holds

$$f^t(x^{*,t}) \in [L_f, U_f], \tag{7}$$

where $x^{*,t}$ is the solution of (6) at time t.

3. PERFORMANCE METRICS

Standard results on online optimization usually rely on the analysis of the so-called "*regret*", which quantifies the accumulation of the errors made by an algorithm as compared to the optimal solution over a finite number of time steps T. In this work, we follow a similar approach to analyze the performance of a given algorithm as compared to two possible strategies. Due to the definition of our problem, the conclusion is however expected to differ from classical online optimization. We consider the three following strategies for the study of the system:

- **Perfect collaboration**: we assume that at each time instant t the agents know the optimal solution denoted by $x^{*,t}$, which solves (6);
- **Selfish players**: we assume that the players do not collaborate to minimize f^t, and they operate at their individual desired point so that $x^{s,t} = \mathbb{1}_n$ at all t;
- **Decided strategy**: this case corresponds to the action given by a specific algorithm used to solve the problem, resulting in the estimate x^t at time t.

From the definitions, it is clear that for a well-designed algorithm it is expected that:

$$\sum_{t=1}^{T} f^t(x^{*,t}) \leq \sum_{t=1}^{T} f^t(x^t) \leq \sum_{t=1}^{T} f^t(x^{s,t}).$$

However, due to the replacements, there could be time instants where the selfish strategy behaves better than the decided strategy. An illustration of the evolution of these strategies is given in Fig. 1, where the decided strategy is the RCD algorithm defined in the previous section.

Based on these strategies and motivated by the techniques used on online optimization, we define these three quantities:

- **Dynamical Regret**:

$$\mathrm{Reg}_T := \sum\nolimits_{t=1}^{T} \left(f^t(x^t) - f^t(x^{*,t})\right); \tag{8}$$

- **Benefit**:

$$\mathrm{Ben}_T := \sum\nolimits_{t=1}^{T} \left(f^t(x^{s,t}) - f^t(x^t)\right); \tag{9}$$

- **Potential Benefit**:

$$\mathrm{Pot}_T := \sum\nolimits_{t=1}^{T} \left(f^t(x^{s,t}) - f^t(x^{*,t})\right). \tag{10}$$

The "*dynamical regret*" corresponds to the accumulation of the instantaneous errors obtained from using the decided strategy with respect to the optimal solution $x^{*,t}$. Similarly, the "*benefit*" quantifies the accumulated gain obtained from using the decided strategy instead of the selfish strategy $x^{s,t}$. Finally, the "*potential benefit*" represents the accumulated advantage of the optimal strategy with respect to the selfish one, and links the three quantities together as $\mathrm{Pot}_T = \mathrm{Ben}_T + \mathrm{Reg}_T$. Our goal is to analyze the evolution of all these quantities in expectation.

4. PRELIMINARY RESULTS

From Assumption 5, and following an approach similar to that used in (Monnoyer de Galland et al., 2021), we can study the evolution of the quantities defined in (8) – (10) in expectation by analyzing their evolution with each type of event independently (in our case, single replacements of agents and RCD iterations).

Observe that both $f^t(x^{*,t})$ and $f^t(x^{s,t})$ are only impacted by replacements, whereas $f^t(x^t)$ changes with replacements on the one hand, and on the other hand with RCD updates accordingly with the results presented in (Necoara, 2013). Hence, by properly analyzing the effect of replacements on the quantities of interest, we can show that the expected dynamical regret, the benefit and the potential benefit all grow in $O(T)$, so that on average over T they converge to a constant. In particular, we show the following result.

Theorem 1. In the setting described in Section 2, there holds

$$\lim_{T\to\infty} \frac{\mathbb{E}\mathrm{Pot}_T}{T} \leq \frac{\alpha}{2}(\kappa - 1)n; \tag{11}$$

$$\lim_{T\to\infty} \frac{\mathbb{E}\mathrm{Reg}_T}{T} \leq \rho_R \theta \kappa (n-1), \tag{12}$$

for some $\theta \geq 0$ which depends on β and α, and with $\rho_R = \frac{1-p}{p}$.

The detailed proof of Theorem 1 is omitted here, and will be presented elsewhere. Nevertheless, we provide a bit of insights about it below.

The first result of Theorem 1 is obtained from studying the largest possible improvement of using the optimal solution as compared to the selfish strategy at each time-step. In particular, using strong convexity and smoothness, one can show that $f^t(x^{s,t}) - f^t(x^{*,t}) \leq \frac{\beta}{2}\|\mathbb{1}\|^2 - \frac{\alpha}{2}\|x^{*,t}\|^2$, which ultimately yields (11). The second result of Theorem 1 relies on the separated analysis of $f^{t+1}(x^{t+1}) - f^t(x^t)$ and $f^{t+1}(x^{*,t+1}) - f^t(x^{*,t})$, which allow building the evolution of $f^t(x^t) - f^t(x^{*,t})$ as a recurrence on these quantities over the iterations. One can then show that the sum of the latter over the iterations is bounded using (7), thus avoiding the introduction of an additive term related to the optimal value of the function at each time-step. Additional computations then ultimately lead to (12).

Consistently with the definition of the problem and of the quantities of interest, the results above depend on the condition number κ and on the system size n. Moreover, only the regret, which depends on RCD updates, depends on $\rho_R = \frac{1-p}{p}$, *i.e.*, the expected number of replacements between two RCD updates, and thus illustrates how the openness of the system interferes in the behavior of the algorithm. Finally, the qualitative behavior of the bounds matches that of the simulated results obtained with a system of 5 agents subject to replacements, as illustrated in Fig. 2. The derivation of a proper upper bound on the

expected benefit, parallel to (11) and (12) is the next step in this analysis. Furthermore, deriving the corresponding lower bounds and showing that they grow linearly with T as well would be the natural prosecution of these preliminary results, as they would validate the behavior illustrated in Fig. 2 and show that it is not possible to obtain a sublinear behavior.

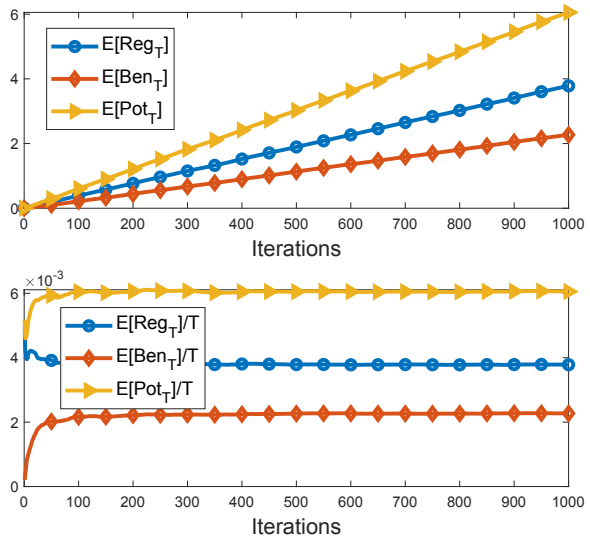

Fig. 2. Evolution of $\mathbb{E}\mathrm{Reg}_T$, $\mathbb{E}\mathrm{Ben}_T$ and $\mathbb{E}\mathrm{Pot}_T$ (top) and of the corresponding quantities averaged with respect to the time (bottom) simulated in a system of 5 agents subject to replacements as frequent as RCD steps.

5. CONCLUSION

We analyzed the performance and behavior of the Random Coordinate Descent algorithm (RCD) for solving the optimal resource allocation problem in an open system subject to replacements of agents, resulting in variation of the total cost function and of the total amount of resource to be allocated. We considered a simple preliminary setting where the budget is homogeneous and where the graph is complete, and used tools inspired from online optimization to show that it is not possible to achieve convergence to the optimal solution with the RCD algorithm in expectation in open system, but that the error is expected to remain reasonable.

We have derived upper bounds on the evolution of the regret and the potential benefit in expectation. A natural continuation of this work is thus the derivation of the corresponding upper bound for the benefit, and of lower bounds for this quantities in order to validate the observed behavior. More generally, our bounds could be extended to more general settings, and their tightness can be improved to match more accurately the actual performance of the algorithm. Moreover, since our approach is based on the analysis of the effect of arrivals and departures of agents combined into replacements, the next step of this study is to generalize it to the case where the system size changes with the time, *i.e.*, where arrivals and departures are decoupled.

Data-driven Approximation of the Koopman Generator on Rich Approximation Spaces

Feliks Nüske*

**Max-Planck-Institute for Dynamics of Complex Technical Systems, Magdeburg, 39106 Germany (e-mail: nueske@mpi-magdeburg.mpg.de)*

Abstract: In the context of Koopman operator based analysis of dynamical systems, the generator of the Koopman semigroup is of central importance. Models for the Koopman generator can be used, among others, for system identification, coarse graining, and control of the system at hand. A critical modeling choice is the subspace or dictionary used for Koopman estimation. In this talk, I will present recent advances allowing for the approximation of the generator on reproducing kernel Hilbert spaces (RKHS), and on tensor-structured subspaces by means of low-rank representations. Both approaches allow modelers to employ high-dimensional, or even infinite-dimensional approximation spaces, while controlling the computational effort at the same time. In both cases, I will discuss the algorithmic realization and computational complexity in detail. I will also discuss recent results on estimating the finite-data estimation error for Koopman generator models.

Abstract: We study input-to-state stability (ISS) of systems with a linear control and a bilinear feedback term, depending on the state trajectory itself and the output of the system. Both, the control and the bilinear feedback enter the system through possibly unbounded operators. Further, the observation operator, associated to the output, is also considered to be unbounded. We derive sufficient conditions for a global in time well-posedness result for small initial data as well as sufficient conditions for an ISS-estimate. This extends recent investigations on bilinear systems, where a second control was considered instead of an output. The developed results are applied to a Burgers equation.

Keywords: Input-to-state stability, well-posed distributed parameter systems, semigroup and operator theory, stability of nonlinear systems, robust control.

1. INTRODUCTION

The concept of *input-to-state stability* (ISS) as introduced in Sontag (1989) unifies both asymptotic stability with respect to initial values and robustness with respect to external inputs. More specific, if we consider a system Σ as a mapping which maps initial values $z_0 \in X$ and inputs $u : [0,\infty) \to U$ to the (unique) state trajectory $z : [0,T) \to X$, defined on its maximal existence interval, then, Σ is said to be ISS if for all initial values $z_0 \in X$ and inputs $u \in \mathrm{L}^\infty_{\mathrm{loc}}(0,\infty;U)$ there exists a unique global (i.e $T = \infty$) state trajectory and for all $t \in [0,\infty)$,

$$\|z(t)\|_X \leq \beta(\|z_0\|,t) + \gamma(\|u\|_{\mathrm{L}^\infty(0,t;U)}),$$

for some functions $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}$ where the Lyapunov classes $\mathcal{K}$ and $\mathcal{KL}$ are given by

$$\mathcal{K} = \left\{\gamma \in C(\mathbb{R}_0^+;\mathbb{R}_0^+) \,\middle|\, \gamma \text{ is strictly increasing, } \gamma(0) = 0\right\}$$

$$\mathcal{KL} = \left\{ \beta \in C(\mathbb{R}_0^+ \times \mathbb{R}_0^+;\mathbb{R}_0^+) \,\middle|\, \begin{array}{c} \beta(\cdot,t) \in \mathcal{K} \ \forall t \geq 0 \text{ and} \\ \beta(s,\cdot) \text{ is strictly} \\ \text{decreasing to } 0 \ \forall s > 0 \end{array} \right\}.$$

The Banach spaces X and U with norms $\|\cdot\|_X$ and $\|\cdot\|_U$ are called the *state space* and *input space* of Σ.
Often one would like to consider a larger class of inputs than $\mathrm{L}^\infty_{\mathrm{loc}}$. For this reason we consider the following adoption which is referred to as L^2-ISS

$$\|z(t)\|_X \leq \beta(\|z_0\|,t) + \gamma(\|u\|_{\mathrm{L}^2(0,t;U)}),$$

with β and γ as before.

In this work abstract we investigate L^2-ISS of unbounded bilinear feedback systems

$$\begin{cases} \dot{z}(t) = Az(t) + B_1u_1(t) + B_2N(z(t),y(t)), \\ y(t) = Cz(t), \end{cases} \tag{1}$$

where A is the generator of a C_0-semigroup and B_i, $i = 1,2$, and C are possibly unbounded operators. The precise setting is introduced in Section 2.
For the simple case of linear systems

$$\dot{z}(t) = Az(t) + Bu(t)$$

where $B \in \mathcal{L}(U,X)$, i.e. B is bounded from U to X, L^2-ISS is equivalent to uniform exponential stability of the semigroup. For unbounded B, which appears naturally when considering boundary control, L^2-ISS becomes non-trivial. Indeed, it is related to L^2-admissibility of the control operator B, see e.g. Jacob et al. (2018).

We refer to Karafyllis and Krstic (2019); Mironchenko and Prieur (2020); Schwenninger (2020) for an overview on ISS for infinite-dimensional systems and to Sontag (2008) for a survey on ISS for ODEs. Recent results for infinite-dimensional systems can be found in Dashkovskiy and Mironchenko (2013a,b); Guiver et al. (2019); Jayawardhana et al. (2008); Mironchenko and Wirth (2018) and in Jacob et al. (2019); Karafyllis and Krstic (2017); Mazenc and Prieur (2011); Mironchenko and Ito (2015); Mironchenko et al. (2019); Zheng and Zhu (2018) for (semi-)linear systems with a slight focus on the parabolic case.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

The results from Mironchenko and Ito (2016) on ISS for bounded bilinear control systems has been generalized in Hosfeld et al. (2022) to unbounded bilinear control systems of the form

$$\dot{z}(t) = Az(t) + B_1u_1(t) + B_2N(z(t), u_2(t))$$

with unbounded operators B_1, B_2 and suitable boundedness and Lipschitz assumptions on the non-linearity N. The question of ISS becomes more delicate as soon as a feedback law $u_2 = y = Cz$ is present which turns the above system into (1). Even the question of well-posedness of such systems is far from being evident. A local in time well-posedness result for (1) can be found in Tucsnak and Weiss (2014). This is insufficient for our considerations since global in time well-posedness is a necessity for ISS.

This work is structured in the following way. In Section 2 we formalize the setting of a bilinear feedback system. Afterwards we recall the concept of well-posedness of linear systems in order to state the solution concept of the bilinear feedback system. We close the section with an existence and uniqueness result for the solution of the bilinear feedback system with small input data. In Section 3 an ISS result on the bilinear feedback system for certain parabolic and hyperbolic systems is given which we apply in Section 4 to a Burgers equation.

2. A BILINEAR FEEDBACK SYSTEM

Let X, U_1, U_2, Y be Banach spaces. We now consider the unbounded bilinear feedback system of the form

$$\begin{cases} \dot{z}(t) &= Az(t) + B_1u_1 + B_2N(z(t), y(t)),\ t \geq 0, \\ z(0) &= z_0, \\ y(t) &= Cz(t),\ t \geq 0, \end{cases} \tag{Σ^N}$$

where

- A generates a C_0-semigroup $(T(t))_{t\geq 0}$ on X,
- $B_1 \in \mathcal{L}(U_1, X_{-1})$, $B_2 \in \mathcal{L}(U_2, X_{-1})$ are the (unbounded) *control operators*,
- $C \in \mathcal{L}(X_1, Y)$ is the (unbounded) *observation operator*,
- $Y \subseteq X$ with continuous embedding and C has an extension $C \in \mathcal{L}(X)$,
- $N : X \times Y \to U_2$ is a continuous bilinear mapping which satisfies for some $K > 0$, $p \in (0, 1)$ and all $x \in X$, $y \in Y$

$$\|N(z, y)\|_{U_2} \leq K\|z\|_X\|y\|_X^{1-p}\|y\|_Y^p. \tag{2}$$

The spaces X, U_1, U_2 and Y are referred as the *state space* (X), the *input spaces* (U_1, U_2) and the *output space* (Y). By X_1 and X_{-1} we denote the standard inter- and extrapolation spaces associated to the generator A. That is, X_1 is $D(A)$, the domain of A, equipped with the graph norm and X_{-1} is the completion of X with respect to the norm

$$\|x\|_{X_{-1}} = \|(\beta - A)^{-1}x\|_X$$

for some $\beta \in \rho(A)$, the resolvent set of A. We have the continuous and dense embeddings $X_1 \hookrightarrow X \hookrightarrow X_{-1}$. Furthermore, $(T(t))_{t\geq 0}$ extends uniquely to a C_0-semigroup $(T_{-1}(t))_{t\geq 0}$ on X_{-1} whose generator, denoted by A_{-1}, is an extension of A with domain $D(A_{-1}) = X$. By $\omega_0((T(t))_{t\geq 0})$ we denote the the growth bound of the semigroup $(T(t))_{t\geq 0}$. The semigroup $(T(t))_{t\geq 0}$ is exponentially stable if $\omega_0((T(t))_{t\geq 0}) < 0$, i.e. there exist $M, \omega_0 > 0$ such that

$$\|T(t)\|_X \leq M\,\mathrm{e}^{-\omega_0 t} \quad \text{for all } t \geq 0. \tag{3}$$

Next we recall the definition and standard facts on well-posedness (in the L^2-sense, see e.g. Tucsnak and Weiss (2014); Weiss (1989a,b); Curtain and Weiss (1989)) of the to Σ^N associated linear systems

$$\begin{cases} \dot{x}(t) &= Ax(t) + B_1u_1(t) + B_2u_2(t),\ t \geq 0, \\ x(0) &= x_0, \\ y(t) &= Cx(t),\ t \geq 0 \end{cases} \tag{Σ_{lin}}$$

with spaces and operators as before. For simplicity we understand $\mathrm{L}^2(0, t; U)$ as a subspace of $\mathrm{L}^2(0, \infty; U)$ with the usual conventions of truncating and extending functions by zero. The linear system Σ_{lin} is *well-posed*, if

(i) A generates a C_0-semigroup $(T(t))_{t\geq 0}$ on X;

(ii) B_i, $i = 1, 2$, are L^2-*admissible control operators*, i.e. for some (and hence for all) $t > 0$ it holds that the *input maps* $\Phi_t^i \in \mathcal{L}(\mathrm{L}^2(0, t; U_i), X)$, where

$$\Phi_t^i u_i := \int_0^t T_{-1}(t - s)B_iu_i(s)\,\mathrm{d}s, \quad u_i \in \mathrm{L}^2(0, t; U_i);$$

(iii) C is an L^2-*admissible observation operator*, i.e. for some (and hence for all) $t > 0$ it holds that the *output maps* $\Psi_t \in \mathcal{L}(X, \mathrm{L}^2(0, t; Y))$, where Ψ_t is the extension of

$$\Psi_t x = CT(\cdot)x, \quad x \in D(A);$$

(iv) Some (and hence any) function $G_i : \mathbb{C}_{\omega_0((T(t))_{t\geq 0})} \to \mathcal{L}(U_i, Y)$, $i = 1, 2$, satisfying

$$G_i(\alpha) - G_i(\beta) = C[(\alpha - A_{-1})^{-1} - (\beta - A_{-1})^{-1}]B_i$$

is bounded on some right half-plane $\mathbb{C}_\gamma = \{\lambda \in \mathbb{C} \mid \mathrm{Re}\,\lambda > \gamma\}$.

The functions G_i, $i = 1, 2$ are called the *transfer functions* associated to the triples (A, B_i, C), $i = 1, 2$ and they are unique up to a constant operator. Given such a transfer function, we can define the so called *input output maps* $\mathbb{F}_t^i : \mathrm{L}^2(0, t; U_i) \to \mathrm{L}^2(0, t; Y)$, which are given by

$$\begin{aligned}(\mathbb{F}_t^i u_i)(\cdot) = C\left[\int_0^\cdot T_{-1}(\cdot - s)B_iu_i(s)\,\mathrm{d}s - (\alpha - A)^{-1}B_iu_i(\cdot)\right] \\ + G_i(\alpha)u_i(\cdot),\end{aligned}$$

where $u_i \in W_0^{1,2}(0, t; U_i)$ (dense in $\mathrm{L}^2(0, t; U_i)$) and $\mathrm{Re}\,\alpha$ large enough. To see that $\mathbb{F}_t^i$ is well-defined we refer to Curtain and Weiss (1989).

The functions $z \in C([0, \infty); X)$ and $y \in \mathrm{L}^2_{\mathrm{loc}}(0, \infty; Y)$ are called the *solution* (or *state trajectory*) and the *output function* (or *output*) of Σ_{lin} with input data $z_0 \in X$ and $u_i \in \mathrm{L}^2(0, \infty; U_i)$, $i = 1, 2$, if they satisfy

$$\begin{aligned} z(t) &= T(t)z_0 + \Phi_t^1u_1 + \Phi_t^2u_2, \\ y_{|_{[0,t]}} &= \Psi_t z_0 + \mathbb{F}_t^1u_1 + \mathbb{F}_t^2u_2. \end{aligned}$$

In particular z satisfies the integrated version of the differential equation in Σ_{lin}. From the above formula it follows immediately that a well-posed linear system admits a unique solution z and and output y for all $z_0 \in X$ and $u_i \in \mathrm{L}^2(0, \infty; U_i)$ and for $t \geq 0$ there exist positive constants $k_{1,t}$ and $k_{2,t}$ such that

$$\begin{aligned} \|z(t)\|_X &\leq k_{1,t}(\|z_0\|_X + \|u_1\|_{\mathrm{L}^2(0,t;U_1)} + \|u_2\|_{\mathrm{L}^2(0,t;U_2)}), \\ \|y\|_{\mathrm{L}^2(0,t;Y)} &\leq k_{2,t}(\|z_0\|_X + \|u_1\|_{\mathrm{L}^2(0,t;U_1)} + \|u_2\|_{\mathrm{L}^2(0,t;U_2)}). \end{aligned} \tag{4}$$

If A generates an exponential stable semigroup, then $k_{1,t}$ and $k_{2,t}$ can be chosen independent of t, see e.g. Weiss (1989b,a); Curtain and Weiss (1989).

Definition 1. Let Σ_{lin} be well-posed. The functions $z \in C([0,\infty);X)$ and $y \in \mathrm{L}^2_{\text{loc}}(0,\infty;Y)$ are called the *solution* and *output* of Σ^N with input data $z_0 \in X$ and $u_1 \in \mathrm{L}^2(0,\infty;U_1)$ if they satisfy

$$z(t) = T(t)z_0 + \Phi^1_t u_1 + \Phi^2_t N(z,y),$$
$$y_{|_{[0,t]}} = \Psi_t z_0 + \mathbb{F}^1_t u_1 + \mathbb{F}^2_t N(z,y).$$

Theorem 2. Let A be the generator of the exponentially stable semigroup $(T(t))_{t\geq 0}$ and choose $M, \omega_0 > 0$ according to (3). If Σ_{lin} is well-posed then for every $\omega \in (0,\omega_0)$ there exists a constant $\varepsilon > 0$ such that for all input data $z_0 \in X$ and $u_1 \in \mathrm{L}^2(0,\infty;U_1)$ with

$$\|z_0\|_X + \|\mathrm{e}^{\omega\cdot}\, u_1\|_{\mathrm{L}^2(0,\infty;U_1)} \leq \varepsilon \tag{5}$$

it holds that Σ^N admits a unique solution $z \in C([0,\infty);X)$ and an output $y \in \mathrm{L}^2(0,\infty;Y)$. Furthermore, there exists a constant $k_1 > 0$ such that

$$\|z(t)\|_X \leq 2k_1\varepsilon\, \mathrm{e}^{-\omega t}\,. \tag{6}$$

3. ISS-ESTIMATES FOR A SPECIAL CLASS OF UNBOUNDED BILINEAR FEEDBACK SYSTEMS

Throughout this section we assume X, U_1, U_2, Y to be Hilbert spaces.

Definition 3. System Σ^N is called L^2-ISS with respect to a non-empty subset $\mathcal{S} \subseteq X \times \mathrm{L}^2(0,\infty;U_1)$ if Σ^N admits for all input data $(z_0,u_1) \in \mathcal{S}$ a unique solution $z \in C([0,\infty);X)$ which satisfies

$$\|z(t)\|_X \leq \beta(\|z_0\|_X, t) + \gamma(\|u_1\|_{\mathrm{L}^2(0,t;U_1)})$$

for all $t \geq 0$ and some functions $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}$.
If $\mathcal{S} = \{(z_0,u_1) \in X \times \mathrm{L}^2(0,\infty;U_1) \mid z_0, u_1 \text{ satisfy (5)}\}$ for some $\varepsilon > 0$ then Σ^N is called L^2-ISS for small input data (independent of $\varepsilon > 0$).

Recall that an operator A on X is called strictly dissipative if there exists a constant $w_A < 0$ such that

$$\operatorname{Re}\langle Az, z\rangle_X \leq w_A\|z\|^2_X \quad \text{for all } x \in D(A). \tag{7}$$

Additionally, if $\langle Az,z\rangle_X \in \mathbb{R}$ for all $z \in D(A)$, then A is called strictly negative.
We consider the following two assumptions:

Assumption 1. The operator A is selfadjoint and strictly negative, $B_i \in \mathcal{L}(U_i, X_{-\frac{1}{2}})$ and $C \in \mathcal{L}(X_{\frac{1}{2}}, Y)$, where the spaces $X_{\frac{1}{2}}$ and $X_{-\frac{1}{2}}$ are introduced below.

Assumption 2. The operator A is of the form $A = A_0 + K$, where A_0 is skew-adjoint and $K \in \mathcal{L}(X)$ is strictly dissipative, $B_i \in \mathcal{L}(U_i, X)$, $i = 1,2$ and $C \in \mathcal{L}(X,Y)$.

Remark 4. Under Assumption 2, A is the strictly dissipative generator of an exponentially stable semigroup and one could choose $w_A = w_K$, where w_A and w_K are the (negative) constants according to (7).

If A is a selfadjoint and strictly dissipative operator on X then it follows from Engel and Nagel (2000), Chapter II, Corollary 4.7 & Chapter IV, Corollary 3.12 and the fact that $\sigma(A) \subset (-\infty, w_A]$ that A is the generator of an exponentially stable analytic semigroup on X. One can define (c.f. Tucsnak and Weiss (2009), Section 3.4) the spaces $X_{\frac{1}{2}}$ as the completion of $D(A)$ with respect to the norm

$$\|z\|_{X_{\frac{1}{2}}} = \sqrt{\langle -Az, z\rangle_X}, \quad z \in D(A)$$

and $X_{-\frac{1}{2}}$ as its dual space with respect to the pivot space X. We have the continuous and dense embeddings

$$X_1 \hookrightarrow X_{\frac{1}{2}} \hookrightarrow X \hookrightarrow X_{-\frac{1}{2}} \hookrightarrow X_{-1}.$$

From the concept of dual spaces with respect to pivot space and the fact that A is selfadjoint we obtain a natural continuous dual pairing $\langle\cdot,\cdot\rangle_{X_{-\frac{1}{2}},X_{\frac{1}{2}}} : X_{-\frac{1}{2}} \times X_{\frac{1}{2}} \to \mathbb{C}$ which simplifies for $z \in X$ and $y \in X_{\frac{1}{2}}$ to

$$\langle z,y\rangle_{X_{-\frac{1}{2}},X_{\frac{1}{2}}} = \langle z,y\rangle_X\,.$$

Further, it is easy to see that $A_{-1} : X_{\frac{1}{2}} \to X_{-\frac{1}{2}}$ is isometric. This allows to extend (7) to

$$\langle A_{-1}z, z\rangle_{X_{-\frac{1}{2}},X_{\frac{1}{2}}} = -\|z\|_{X_{\frac{1}{2}}} \leq w_A\|z\|^2_X, \tag{8}$$

for every $z \in X_{\frac{1}{2}}$.

Remark 5. In order to obtain such a dual pairing it is crucial to have $D(A) = D(A^*)$.

Theorem 6. If Assumption 1 or Assumption 2 holds and for some $\delta > 0$ there exist $m_1, m_2 \in \mathbb{R}$ such that

$$1 - m_1 > 0, \quad (1-m_1)w_A + m_2 < 0$$

and

$$\operatorname{Re}\langle N(z,Cz), B_2^*z\rangle_{U_2} \leq -m_1 \operatorname{Re}\langle Az,z\rangle_X + m_2\|z\|^2_X \tag{9}$$

for all $z \in D(A)$ with $\|z\|_X \leq \delta$, then there exists $\varepsilon > 0$ such that Σ^N admits for all small input data $z_0 \in X$ and $u_1 \in \mathrm{L}^2(0,\infty;U_1)$ in the sense of (5) a unique solution z which satisfies

$$\|z(t)\|_X \leq \mathrm{e}^{-\omega t}\|z_0\|_X + c\|u_1\|_{\mathrm{L}^2(0,t;U_1)} \tag{10}$$

for all $t \geq 0$ and some constants $\omega, c > 0$. In particular Σ^N is L^2-ISS for small input data.

4. EXAMPLE: BURGERS EQUATION

Consider the following controlled version of the Burgers equation

$$\begin{cases} \dot z(t,x) = z_{xx}(t,x) - zz_x(t,x) + u_1(t), & t > 0,\ x \in (0,1) \\ z(t,0) = z(t,1) = 0, & t \geq 0, \\ z(0,x) = z_0(x), & x \in [0,1], \\ y(t,x) = z(t,x), & t \geq 0,\ x \in [0,1]. \end{cases}$$

Let the state, input and output spaces be given as in Tucsnak and Weiss (2014), i.e.

$$X = \mathrm{H}^1_0(0,1),$$
$$U_1 = U_2 = \mathrm{L}^2(0,1),$$
$$Y = \mathrm{H}^2(0,1) \cap \mathrm{H}^1_0(0,1),$$

where all spaces are assumed to be real valued. We equip $\mathrm{H}^1_0(0,1)$ with the norm

$$\|z\|_{\mathrm{H}^1_0} = \|z_x\|_{\mathrm{L}^2}.$$

which is equivalent to the standard norm on $\mathrm{H}^1_0(0,1)$ by the Poincaré inequality.
Let the operator A on X be defined by

$$A\varphi = \varphi_{xx}, \quad D(A) = \{\varphi \in \mathrm{H}^3(0,1) \mid \varphi, \varphi_{xx} \in \mathrm{H}^1_0(0,1)\}.$$

It is known that A is a selfadjoint and strictly dissipative and hence the generator of an exponentially stable analytic semigroup.

Note that (see Tucsnak and Weiss (2014) and the references therein)

$$X_{\frac{1}{2}} = \mathrm{H}^2(0,1) \cap \mathrm{H}_0^1(0,1) \quad \text{and} \quad X_{-\frac{1}{2}} = \mathrm{L}^2(0,1).$$

Further, we consider the operators $B_i \in \mathcal{L}(U_i, X_{-\frac{1}{2}})$, $i = 1, 2$ and $C \in \mathcal{L}(X_{\frac{1}{2}}, Y)$ to be the identity on the respective spaces. The bilinear feedback law is defined by

$$N : X \times Y \to U_2, \quad N(z, y) = -zy_x.$$

The validity of (2) for any $p \in (0, 1)$ is not difficult to check and can also be found in Tucsnak and Weiss (2014).

Theorem 7. The Burgers equation (4), with the above spaces and operators, is a bilinear feedback system of the form Σ^N which is L^2-ISS for small input data $z_0 \in \mathrm{H}_0^1(0,1)$ and $u_1 \in \mathrm{L}^2(0, \infty; \mathrm{L}^2(0,1))$.

A deterministic least squares approach for simultaneous input and state estimation ⋆

Grigorios Gakis * **Malcolm C. Smith** *

* *Department of Engineering, University of Cambridge, UK, (e-mail: gg402@cam.ac.uk and mcs@eng.cam.ac.uk).*

Abstract: This paper considers a deterministic estimation problem to find the input and state of a linear dynamical system which minimise a weighted integral squared error between the resulting output and the measured output. A completion of squares approach is used to find the unique optimum in terms of the solution of a Riccati differential equation. The optimal estimate is obtained from a two-stage procedure that is reminiscent of the Kalman filter. The first stage is an end-of-interval estimator for the finite horizon which may be solved in real time as the horizon length increases. The second stage computes the unique optimum over a fixed horizon by a backwards integration over the horizon. A related tracking problem is solved in an analogous manner. Making use of the solution to both the estimation and tracking problems a constrained estimation problem is solved which shows that the Riccati equation solution has a least squares interpretation that is analogous to the meaning of the covariance matrix in stochastic filtering. The paper shows that the estimation and tracking problems considered here include the Kalman filter and the linear quadratic regulator as special cases.

Keywords: Input and state estimation, least squares optimisation, Kalman filtering, optimal trajectory tracking.

1. INTRODUCTION

Our goal in this paper is to pose and solve a filtering/estimation problem for the simultaneous estimation of inputs and states in a continuous time linear finite dimensional dynamical system. The problem set-up is illustrated in Fig. 1. A model of the physical system is assumed to be available. The output of the dynamical system is the vector z of *all* variables that are measured (e.g. by means of sensors). The measurement of this output in an experiment is denoted by $\tilde{z}$. The filter should make use only of these measured outputs for the estimation and should produce the best estimate of the system variables treating the exogenous inputs and states on an equal footing. The meaning of "best" is to minimise a weighted integral squared error between output z and measured output $\tilde{z}$. The filtered signals $w_1(t), x_1(t)$ provide best estimates of w and x at a given time instant t based on measurements up to that time, while the estimates $\hat{w}(t), \hat{x}(t)$ provide the best estimates over a time interval $[0, T]$.

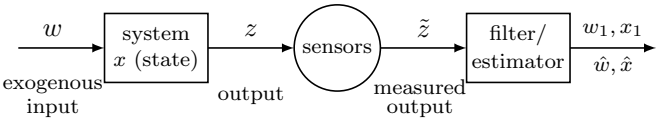

Fig. 1. Estimation problem for a dynamical system with state x, exogenous input w and output z which is measured.

Our solution to the problem of Fig. 1 is based on the method of completion of squares and builds on the work of Willems (2004) which gave a deterministic derivation of the filter of Kalman and Bucy (1961). The structure of the solution is reminiscent of the standard (causal) Kalman filter and the non-causal process of smoothing, though the solution to the present problem has a more general structure through placing the estimation of state and exogenous input on an equal footing, and without prior assumption on the nature of the exogenous input. An important further contribution of the paper is to provide a deterministic interpretation of the solutions of the resulting matrix Riccati differential equations (which correspond to the covariance matrices in the standard Kalman filter). We note that the simpler version of the question of providing such a deterministic interpretation for the standard Kalman filter has not been addressed in the literature so far.

Proofs are contained in a full version of this paper (see Gakis and Smith (2022)) and are omitted from this extended abstract.

2. ESTIMATION PROBLEM

Consider the linear, finite-dimensional, continuous time system with the state space description:

$$\dot{x} = Ax + Bw, \tag{1}$$

$$z = Cx + Dw \tag{2}$$

where $A \in \mathbb{R}^{n\times n}, B \in \mathbb{R}^{n\times m}, C \in \mathbb{R}^{p\times n}$ and $D \in \mathbb{R}^{p\times m}$ (full column rank) are fixed known matrices [1] and $w \in \mathcal{L}^m_{2,e}$, $x \in \mathcal{L}^n_{2,e}$ and $z \in \mathcal{L}^p_{2,e}$ are input, state and output related through this linear system. We consider the

⋆ The first author would like to acknowledge McLaren Automotive ltd for a CASE studentship awarded for doctorate research.

[1] The assumption that the system matrices are constant is for notational convenience. We note that all results are valid if the system matrices A, B, C, D are time-varying, with no change required in the proofs.

problem to estimate w and x from the measurement of the signal z, which is the same as estimating w and $x(0)$ since x is generated by (1). We assume that the state x and driving input w are not measured directly, other than (indirectly) through the measurement of z (i.e. all measurements of the system are made through the output vector z). Each element of z may correspond to an individual sensor or multiple entries of z may be generated by a single device. We will denote by $\tilde{z}$ the actual measured output signal in an experiment (see Fig. 1). We introduce the performance index:

$$C_T(w, x(0)) = \int_0^T \|\tilde{z}(t) - z(t)\|^2_{R^{-1}} dt + \|x(0) - \gamma\|^2_{\Gamma^{-1}} \tag{3}$$

where $0 < R \in \mathbb{R}^{p\times p}$, $0 < \Gamma \in \mathbb{R}^{n\times n}$, $\gamma \in \mathbb{R}^n$, $0 < T \in \mathbb{R}$ are specified. The second term on the RHS of (3) plays the role of a penalty on the deviation of the initial state from an assumed value γ. The problem we wish to solve is:

$$\inf_{w,x(0)} C_T(w, x(0)) \tag{4}$$

subject to (1) and (2). In particular we wish to compute the optimal w and $x(0)$ which we will denote by $\hat{w}$ and $\hat{x}(0)$. Using a "completion of squares" construction for the performance index (3) we can show that (4) has a unique solution (Theorem 1). First consider the system:

$$\dot{x}_1 = (A_1 - K_1C_1)x_1 + (B_1 + K_1)\tilde{z}, \tag{5}$$
$$\dot{P}_1 = A_1P_1 + P_1A_1^T - K_1RK_1^T + B_1RB_1^T, \tag{6}$$
$$K_1 = P_1C_1^TR^{-1}, \tag{7}$$
$$w_1 = D^\dagger(\tilde{z} - z_1), \tag{8}$$
$$z_1 = Cx_1 \tag{9}$$

with the initial conditions $P_1(0) = \Gamma$ and $x_1(0) = \gamma$, where we have defined:

$$A_1 = A - B_1C, \tag{10}$$
$$B_1 = BD^\dagger, \tag{11}$$
$$C_1 = (\mathrm{I} - \Pi)C, \tag{12}$$
$$\Pi = DD^\dagger, \tag{13}$$
$$D^\dagger = (D^TR^{-1}D)^{-1}D^TR^{-1}. \tag{14}$$

Then the RDE (6) has a unique positive definite solution $P_1(t) > 0$ for all $t \in [0, T]$.

Theorem 1. The optimisation problem in (4) has a unique solution $\hat{w}$, $\hat{x}(0)$ which is obtained as follows: first integrate (5)–(7) forwards in time in the interval $0 \le t \le T$ with initial conditions $P_1(0) = \Gamma$ and $x_1(0) = \gamma$; then integrate:

$$\dot{\hat{x}} = A_2\hat{x} + B_2\tilde{z}_2 \tag{15}$$

backwards in time with terminal condition:

$$\hat{x}(T) = x_1(T) \tag{16}$$

to compute $\hat{x}(0)$ (and indeed $\hat{x}$); and lastly set:

$$\hat{w} = D^\dagger(\tilde{z}_2 - C_2\hat{x}) \tag{17}$$

where:

$$A_2 = A - B_2C_2, \tag{18}$$
$$B_2 = B_1, \tag{19}$$
$$C_2 = C - RB_1^TP_1^{-1}, \tag{20}$$
$$\tilde{z}_2 = \tilde{z} - RB_1^TP_1^{-1}x_1. \tag{21}$$

Furthermore, the minimum of the performance index (3) is:

$$\inf_{w,x(0)} C_T(w, x(0)) = \int_0^T \|(\mathrm{I} - \Pi)(\tilde{z}(t) - z_1(t))\|^2_{R^{-1}} dt$$
$$= \int_0^T \|\tilde{z}(t) - \hat{z}(t)\|^2_{R^{-1}} dt + \|\hat{x}(0) - \gamma\|^2_{\Gamma^{-1}} \tag{22}$$

where we have denoted the optimal output by:

$$\hat{z} = C\hat{x} + D\hat{w}. \tag{23}$$

3. TRACKING PROBLEM

In this section we will consider a related tracking problem. Assume the state q and input u satisfy:

$$\dot{q} = Fq + Gu, \tag{24}$$
$$y = Hq + Ju \tag{25}$$

where $F \in \mathbb{R}^{n\times n}, G \in \mathbb{R}^{n\times m}, H \in \mathbb{R}^{p\times n}$ and $J \in \mathbb{R}^{p\times m}$ (full column rank) are fixed known matrices and $u \in \mathcal{L}^m_{2,e}$, $q \in \mathcal{L}^n_{2,e}$ and $y \in \mathcal{L}^p_{2,e}$ are input, state and output related through this linear system. We wish to find an input u such that the output y best tracks a desired signal $\tilde{y} \in \mathcal{L}^p_{2,e}$ over a finite horizon T together with a penalty on the deviation of the terminal state from a desired state ξ for a given but arbitrary initial state η. More precisely, we introduce the performance index:

$$W_T(u) = \int_0^T \|\tilde{y}(t) - y(t)\|^2_{R^{-1}} dt + \|q(T) - \xi\|^2_{\Xi^{-1}} \tag{26}$$

where $\xi \in \mathbb{R}^n$, $0 < \Xi \in \mathbb{R}^{n\times n}$ and propose the problem:

$$\inf_u W_T(u) \tag{27}$$

subject to (24), (25) and $q(0) = \eta$. We denote the optimal solution to (27) by $\hat{u}$. Similarly to Section 2 a completion of squares construction is used to solve (27) in Theorem 2. We first consider the system:

$$\dot{q}_1 = (F_1 + M_1H_1)q_1 + (G_1 - M_1)\tilde{y}, \tag{28}$$
$$\dot{S}_1 = F_1S_1 + S_1F_1^T + M_1RM_1^T - G_1RG_1^T, \tag{29}$$
$$M_1 = S_1H_1^TR^{-1}, \tag{30}$$
$$u_1 = J^\dagger(\tilde{y} - y_1), \tag{31}$$
$$y_1 = Hq_1 \tag{32}$$

with the terminal conditions $S_1(T) = \Xi$ and $q_1(T) = \xi$, where we have defined the matrices:

$$F_1 = F - G_1H, \tag{33}$$
$$G_1 = GJ^\dagger, \tag{34}$$
$$H_1 = (\mathrm{I} - \Lambda)H, \tag{35}$$
$$\Lambda = JJ^\dagger, \tag{36}$$
$$J^\dagger = (J^TR^{-1}J)^{-1}J^TR^{-1}. \tag{37}$$

Then the RDE (29) has a unique positive definite solution $S_1(t) > 0$ for all $t \in [0, T]$.

Theorem 2. The optimisation problem in (27) has a unique solution $\hat{u}$ which is obtained as follows: first integrate (28)–(30) backwards in time with terminal conditions $S_1(T) = \Xi$ and $q_1(T) = \xi$; then integrate:

$$\dot{\hat{q}} = F\hat{q} + G\hat{u} \tag{38}$$

forwards in time with $\hat{u}$ given by the feedback law:

$$\hat{u} = J^\dagger(\tilde{y}_2 - H_2\hat{q}) \tag{39}$$

and initial condition $\hat{q}(0) = \eta$, where we have defined:

$$H_2 = H + RG_1^TS_1^{-1}, \tag{40}$$
$$\tilde{y}_2 = \tilde{y} + RG_1^TS_1^{-1}q_1. \tag{41}$$

Furthermore, the minimum of the performance index (26) is:

$$\inf_u W_T(u) = \int_0^T \|(\mathrm{I}-\Lambda)(\tilde{y}(t)-y_1(t))\|^2_{R^{-1}}dt + \|\eta - q_1(0)\|^2_{S_1(0)^{-1}}. \quad (42)$$

4. CONSTRAINED ESTIMATION PROBLEM

We now turn our attention to the constrained optimisation problem:

$$\inf_{w,x(0)} C_T(w,x(0)) \text{ subject to } x(\tau)=\zeta \quad (43)$$

for $\zeta \in \mathbb{R}^n$ and $0 \le \tau \le T$ where (1) and (2) hold. Here $C_T(w,x(0))$ is defined as in (3) with the same meaning for $\tilde{z}$, γ and Γ. Again we wish to compute the optimal w and $x(0)$ which we will denote by $\hat{w}$ and $\hat{x}(0)$. A solution of this optimisation problem will show how the optimal cost increases compared to the unconstrained value when we demand that the state passes through a prescribed point at a given time. This will give an indication in a least squares sense of how "likely" it is that the state passes through the optimum point for the unconstrained problem. For example, if there is a sharp rise in the cost when the state is required to pass through a different point, then we may have more confidence in the value of the unconstrained optimum state at that time. We first consider the system:

$$\dot{x}_2 = A_2x_2 + B_2\tilde{z}_2, \quad (44)$$

$$\dot{P}_2 = A_2P_2 + P_2A_2^T - B_2RB_2^T, \quad (45)$$

$$w_2 = D^\dagger(\tilde{z}_2 - C_2x_2). \quad (46)$$

Theorem 3. The optimisation problem (43) has a unique solution $\hat{w}$, $\hat{x}(0)$ which is obtained as follows: first integrate (5)–(7) forwards in time in the interval $0 \le t \le T$ with initial conditions $P_1(0)=\Gamma$ and $x_1(0)=\gamma$ which gives x_1 and P_1 in the interval $0 \le t \le T$; then integrate (44)–(46) backwards in time in the interval $\tau \le t \le T$ with terminal conditions $P_2(T)=P_1(T)$ and $x_2(T)=x_1(T)$ which gives x_2 and P_2 in the interval $\tau \le t \le T$; then integrate:

$$\dot{\hat{x}} = A\hat{x} + B\hat{w} \quad (47)$$

backwards in time in the interval $0 \le t \le \tau$ with the feedback law:

$$\hat{w} = D^\dagger(\tilde{z}_2 - C_2\hat{x}); \quad (48)$$

and the terminal condition $x(\tau)=\zeta$ to find $\hat{x}$, $\hat{w}$ in the interval $0 \le t \le \tau$; then integrate (47) forwards in time in the interval $\tau \le t \le T$ with the feedback law:

$$\hat{w} = D^\dagger(\tilde{z}_3 - C_3\hat{x}) \quad (49)$$

and the initial condition $x(\tau)=\zeta$ to find $\hat{x}$, $\hat{w}$ in the interval $\tau \le t \le T$. The minimum of the performance index is:

$$\int_0^T \|(\mathrm{I}-\Pi)(\tilde{z}(t)-z_1(t))\|^2_{R^{-1}}dt + \|\zeta - x_2(\tau)\|^2_{P_2^{-1}(\tau)}. \quad (50)$$

The solution to the constrained optimisation problem (43) given in Theorem 3 introduced the vector and matrix variables x_2, w_2 and P_2. We recall that x_2 and w_2 coincide with the state and input trajectories on the interval $[0,T]$ that minimise the performance criterion (3) as shown in Theorem 1. We may now provide an interpretation of the matrix variable P_2. In Theorem 3 it is shown that the unique minimum of (43) takes the same form as the first expression on the right hand side of (22) but with an additional quadratic term which is zero when $\zeta = x_2(\tau)$, in which case we recover the results of Theorem 1. Consider now the eigenvector-eigenvalue decomposition of $P_2(\tau)$. Components of $\zeta - x_2(\tau)$ in those eigenvector directions of $P_2(\tau)$ which have small eigenvalues (i.e. large eigenvalues of $P_2^{-1}(\tau)$) give a large contribution to the second term in (50). Hence the measurements provide high confidence that the state $x(\tau)$ should be close to $x_2(\tau)$ in those directions. Fig. 2 illustrates the interpretation of $P_2(\tau)$ in the 2-D case. The figure shows an ellipse with centre $x_2(\tau)$ whose axes are aligned with the eigenvectors of $P_2(\tau)$ and lengths given by the corresponding eigenvalue square roots. All points on the ellipse increase the minimum performance index (50) by 1.

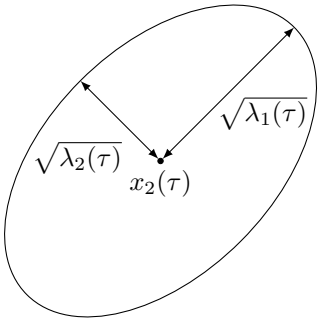

Fig. 2. An ellipse with semi-axes of length given by the eigenvalue square roots of $P_2(\tau)$, $\sqrt{\lambda_1(\tau)}$ and $\sqrt{\lambda_2(\tau)}$, and aligned with the corresponding eigenvectors.

5. SPECIAL CASES

5.1 Standard Kalman filter

We now show how the continuous time Kalman filter can be derived as a special case of the filter in Theorems 1. We therefore consider a system described by:

$$\dot{x} = Ax + Bw \quad (51)$$

$$z = Cx \quad (52)$$

with noisy measurement $\tilde{z}$ of z. Note that we assume as standard that sensor measurements of the state are not directly affected by the process noise w. In the standard Kalman filter the process noise w can be interpreted as a small magnitude disturbance to the system. To translate into our framework we need to incorporate a weighted 2-norm constraint on w in the performance index (3). In particular, we consider the following optimisation problem:

$$\inf_{w,x(0)} \left(\int_0^T \|\tilde{z}(t)-z(t)\|^2_{R^{-1}}dt + \int_0^T \|w\|^2_{Q^{-1}}dt + \|x(0)-\gamma\|^2_{\Gamma^{-1}} \right). \quad (53)$$

To translate this into the framework of this paper we introduce a virtual measurement of w which is equal to zero. More precisely, we consider an augmented system with (real and virtual) outputs given by:

$$z_a = \begin{bmatrix} C \\ 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ \mathrm{I} \end{bmatrix} w \quad (54)$$

and for which we have the measurement:

$$\tilde{z}_a = \begin{bmatrix} \tilde{z} \\ 0 \end{bmatrix}. \tag{55}$$

We define an augmented block diagonal weighting matrix R_a given by:

$$R_a = \begin{bmatrix} R & 0 \\ 0 & Q \end{bmatrix}. \tag{56}$$

The following result is obtained by applying Theorem 1 to this augmented system.

Theorem 4. Consider the system:

$$\dot{x}_1 = Ax_1 + K(\tilde{z} - Cx_1), \tag{57}$$

$$\dot{P}_1 = AP_1 + P_1A^T - KRK^T + BQB^T, \tag{58}$$

$$K = P_1C^TR^{-1} \tag{59}$$

for $P_1(0) = \Gamma$ and $x_1(0) = \gamma$. The optimisation problem (53) where z is defined by (51)–(52) has a unique solution $\hat{w}$, $\hat{x}(0)$ where $\hat{w}$ is defined by the feedback law:

$$\hat{w} = QB^TP_1^{-1}(\hat{x} - x_1) \tag{60}$$

and $\hat{x}(t)$ is obtained by solving $\dot{\hat{x}} = A\hat{x} + B\hat{w}$ backwards on the interval $[0, T]$ with terminal condition $\hat{x}(T) = x_1(T)$. Furthermore, the optimal cost (53) is given by:

$$\int_0^T \|\tilde{z} - Cx_1\|^2_{R^{-1}} dt. \tag{61}$$

The filter (57)–(59) is an end-of-interval estimator in the sense that $\hat{x}(T) = x_1(T)$, $\hat{w}(T) = w_1(T)$ and takes the form of the standard Kalman filter with gain K. The above result reduces to that given in Willems (2004) with $R = \mathrm{I}$ and $Q = \mathrm{I}$.

It is interesting to note that by substituting for $\hat{w}$ from (60) we obtain an equation for the optimal state estimate:

$$\dot{\hat{x}} = A\hat{x} + BQB^TP_1^{-1}(\hat{x} - x_1) \tag{62}$$

where $\hat{x}(T) = x_1(T)$ that coincides with the standard form for the smoothed estimate in Kalman filtering (see Kailath and Frost (1968) eqn. 34(a)). Similarly by specialising (45) to the present case we have the equation:

$$\dot{P}_2 = (A + BQB^TP_1^{-1})P_2 + P_2(A + BQB^TP_1^{-1})^T - BQB^T \tag{63}$$

where $P_2(T) = P_1(T)$, which is the corresponding form for the smoothed covariance (see Kailath and Frost (1968) eqn. 34(b)).

5.2 Standard LQR on a finite time horizon

We now show how the solution of the standard linear quadratic regulator (LQR) on a finite time horizon can be derived as a special case of the tracking problem in Theorem 2. In the standard LQR we wish to find a low energy input u that brings the state q to the origin. More precisely, we consider the optimisation problem:

$$\inf_u \left(\int_0^T \|q(t)\|^2_{R_q^{-1}} + \|u(t)\|^2_{R_u^{-1}} dt + \|q(T)\|^2_{\Xi^{-1}} \right) \tag{64}$$

where the state q and input u satisfy:

$$\dot{q} = Fq + Gu \tag{65}$$

and the initial state $q(0) = \eta$ is known. To put this into the form required to apply Theorem 2 we choose:

$$y = \begin{bmatrix} \mathrm{I} \\ 0 \end{bmatrix} q + \begin{bmatrix} 0 \\ \mathrm{I} \end{bmatrix} u, \tag{66}$$

$\tilde{y} = 0$, $\xi = 0$ and:

$$R = \begin{bmatrix} R_q & 0 \\ 0 & R_u \end{bmatrix}. \tag{67}$$

Theorem 5. Consider the RDE:

$$\dot{S}_1 = FS_1 + S_1F^T + S_1R_q^{-1}S_1^T - GR_uG^T \tag{68}$$

with the terminal condition $S_1(T) = \Xi$. The optimisation problem (64) has a unique solution $\hat{u}$ which is defined by the feedback law:

$$\hat{u} = -R_uG^TS_1^{-1}\hat{q} \tag{69}$$

and $\hat{q}(t)$ is obtained by solving $\dot{\hat{q}} = F\hat{q} + G\hat{u}$ forwards in the interval $[0, T]$ with the initial condition $\hat{q}(0) = \eta$. Furthermore, the optimal cost (64) is:

$$\|\eta\|^2_{S_1(0)^{-1}}. \tag{70}$$

This is recognised as the classical LQR result on a finite time horizon.

6. CONCLUSIONS

The paper has proposed a framework for estimation in which the output of the dynamical system comprises *all* variables that are measured, and the variables to be estimated comprise, equally, system states and exogenous inputs. This framework is quite general in that if an exogenous input is measured then we may include a direct feedthrough component in the output vector to reflect this. This estimation problem was solved for linear systems with a full column rank feedthrough matrix. The unique optimum solution on a finite horizon takes a two-stage form in which the first stage provides an end-of-interval estimator which can be solved in real time as the horizon length increases. The full rank assumption is general enough to include the Kalman filter and, for the dual tracking problem, the linear quadratic regulator as special cases. Generalising the result to the case where this condition, or similar full rank assumptions on the Markov parameters, does not hold remains an open problem.

A contribution of this paper has been to provide an interpretation of the solution of the Riccati differential equation which is analogous to the meaning of the covariance matrix in stochastic filtering. The solution of a matrix Lyapunov differential equation $P_2(t)$ is shown to have an analogous interpretation to the smoothed covariance in the stochastic case. This has been achieved by considering the least-squares estimation problem with an additional constraint that the state passes through a prescribed point at a given time in the fixed horizon. To solve this problem a tracking problem was also considered which is dual to our estimation problem.

Abstract: We present a new variant of the McEliece cryptosystem that possesses several interesting properties, including a reduction of the public key for a given security level. In contrast to the classical McEliece cryptosystems, where block codes are used, we propose the use of a convolutional encoder to be part of the public key. The secret key is constituted by a Generalized Reed-Solomon code and two Laurent polynomial matrices that contain large parts that are generated completely at random. In this setting the message is a sequence of messages instead of a single block message and the errors are added randomly throughout the sequence. We analyse its security against ISD attacks in the first instants and when the whole message is transmitted, as well as against structural attacks.

Keywords: Convolutional codes, Generalized Reed-Solomon codes, McEliece Cryptosystem, Information Set Decoding.
AMS Subject Classification: 94A60, 94B10, 11T71.

1. INTRODUCTION

Code-based cryptosystems are considered promising alternatives for Public Key Cryptography (PKC) since their security relies on well-known NP-hard problems and allow fast encryption and decryption procedures. Moreover, they are immune to attacks that use Shor's algorithm and therefore are candidates for post-quantum cryptography. However, one of the main disadvantages of code-based schemes is the large keys whose size is inherently determined by the underlying Goppa block code used in the original cryptosystem. For this reason, there have been several attempts to substitute Goppa codes by other classes of block codes, e.g. Generalized Reed-Solomon (GRS) codes among many others. GRS codes are Maximum Distance Separable (MDS) codes which, in the McEliece scheme, translates into smaller key sizes. Hence, a major improvement would be achieved if these codes could be securely used in these cryptosystems. Unfortunately, due to their strong algebraic structure, they are vulnerable to many structural attacks. One recent interesting idea to remove this algebraic structure was to replace the permutation used in the original McEliece cryptosystem with a more general transformation (see Baldi et al. (2016)). However, this variant has also been fully broken using an attack based on the Schur square code distinguisher that permit to distinguish GRS codes from random ones in Couvreur et al. (2015) and Couvreur and Lequesne (2020).

We continue this line of research and explore a new variant that allows the use of GRS codes using a convolutional mask. In our scheme, the plaintext is not a block vector but a stream of smaller vectors sent in a sequential fashion. The public key is given by the polynomial convolutional encoder $G'(D) = S(D)GP(D^{-1}, D)$ where G is the generator matrix of a GRS, $S(D)$ a polynomial matrix and $P(D^{-1}, D)$ an invertible Laurent polynomial matrix. Hence, the proposed class of convolutional codes uses GRS codes and adds a convolutional layer to it in order to thwart the key recovery attack against GRS codes and at the same time admits a simple iterative algebraic decoding algorithm. This idea is different from the above ideas and therefore the cryptanalysis has to be adapted to this case.

The matrices $S(D)$ and $P(D^{-1}, D)$ are selected to protect against both ISD and structural attacks. A crucial fact to ensure security against ISD attacks to the first blocks and bootstrap from there, is that the truncated sliding matrices of the convolutional encoder are not full row rank and have distance equal to one, so recovering the initial blocks is not

possible. As for structural attacks, we build our matrix $P(D^{-1}, D)$ to provide weight-2 masking at every instant. As pointed out in Bolkema et al. (2017); Khathuria et al. (2018), (see also Khathuria et al. (2021)), the weight-two masking appears to be enough to remove any identifiable algebraic structure from the public code and therefore structural attacks, and in particular any distinguisher attack based on the Schur product, seems to fail as well. We note that our construction uses matrices with large parts generated completely at random and can be easily constructed. We present several examples for comparison with previous variants of the McEliece cryptosystem to illustrate the key size reduction of the public key achieved by this novel scheme.

2. A MCELIECE CRYPTOSYSTEM WITH A CONVOLUTIONAL ENCODER

For the purposes of this work we need to construct convolutional codes with certain properties that will allow the cryptosystem to work efficiently and resist cryptanalysis. The ingredients for building up our cryptosystem are the following: let F be a finite field with q elements, $G \in F^{k\times n}$ be an encoder of an (n, k) block code that admits an efficient decoding algorithm and can correct up to t errors,

$$S(D) = S_1 D + S_2 D^2 \in F^{k\times k}[D] \tag{1}$$

where $S_1 \in F^{k\times k}$ is an invertible constant matrix and $S_2 \in F^{k\times k}$ is generated at random and

$$T(D^{-1}, D) = T_{-1}D^{-1} + T_0 + T_1 D \in F^{n\times n}[D^{-1}, D] \tag{2}$$

is an invertible (in $F(D)$) Laurent polynomial matrix with:

(i) The determinant satisfies $|T(D^{-1}, D)| \in F \setminus \{0\}$.
(ii) Nonzero rows of T_j have 2 nonzero elements, for $j \in \{-1, 0, 1\}$.
(iii) Indices of nonzero columns of T_{-1}, T_0 and T_1 form a partition of n.
(iv) If we denote

$$T^{-1}(D^{-1}, D) = P(D^{-1}, D) = P_{-1}D^{-1} + P_0 + P_1 D,$$

then, the nonzero columns of each matrix P_{-1}, P_0 and P_1, have at least 2 nonzero entries.

With them, we construct the convolutional encoder

$$\begin{aligned} G'(D) &= S(D)\ G\ P(D^{-1}, D) \\ &= G'_0 + G'_1 D + G'_2 D^2 + G'_3 D^3. \end{aligned} \tag{3}$$

Let $\mathrm{wt}(\mathbf{v})$ be the Hamming weight of a vector $\mathbf{v} \in F^n$, i.e. the number of the nonzero components of $\mathbf{v}$. This definition can be extended to polynomial vectors $\mathbf{v}(D^{-1}, D) = \sum_{i\in Z} \mathbf{v}_i D^i$ in a natural way as $\mathrm{wt}(\mathbf{v}(D^{-1}, D)) = \sum_{i\in Z} \mathrm{wt}(\mathbf{v}_i)$.

For the sake of simplicity we shall consider information vectors that start at time instant zero and have finite support, i.e., $\mathbf{u}(D) \in F^k[D]$ is polynomial. We will also consider the error vectors $\mathbf{e}(D) \in F^n[D]$ to be polynomial.

Lemma 1. Let $T(D^{-1}, D)$ be as described above and $\mathbf{e}(D) = \sum_{i\geq 0} \mathbf{e}_i D^i \in F^n[D]$ a random vector satisfying

$$\mathrm{wt}([\mathbf{e}_i\ \mathbf{e}_{i+1}\ \mathbf{e}_{i+2}]) \leq \frac{t}{2} \tag{4}$$

for all $i \geq 0$. Then all the coefficients of $\mathbf{e}(D)T(D^{-1}, D)$ have weight less than or equal to t.

Proof. The coefficient of degree ℓ of $\mathbf{e}(D)T(D^{-1}, D)$ is

$$T_{-1}\mathbf{e}_{\ell+1} + T_0\mathbf{e}_\ell + T_1\mathbf{e}_{\ell-1.},$$

where $\mathbf{e}_i = 0$ for $i < 0$. Since each row of T_j has at most 2 nonzero elements, then $\mathrm{wt}(\mathbf{e}_i T_j) \leq 2\mathrm{wt}(\mathbf{e}_i)$ for all $i \geq 0$ and $j \in \{-1, 0, 1\}$, and the result follows.

Condition (4) describes the maximum number of errors allowed within a time interval and is similar to the sliding window condition introduced in Badr et al. (2017) to describe the possible error patterns that can occur in a given channel.

Theorem 2. Let $G'(D)$ be the encoder as described in (3), t the correcting error capability of G,

$$\mathbf{u}(D) = \mathbf{u}_0 + \mathbf{u}_1 D + \cdots + \mathbf{u}_s D^s$$

the information sequence and

$$\mathbf{e}(D) = \mathbf{e}_0 + \mathbf{e}_1 D + \cdots + \mathbf{e}_{s+3} D^{s+3}$$

an error vector satisfying (4). Then, the received data $\mathbf{y}(D) = \mathbf{u}(D)G'(D) + \mathbf{e}(D) \in F^n[D]$ can be decoded.

Proof. Multiplying $\mathbf{y}(D)$ by $T(D^{-1}, D)$ from the right yields the polynomial equation

$$\mathbf{y}(D)T(D^{-1}, D) = \mathbf{u}(D)S(D)G + \mathbf{e}(D)T(D^{-1}, D).$$

Hence, for some coefficients $\widehat{\mathbf{u}}_i \in F^k$, we can write

$$\mathbf{u}(D)S(D) = \sum_{i=1}^{s+2} \widehat{\mathbf{u}}_i D^i \tag{5}$$

and for some coefficients $\widehat{\mathbf{e}}_i \in F^n$, we can write

$$\mathbf{e}(D)T(D^{-1}, D) = \sum_{i=-1}^{s+4} \widehat{\mathbf{e}}_i D^i,$$

and therefore each coefficient of $\mathbf{y}(D)T(D^{-1}, D)$ is of the form $\widehat{\mathbf{u}}_i G + \widehat{\mathbf{e}}_i$. By Lemma 1 it follows that $\mathrm{wt}(\widehat{\mathbf{e}}_i) \leq t$, for $-1 \leq i \leq s + 4$ and, therefore, each $\widehat{\mathbf{u}}_i$ can be recovered. Further, from (5) we have that

$$[\,\widehat{\mathbf{u}}_1\ \widehat{\mathbf{u}}_2\ \cdots\ \widehat{\mathbf{u}}_{s+2}\,] = [\,\mathbf{u}_0\ \mathbf{u}_1\ \cdots\ \mathbf{u}_s\,] \begin{bmatrix} S_1 & S_2 & & & \\ & S_1 & S_2 & & \\ & & \ddots & \ddots & \\ & & & S_1 & S_2 \end{bmatrix},$$

so, one can recover each $\mathbf{u}_i$ sequentially as

$$\begin{aligned} \mathbf{u}_0 &= \widehat{\mathbf{u}}_1 S_1^{-1}, \\ \mathbf{u}_1 &= (\widehat{\mathbf{u}}_2 - \mathbf{u}_0 S_2)\, S_1^{-1}, \\ \mathbf{u}_2 &= (\widehat{\mathbf{u}}_3 - \mathbf{u}_1 S_2)\, S_1^{-1}, \\ &\vdots \\ \mathbf{u}_i &= (\widehat{\mathbf{u}}_{i+1} - \mathbf{u}_{i-1} S_2)\, S_1^{-1}. \end{aligned}$$

The proposed scheme works as follows:

Secret key: Generate a triple $\{S(D), G, T(D^{-1}, D)\}$, compute $G'(D) = G'_0 + G'_1 D + G'_2 D^2 + G'_3 D^3$ and define the following sets

$$N_j = \{\text{indices of the null columns of } G'_j\}, \ \ j \in \{0, 1, 2, 3\}.$$

$$J_0 = \{1, \ldots, n\} \setminus N_0, \ J_1 = N_0 \setminus N_1, \ J_2 = (N_0 \cap N_1) \setminus N_2.$$

Let $\widetilde{G}_j$ be the submatrix of G'_j whose columns are indexed by J_j, and define $\widetilde{G} = [\widetilde{G}'_0 | \widetilde{G}'_1 | \widetilde{G}'_2]$. Let $E(G'_0)$ and $E(\widetilde{G})$ be the reduced row echelon form of G'_0 and $\widetilde{G}$ and check if the following conditions are satisfied:

(a) $E(G'_0)$ has rows of weight 1.
(b) $E(\widetilde{G})$ has rows of weight 1.

If this is the case, then $\{S(D), G, T(D^{-1}, D)\}$ is correctly generated. If not, generate another instance of $S(D)$, G and $T(D^{-1}, D)$.

Remark 3. After randomly generating a sample of 500 matrices $T(D^{-1}, D)$ of the form described in Section 2.1, we found that about a 4% of them fulfill **(a)** and **(b)**.

Public key: $\{G'(D) = S(D)GT^{-1}(D^{-1}, D), \ t/2\}$.

Encryption: Let $\pi_I(\mathbf{v})$ be the projection of $\mathbf{v}$ into the coordinates in I and let us define the following sets:

$$L = \{\text{column indices of } [G'_0 | G'_1 | G'_2] \text{ where the rows of weight 1 of } E(\widetilde{G}) \text{ have the nonzero elements}\},$$

$$L' = \{\text{column indices of the nonzero elements of the rows of weight 1 of } E(G'_0)\}.$$

To encrypt a message

$$\mathbf{u}(D) = \mathbf{u}_0 + \mathbf{u}_1 D + \mathbf{u}_2 D^2 + \cdots + \mathbf{u}_s D^s \in F^k[D],$$

Alice selects an error vector

$$\mathbf{e}(D) = \mathbf{e}_0 + \mathbf{e}_1 D + \cdots + \mathbf{e}_{s+3} D^{s+3} \in F^n[D],$$

satisfying (4) and the following additional conditions:

$$\mathrm{wt}(\pi_{L'}(\mathbf{e}_0)) = \mathrm{wt}(\mathbf{e}_0), \tag{6}$$

$$\mathrm{wt}(\pi_{J_2}(\mathbf{e}_1)) = 0, \tag{7}$$

$$\mathrm{wt}(\pi_L([\mathbf{e}_0 \ \mathbf{e}_1 \ \mathbf{e}_2])) = \mathrm{wt}([\mathbf{e}_0 \ \mathbf{e}_1 \ \mathbf{e}_2]), \tag{8}$$

$$\mathrm{wt}(\pi_L([\mathbf{e}_i \ \mathbf{e}_{i+1} \ \mathbf{e}_{i+2}]) \geq 1, \quad 0 \leq i \leq s+1 \tag{9}$$

$$\mathrm{wt}(\pi_{L'}(\mathbf{e}_i)) \geq 1, \quad 0 \leq i \leq s \tag{10}$$

and encrypts the message as

$$\mathbf{y}(D) = \mathbf{u}(D)G'(D) + \mathbf{e}(D). \tag{11}$$

Decryption: Bob multiplies (11) from the right by the matrix $T(D^{-1}, D)$ to obtain

$$\mathbf{u}(D)S(D)G + \mathbf{e}(D)T(D^{-1}, D), \tag{12}$$

he decodes using G and recovers the message $\mathbf{u}(D)$ from $\mathbf{u}(D)S(D)$, as explained in the proof of Theorem 2.

2.1 Constructing $T(D^{-1}, D)$

In this subsection we present a large family of matrices $T(D^{-1}, D)$ satisfying properties **(i)**, **(ii)**, **(iii)** and **(iv)**. To this end, we first recall a technical lemma about the determinant and inverse of a block matrix, first obtained by I. Schur (Schur (1917)).

Lemma 4. (Cottle, 1974, Formulas (2) and (4)) Let T be a block matrix of the form

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix},$$

where A and D are nonsingular. Then

a) $|T| = |A| \ |D - CA^{-1}B|$.
b) If T is invertible, the inverse of T is

$$P = -\begin{bmatrix} -(A - BD^{-1}C)^{-1} & A^{-1}B(D - CA^{-1}B)^{-1} \\ D^{-1}C(A - BD^{-1}C)^{-1} & -(D - CA^{-1}B)^{-1} \end{bmatrix}.$$

Starting from a 2×2 block matrix facilitates the construction of a matrix satisfying **(ii)**. Moreover, since the above lemma tells us how the determinant and the inverse matrix are, properties **(i)** and **(iv)** can be easily achieved as well. The blocks we use to construct $T(D^{-1}, D)$ are denoted by $A(D^{-1}, D)$ and are of size $\frac{n}{2} \times \frac{n}{2}$, where n is the size of the code (we use even values for n). These blocks are randomly generated satisfying the following properties:

Properties 5. $A = A(D^{-1}, D) \in F^{\frac{n}{2} \times \frac{n}{2}}[D^{-1}, D]$ satisfies:

(1) A is an upper triangular matrix;
(2) The entries of the principal diagonal of A are of the form aD^j, with $a \in F \setminus \{0\}$, and $j \in \{-1, 0, 1\}$ in such a way that there are δ_j entries with power D^j, satisfying
$$\delta_{-1} = \delta_1; \tag{13}$$
(3) Each row of A has at most one entry of the form γD^j for each $j \in \{-1, 0, 1\}$, with $\gamma \in F \setminus \{0\}$;
(4) All nonzero entries of a column of A have the same exponent of D.

Condition (13) can be understood as the sum of the exponents of D along the diagonal is 0. Since A is upper triangular and the diagonal entries are nonzero, this implies that $|A| \in F \setminus \{0\}$, i.e., the determinant is a nonzero constant. Once we have determined how the blocks we will use are, we can construct $T(D^{-1}, D)$ satisfying properties **(i)**, **(ii)**, **(iii)** and **(iv)**, as it shown the next theorem.

Lemma 6. Suppose $|F| > 2$. Let $\Gamma \in F^{n \times n}$ be a permutation matrix, $A = A(D^{-1}, D)$ be a matrix satisfying Properties 5, take $\beta \in F \setminus \{0, 1\}$ and consider $\Delta(D^{-1}, D)$ to be the block matrix

$$\Delta(D^{-1}, D) = \begin{bmatrix} A & \beta A \\ A & A \end{bmatrix} \in F^{n \times n}[D^{-1}, D].$$

Then $T(D^{-1}, D) = \Gamma \, \Delta(D^{-1}, D)$ satisfies properties **(i)**, **(ii)**, **(iii)** and **(iv)**.

Proof. Using Lemma 4 **a)**, we have

$$|\Delta(D^{-1}, D)| = |A| \, |A - AA^{-1}(\beta A)| \ = |A|^2 |I - \beta I|.$$

Since $|A| \in F \setminus \{0\}$ and $\beta \neq 1$ then $|T(D^{-1}, D)| \in F \setminus \{0\}$, so condition **(i)** holds.

Conditions **(ii)** and **(iii)** hold due to Properties 5 and our construction of $\Delta(D^{-1}, D)$. Condition **(iv)** is obtained using Lemma 4 **b)** since we have

$$\Delta^{-1}(D^{-1}, D) = \begin{bmatrix} \frac{1}{1-\beta}A^{-1} & \frac{\beta}{\beta-1}A^{-1} \\ \frac{1}{\beta-1}A^{-1} & \frac{1}{1-\beta}A^{-1} \end{bmatrix}.$$

If we write $\Delta(D^{-1}, D) = \sum_{j=-1}^{1} \Delta_j D^j$ then, by construction, all rows of Δ_j, and hence all columns of P_j, will have an even number of nonzero entries, for $j \in \{-1, 0, 1\}$.

3. ATTACKS AGAINST THE PROPOSED CRYPTOSYSTEM

In this section, we briefly comment some of possible attacks to the proposed cryptosystem and show how the properties analyzed in previous sections provide increased key security with respect to previous variants of the McEliece cryptosystem.

An attacker could consider the full row rank matrix

$$\begin{bmatrix} G'_0 & G'_1 & G'_2 & G'_3 & & & \\ & G'_0 & G'_1 & G'_2 & G'_3 & & \\ & & \ddots & \ddots & \ddots & \ddots & \\ & & & G'_0 & G'_1 & G'_2 & G'_3 \end{bmatrix}$$

as the generator matrix of a block code. Note, however, that the size of this block code is $k(s+1) \times n(s+4)$ and therefore it will be very large for large values of s, even if n and k are small. Table 1 illustrates a few specific examples with the work factor (WF) needed to recover $\mathbf{u}(D)$ using ISD attacks on that matrix (see Bolkema et al. (2017) for more details on the computation of the WF).

n	k	s	WF (bin. op.)	Public Key (bits)
New Scheme				
108	60	24	$2^{129.3}$	182695
108	60	51	$2^{256.7}$	182696
180	108	14	$2^{128.5}$	624713
180	108	31	$2^{262.6}$	624714
180	108	62	$2^{512.6}$	624715
180	114	14	$2^{132.0}$	659417
180	114	30	$2^{260.6}$	659418
180	114	61	$2^{513.2}$	659419
Classical McEliece with Goppa codes				
2960	2288		2^{128}	1537536
8192	6528		2^{256}	10862592
GRS with 2-weight mask (Bolkema et al.)				
764	496		$2^{128.10}$	1329280
762	490		$2^{128.02}$	1332800
766	498		$2^{128.35}$	1334640

Table 1. Parameters, work force and public key sizes of PKC

An attacker could also try to use the convolutional structure of the scheme and sequentially decode each block. Notice that if the attacker has a method to recover $\mathbf{u}_0$ and $\mathbf{e}_0$, then by computing $D^{-1}(\mathbf{y}(D) - \mathbf{u}_0 G'(D) - \mathbf{e}_0)$ the process can be repeated to recover the rest of the $\mathbf{u}_i$, $\mathbf{e}_i$, for $i \geq 1$. For this purpose the attacker can start with the block code $\mathcal{C}_0$ associated with G'_0. However, since the distance of the code $\mathcal{C}_0$ is 1, the number codewords in a ball of radius $\leq t$ centered in $\mathbf{y}_0$ is expected to be really huge. Moreover, condition (6) implies that $\mathbf{y}_0$ is indeed a codeword of $\mathcal{C}_0$.

Another way to try to recover $\mathbf{u}_0$ is to consider all the equations involving $\mathbf{u}_0$ and none of the other $\mathbf{u}_i$, for $i \geq 1$. This system of equations is precisely given by the matrix $\widetilde{G}$ and the associated parts of the vector $[\mathbf{y}_0\ \mathbf{y}_1\ \mathbf{y}_2]$. Again, since the distance of the code generated by the matrix $\widetilde{G}$ has distance 1, it is expected to have a large list of codewords centered in that vector and no methods to decide which is the correct one.

For the structural attacks, since the weight of the nonzero columns of P_i, with $i \in \{-1, 0, 1\}$, is larger than or equal to 2 due to condition **(iv)**, the attacks presented in Couvreur et al. (2015) and Couvreur and Lequesne (2020) don't seem to succeed against the proposed scheme.

Abstract: This paper continues the work of Georgiou, Jabbari and Smith on lossless adjustable mechanical devices. Defining equations and mechanical constructions of lossless adjustable springs and inerters for translational and rotational devices will be recalled. The role played by the lossless adjustable two-port transformer will be highlighted. A mechanical design will be described for a lossless adjustable rotational two-port transformer involving a double-cone arrangement, movable carriage and a pair of counter-rotating balls.

Keywords: Passivity-based control; Mechanical networks.

1. INTRODUCTION

In Georgiou et al. (2020) the question was posed as to whether it is possible to build lossless adjustable springs and inerters. A lossless adjustable spring would have a "workless knob" and would behave like a conventional linear spring when the knob is stationary. Energy imparted through compression or extension would be available for extraction again. Adjustment of the knob would not involve any energy transfer between the environment and the contrivance. Current methods to adjust the stiffness of springs do not answer this question, since they require active actuation, dissipation, or restrictive conditions on the switching of the spring constant.

The question is motivated by the ubiquity of the adjustable damper which is extensively used in the control of mechanical systems, e.g. automotive suspensions, see Butsuen and Hedrick (1989), Savaresi et al. (2010), Brezas et al. (2015), Smith et al. (2018). The variable damper constant plays the role of a control input which may be adjusted by a control law that minimises a performance criterion. Such devices are sometimes termed "semi-active" since a (small) power source is employed to effect the adjustment. Nevertheless, the instantaneous power absorbed by the device can never be negative, and so from a terminal point of view it appears passive.

An analogous question arises for the inerter which is a two-terminal mechanical device such that the equal and opposite force at the terminals is proportional to the relative acceleration between them (see Smith (2002), Smith (2020)). The constant of proportionality is termed the inertance. The question is whether an adjustable inerter is physically realisable as a lossless device, i.e. whether an inerter can be manufactured with a "workless knob" which freely adjusts its inertance in real time.

In the robotics field "Variable Stiffness Actuators" have been considered extensively (see Vanderborght et al. (2013), Wolf et al. (2016) for recent surveys and the references therein). Each of the methods described requires some form of active force input, most commonly via electromechanical actuation. In Bobrow et al. (1995), Jabbari and Bobrow (2002) a passive "resettable" spring is proposed which requires minimal energy for switching. The opening of the valve (to reduce the stiffness) is constrained to times at which there is no stored energy in the fluid, otherwise there is energy dissipation. The possible benefits of adjustable inerters have been considered recently in Chen et al. (2014), Brzeski et al. (2015), Lazarek et al. (2018), Garrido et al. (2018) without identifying a method to make the adjustments in a lossless manner.

The present extended abstract is structured as follows. Section 2 highlights the mechanical constructions of Georgiou et al. (2020): an idealised mechanical arrangement of a lever with movable fulcrum to derive device laws for lossless adjustable springs and inerters. The definitions of the varspring and varinerter will be recalled, as well as the rotational counterparts of these concepts. Section 3 focusses specifically on the rotary adjustable transformer and details a specific embodiment of the physical realisation of the device.

2. PLANAR MECHANISM FOR LOSSLESS ADJUSTABLE DEVICES

2.1 Lossless adjustable spring

We consider a theoretical mechanism as depicted in Fig. 1 in which the x- and y-axes are fixed in the device housing. The device terminals are located at $(0,0)$ and $(x_1,0)$ according to the convention of Georgiou et al. (2020) and accordingly we

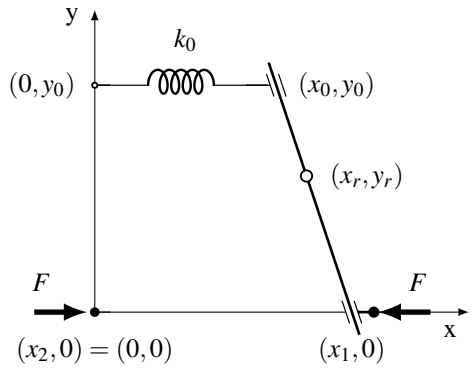

Fig. 1. Spring and lever with movable fulcrum at (x_r, y_r).

define $x = -x_1$ and $v = -\dot{x}_1$. An internal spring with stiffness k_0 is constrained to move parallel to the x-axis with fixed y-coordinate y_0 and generates a force equal to $-k_0 x_0$. An ideal massless lever has a movable fulcrum at (x_r, y_r).

If the fulcrum is movable with an imposed condition that the instantaneous power supplied at the external terminals of the device equals the rate of change of the internal energy of the spring then it can be shown as in Georgiou et al. (2020) that the fulcrum must always move parallel to the bar. Setting $k_0 = 1$ it can be shown that the device is governed by the relation:

$$\dot{x} = p\frac{d}{dt}(pF). \tag{1}$$

where

$$p = y_r/(y_0 - y_r). \tag{2}$$

We can see that $F\dot{x} = \frac{d}{dt}(\mathscr{I})$ where we may define the internal stored energy by:

$$\mathscr{I} = \frac{1}{2}p^2F^2.$$

2.2 Lossless adjustable inerter

We consider the mechanism as depicted in Fig. 2 which is similar to the device in Fig. 1 except that the spring is replaced by an inerter which generates a force equal to $-b\ddot{x}_0$.

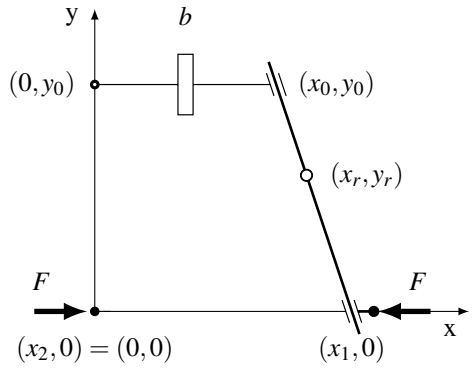

Fig. 2. Inerter and lever with movable fulcrum at (x_r, y_r).

Applying again the condition that the instantaneous power supplied at the external terminals of the device equals the rate of change of the internal energy of the inerter gives, for $b = 1$,

$$F = r\frac{d}{dt}(r\dot{x}) \tag{3}$$

where $r = p^{-1}$. It is immediate to see that $F\dot{x} = \frac{d}{dt}(\mathscr{I})$ where we may define the internal stored energy by:

$$\mathscr{I} = \frac{1}{2}r^2\dot{x}^2.$$

2.3 Physical implementation

A conceptual scheme to realise such adjustability is shown in Fig. 3. A wheel is attached to the bar at the fulcrum and is free to rotate about a vertical axis through the fulcrum and the contact point of the wheel on a supporting table. The wheel is allowed to rotate about a horizontal axis which is perpendicular to the bar to produce a rolling motion on the table which is always instantaneously parallel to the bar. The rolling of the wheel is the means of mechanism adjustment by altering the ratio r or $p = r^{-1}$ with p defined as in (2).

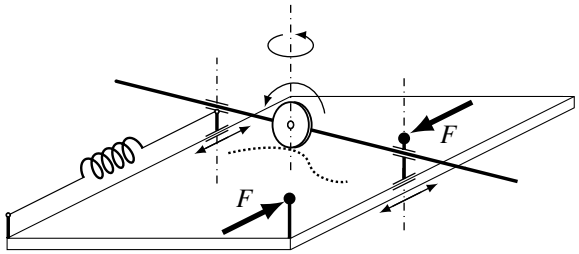

Fig. 3. Schematic of a lever mechanism with movable fulcrum to allow a physical realisation of lossless adjustable springs and inerters.

2.4 The varspring and varinerter

Based on the construction of Fig. 3, it appears justified to introduce a pair of ideal, lossless adjustable mechanical one-ports which we will name the *varspring* and *varinerter*. The ideal devices are defined by the laws:

$$v = p\frac{d}{dt}(pF) \qquad \text{(varspring)} \tag{4}$$

$$F = r\frac{d}{dt}(rv) \qquad \text{(varinerter)} \tag{5}$$

where (F, v) is the force-velocity pair of the mechanical one-port and $p(t)$, $r(t)$ are positive and freely adjustable parameters. The internal energy of the devices is given by $\frac{1}{2}p^2F^2$ and $\frac{1}{2}r^2v^2$ respectively. It is important that physical devices may be constructed which approximate the ideal behaviour, for example, having sufficiently small dissipation through friction, and as in the case of the ideal inerter in Smith (2002), sufficiently small mass, sufficient travel, have no physical attachment to a fixed point in space, and have two terminals which are freely and independently movable (Smith, 2002, Section II.C). The construction of Fig. 3 suggests that devices satisfying these conditions are physically realisable in principle. The varinerter is realised as in Fig. 3 with an inerter replacing the spring. We note that the above construction of the varspring and varinerter in Fig. 3 can be conceptualized as a lossless adjustable two-port transformer with one of the ports terminated with either a spring or an inerter.

2.5 A lossless adjustable transformer

Motivated by the method of constructing the translational varspring and varinerter in Sections 2.1 and 2.2 we consider now the possibility of an adjustable rotary transformer. We consider the construction depicted in Fig. 4 consisting of two right circular cones of equal aperture on parallel rotating shafts,

with opposite orientation, and hence a constant perpendicular distance between the surfaces. Between the cones is an assembly consisting of two balls within a housing which is movable parallel to the surface of the cones to maintain contact of the balls with the cones at the feet of the perpendicular beween the cones. It is assumed that pure rolling is maintained between the balls and the cones, and between themselves, and that there is frictionless sliding between the balls and the housing. With the assumption of negligible mass of the whole system the torques on the two shafts are proportional, with the proportionality being the instantaneous ratio of cone radii. The assumption of pure rolling means that the angular velocities are similarly proportional. Thus we may presume laws of the form:

$$T_1 = pT, \tag{6}$$

$$\omega_1 = -p^{-1}\omega \tag{7}$$

where T, T_1 are the torques on the shafts, ω, ω_1 are their angular velocities, and $p = p(t) > 0$ is the instantaneous ratio of cone radii. We note that $T_1\omega_1 + T\omega = 0$ so that no energy is absorbed or dissipated in the ideal device. Hence we may consider the schematic of Fig. 4 as a physical realisation of a lossless adjustable rotary transformer.

It is important to emphasize that, besides being lossless, an essential feature of the mechanism in Fig. 4 is that the ratio between angular velocities can be freely adjusted, including the case where the angular velocities are zero, as occurs when there is a reversal of sign. This feature contrasts with typical concepts of a continuously variable transmission (CVT), e.g., Brokowski et al. (2002); Rotella and Cammalleri (2018).

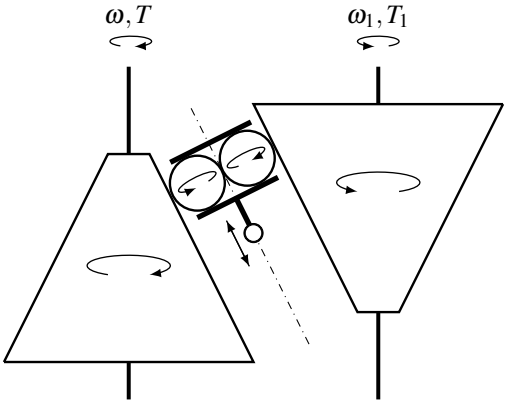

Fig. 4. Schematic of an adjustable rotary transformer with counter-rotating cones and continuously movable connecting assembly consisting of a pair of rotating balls within a housing.

2.6 The rotary varspring and varinerter

We first consider attaching a rotary spring of rotational stiffness $k > 0$ (constant) to the second shaft in Fig. 4 defined by $T_1 = -k\theta_1$ where $\dot{\theta}_1 = \omega_1$. A passive (lossless) rotary mechanical one-port is formed with the following relationship between the equal and opposite torque applied to the external (rotary) terminals T and the relative angular velocity ω between the terminals: $\omega = -p\omega_1 = pk^{-1}\frac{d}{dt}(pT)$. Similarly, if a rotary inerter (see Smith (2001)) with rotational inertance $b > 0$, defined by $T_1 = -b\dot{\omega}_1$, is connected across the second shaft in Fig. 4 a passive (lossless) rotary one-port is formed satisfying $T = -br\dot{\omega}_1 = br\frac{d}{dt}(r\omega)$. The constants k and b can be absorbed into p and r respectively (or equivalently setting $k = 1$ and $b = 1$).

This motivates the following definitions of the rotary varspring and varinerter:

$$\omega = p\frac{d}{dt}(pT) \qquad \text{(rotary varspring)} \tag{8}$$

$$T = r\frac{d}{dt}(r\omega) \qquad \text{(rotary varinerter)} \tag{9}$$

where (T, ω) is the torque-angular-velocity pair of the mechanical one-port and $p(t)$, $r(t)$ are positive and freely adjustable parameters. The internal energy of the devices is given by $\frac{1}{2}p^2T^2$ and $\frac{1}{2}r^2\omega^2$ respectively.

It is interesting to compare the embodiments presented for the translational and rotary varsprings and varinerters. A practical issue that arises with continuous operation of the translational devices, implemented in the manner of Fig. 3, is that the movement of the fulcrum in the x-direction may exceed the allowable travel. No such issue arises with the rotary devices.

3. PHYSICAL REALISATION OF A LOSSLESS ADJUSTABLE TWO-PORT TRANSFORMER

The conceptual embodiment of the adjustable rotary transformer in Fig. 4 encounters the technical challenge to ensure (nearly) frictionless sliding between the balls and the housing, while maintaining pure rolling between the two balls, and also between the balls and the cone surfaces. Next we describe a physical realisation for the housing and carriage assembly that offers a solution to this challenge.

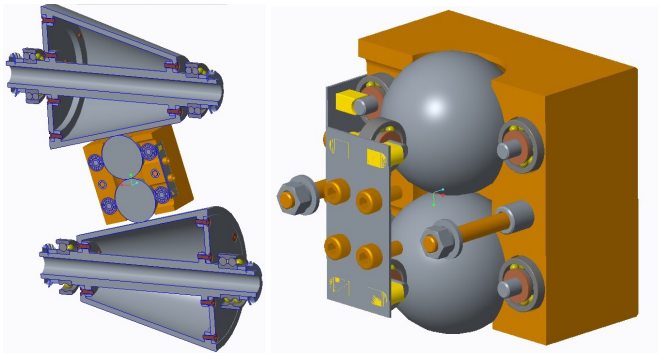

Fig. 5. Drawing of the device that consists of two shafts, two circular cones, and in between a carriage assembly with two counter-rotating balls (together with magnified view).

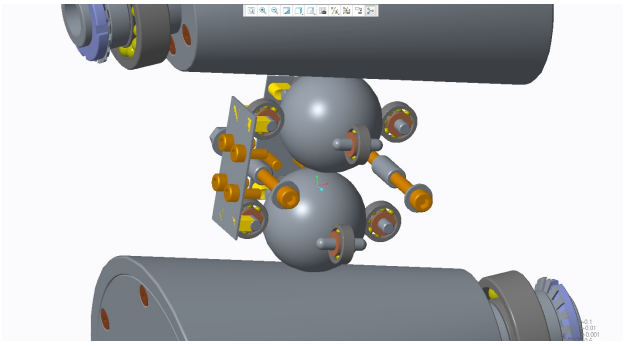

Fig. 6. Detail on the positioning of the counter-rotating balls with the supporting roller bearings.

The drawing in Fig. 5 shows the positioning of the two circular cones together with the housing that supports the two counter-rotating balls. Preloading of the shafts that support the cones can ensure sufficiently large normal forces at the contact points between the two balls, and between the balls and the cones, to ensure rolling (with no slippage) for a given specification on torques applied to the shafts. Preloading needs to ensure that the Hertzian contact stress is small enough so that the resulting strains are within the elastic limit. The housing encloses the two counter-rotating balls each constrained by two pairs of roller bearings positioned on perpendicular axes. Fig. 6 shows the arrangement of the roller bearings, each pair being on perpendicular axes which are themselves perpendicular to the line joining the centres of the two balls. This geometry allows each ball to freely rotate about any axis that lies within the plane whose normal is the line joining the centres of the two balls. This feature allows the carriage assembly to slide and be positioned along the axis (marked with dash-dotted line in Fig. 4) that runs parallel to the contact points between the balls and the two cones. This axis is not shown in Figs. 5–6 to allow a clear view of the internal structure of the housing and the positioning of the roller bearings. A mechanical embodiment of the device is shown in Fig. 7

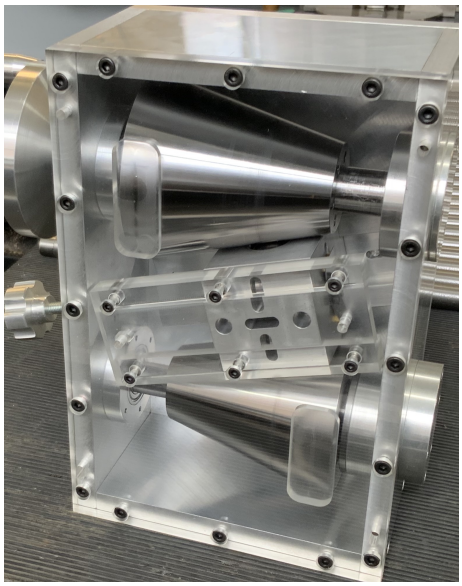

Fig. 7. Mechanical embodiment manufactured in Cambridge University Engineering Department.

With the assumption of negligible mass for the whole system, the torques on the two shafts are proportional, with the proportionality being the instantaneous ratio of cone radii. Further, no (or negligible) energy is absorbed or dissipated since any forces applied at the contact points are perpendicular to any direction that the contact points can be displaced.

4. CONCLUSION

We have shown how adjustable lossless springs and inerters can be realised. The central element of our construction is an adjustable mechanical transformer which is interesting in its own right. In this paper, we discuss the realisation of such a device and describe an embodiment that uses two counter-rotating cones that are coupled through two counter-rotating balls, housed in a carriage assembly that allows (near) friction-less motion of the balls while transfering torque between the shafts of the two cones.

Abstract: We investigate the modelling of sailing races as hybrid stochastic games, either with zero or nonzero sum, where the first case is typical of match races and the second of fleet races. In particular, we provide models of growing complexity and dimension, study the optimal strategies in various racing situations and devise some fast and/or reduced memory implementation.

Keywords: Hybrid Systems, Optimal Control, Stochastic Control and Estimation

1. INTRODUCTION

In its typical formulation, the *route planning* problem consists in driving a sailing vessel towards a target in a partly stochastic wind field. This problem has recently received a certain attention, not only because of its use in sailing competitions, but also for the growing interest in sustainable transport strategies. Actually, various projects of sailing or hybrid commercial ships are currently under consideration, and their use could significantly reduce costs and emissions related to the transport on sea: exploiting in an optimal way the wind field would thus become a crucial point for such projects. In sailing races, the problems of optimizing the boat route appears critical, and has already motivated a certain amount of studies, in particular related to America's Cup competitions (see Philpott (2005); Vinckenbosch (2012)).

The main peculiarity in modelling the motion of sailing boats is that their speed depends on the angle between the boat direction and the (random) direction of the wind, and presents a *no-go* region if the boat attempts to sail opposite to the wind. A second point is that changing from right to left tack of vice versa (i.e., changing the side of the boat from which the wind comes) requires a complex manoeuvre (*tacking* or *gybing*) which causes a speed loss, to be correctly taken into account. A typical polar plot of speeds is shown in Fig. 1, in which the arrows refer to the speed obtained at various angles, on the left tack (i.e., with the wind arriving from left).

The interpretation of the tacking or gybing manoeuvre as a *switch* between two different dynamics allows us to formulate the problem in terms of *hybrid control* (see Ferretti and Festa (2019)), where the angle with the wind on a given tack is considered as a continuous control, while a tacking or gybing represents a commutation between the dynamics associated to respectively right or left tack.

⋆ This research has been partially supported by INdAM–GNCS and by the MIUR grant "Dipartimenti Eccellenza 2018–2022".

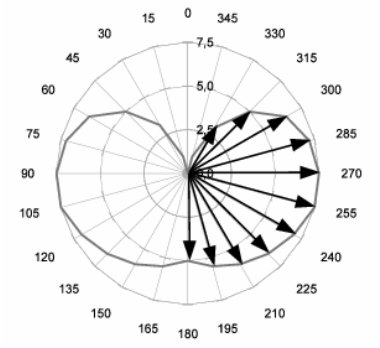

Fig. 1. Polar plot of the speed of a sailing boat with respect to the wind angle

A time loss (in other terms, a cost) is associated to this change of dynamics.

2. MODELLING A RACE

In this work, we will apply this general hybrid stochastic framework to the case of a sailing race, in which a set of players (boats) $A, B, \dots$ are placed in a two-dimensional domain representing the race area. The wind direction $\Theta(t)$ will be modelled, as usual in this framework, by adding a deterministic drift γ to a Brownian motion, so that

$$d\Theta(t) = \gamma dt + \sigma dW(t),$$

while, on the X_1–X_2 plane, the generic sailing boat P has a position evolving as

$$\begin{cases} \dot{X}_1^P(t) = s^P(a^P, X^A, X^B, \dots) \sin\left(\Theta(t) + (-1)^{Q^P(t)} a^P\right) \\ \dot{X}_2^P(t) = s^P(a^P, X^A, X^B, \dots) \cos\left(\Theta(t) + (-1)^{Q^P(t)} a^P\right), \end{cases}$$

where a is the angle of the boat w.r.t. the wind, $s^P(a^P, X^A, X^B, \dots)$ is the boat speed, and the discrete control $Q^P(t) = 1$ for the port tack, $Q^P(t) = 2$ on the

starboard tack. Note that the boat speed depends on the positions of all the players, thus including the effects of mutual disturbance, which occurs in real races (and that represent a key feature of the problem).

2.1 Various settings for the problem

We will consider various settings of increasing complexity, all of them being of hybrid stochastic game type, for a race among players of the form above. The basic problem is sailing to windward in an infinite plane, as a model for windward strategy when far from the target. This setting has been used in Cacace et al. (2020) for treating the case of match races, and in this situation we consider a zero-sum game of pursuit–evasion form, which can be conveniently treated in reduced coordinates with a state space of dimension $n = 3$. Using a dynamic programming approach, the value function v of the game solves an Isaacs equation in the form of a system of quasi-variational inequalities:

$$\max\{v - \mathcal{M}[v], \min\{v - \mathcal{N}[v], F[v]\}\} = 0,$$

where $F[v]$ is the dynamic programming Hamiltonian associated to the continuous controls, and $\mathcal{M}$, $\mathcal{N}$ are the switching operators of the two players. The numerical examples carried out in Cacace et al. (2020) show that the optimal strategy for both players is basically to follow the optimal single player strategy, but as one of the players gains some advantage, this player tends to disturb slightly the other one, whenever in favourable position (see Figures 2–3).

In this work, we will examine various generalizations of this setting, and in particular:

(1) Sailing to windward in an infinite plane, but in a nonzero-sum framework. In this case we expect that a nontrivial Nash equilibrium may appear, in which the players are not interested to disturb each other. This may be a first model for the onset of Nash equilibria in a fleet race. However, the case can no longer be treated in reduced coordinates, and this makes the dimension of the state space raise to $n = 2N + 1$, where N is the number of players;
(2) Sailing to windward, either in a zero- or nonzero-sum game, with a target. In this case, while the nonzero-sum game appears as a multiple minimum time problem, in the zero-sum game we need to define a suitable criterion of advantage for a player. The dimension of the state space is still $n = 2N + 1$, the use of reduced coordinates being impossible.

2.2 Computational issues

As we have outlined above, the state space may rise to a relatively high dimension, as soon as the model becomes realistic. In addition, a slow convergence may occur if the numerical approximation is implemented in the form of a plain value iteration. We will therefore discuss:

(1) A memory reduction technique, which uses the fact that the interplay between two players appears only at small distances, and therefore the coupled game reduces to an optimal control problem for a single player as soon as the players are far enough from each other;
(2) Solvers of *fast marching* or *fast sweeping* type, exploiting the direction of propagation of the value function, along with the degeneracy of the stochastic component of the dynamics;
(3) Solvers of *policy iteration* type.

On the Optimal Control of Lossless Electrical Networks

Richard Pates [1]

Abstract: Electrical networks constructed out of resistors (R), inductors (L), capacitors (C), transformers (T), and gyrators (G) are used throughout engineering and the applied sciences to model physical processes. Synthesising RLCTG networks for control purposes is also important, since in a number application domains the corresponding controllers can be implemented without an energy source. We show that if a process can be modelled by an LCTG network, a controller that maximises robustness with respect to normalised coprime factor perturbations can be synthesised by a decentralised resistive network. The results are illustrated on an example centred on the iterative solution to constrained least squares problems.

Keywords: Dissipativity, Robust and H-infinity control, Large-scale systems

NOTATION

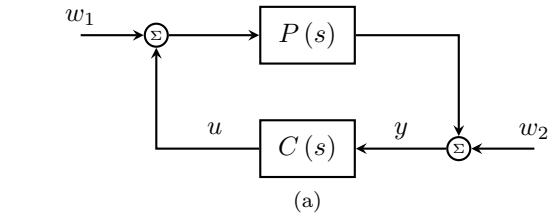
$\mathcal{L}_2^n$ and $\mathcal{L}_2^{\mathrm{loc},n}$ denote the n-vectors of square integrable functions, and locally square integrable functions, respectively. $\mathbb{R}^{n\times m}[s]$ denotes the n by m matrices of polynomials in the indeterminate s with real coefficients. $\|\cdot\|$ denotes either the $\mathcal{L}_2$ norm or the matrix 2-norm depending on whether it acts on a function or matrix. I denotes the identity matrix.

1. INTRODUCTION

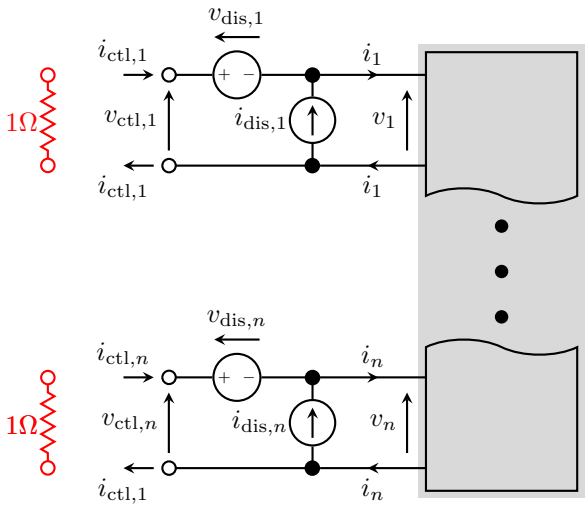
We investigate the H-infinity control problem that underpins the loop-shaping design procedure of McFarlane and Glover (1992) in the context of electrical networks. Our main contribution is to show that when the process to be controlled corresponds to an LCTG network (an electrical network constructed only from inductors, capacitors, transformers and gyrators), the resulting optimal control law is decentralised, and can be implemented by connecting unit resistors across all the external terminal pairs of the network. This is illustrated in Fig. 1. This gives an example of a class of optimal control problems with inherently decentralised solutions, providing motivation for applying decentralised control in applications with lossless (or nearly lossless) dynamics, such as electrical power systems.

As discussed in Camlibel et al. (2003), the dynamics of electrical networks cannot always be described in the input-output framework. However the driving point currents $i \in \mathcal{L}_2^{\mathrm{loc},n}$ and volatages $v \in \mathcal{L}_2^{\mathrm{loc},n}$ of an electrical network constructed out of resistors, inductors, capacitors, transformers and gyrators can always be characterised by the solutions to an equation that takes the form

$$R\left(\tfrac{d}{dt}\right)\begin{bmatrix} i \\ v \end{bmatrix} = 0,$$



(a)



(b)

Fig. 1. (a) The standard setup for the H-infinity control problem that underpins the loop-shaping design procedure of McFarlane and Glover (1992). The objective is to minimise the H-infinity norm of the transfer function from $[w_1^\mathsf{T}\, w_2^\mathsf{T}]^\mathsf{T}$ to $[u^\mathsf{T}\, y^\mathsf{T}]^\mathsf{T}$. (b) Electrical equivalent of the H-infinity control problem in (a). The main contribution of the paper is to show that if the electrical network is an LCTG network (it is constructed using only inductors, capacitors, transformers and gyrators), then this H-infinity performance criterion is minimised by connecting unit resistors across all the open terminal pairs.

Extended Abstracts of the
25th International Symposium on Mathematical Theory of Networks and Systems
Bayreuth, Germany, 12-16 September 2022

where $R(s) \in \mathbb{R}^{n\times 2n}[s]$ (see Hughes (2017b)). We therefore study the following behavioral equivalent of the H-infinity control problem in Fig. 1(a).

Problem 1: Let $G(s) \in \mathbb{R}^{\cdot\times m}[s]$ define the uncontrolled behavior of a process according to

$$\mathfrak{B}_{G(s)} = \left\{(w,z) \in \mathcal{L}_2^{\mathrm{loc},m} \times \mathcal{L}_2^{\mathrm{loc},m} : G\left(\tfrac{d}{dt}\right)(w+z) = 0\right\}.$$

Choose $K(s) \in \mathbb{R}^{\cdot\times m}[s]$ to minimise

$$\sup\left\{\|z\| : w \in \mathcal{L}_2^m, \|w\| = 1, (w,z) \in \mathfrak{B}_{G(s),K(s)}\right\} \quad (1)$$

where $\mathfrak{B}_{G(s),K(s)} = \left\{(w,z) \in \mathfrak{B}_{G(s)} : K\left(\tfrac{d}{dt}\right) z = 0\right\}$.

To see the connection, partition R as

$$R(s) = \left[R_1(s) \ -R_2(s)\right],$$

and suppose that

$$R\left(\tfrac{d}{dt}\right) v = 0 \quad \Leftrightarrow \quad \left[R_2\left(\tfrac{d}{dt}\right)^{-1} R_1\left(\tfrac{d}{dt}\right) \ -I\right] v = 0.$$

That is the behavior associated with $R(s)$ admits an input-output representation with respect to the given partition, with transfer function

$$P(s) = R_2(s)^{-1} R_1(s).$$

Splitting w and z compatibly according to

$$w = \begin{bmatrix} w_1 \\ -w_2 \end{bmatrix} \text{ and } z = \begin{bmatrix} u \\ y \end{bmatrix},$$

we then see that $(w,z) \in \mathfrak{B}_{G(s)}$ if and only if

$$y = w_2 + P\left(\tfrac{d}{dt}\right)(u + w_1),$$

placing Problem 1 in the standard H-infinity control framework. Problem 1 therefore represents a generalisation to cases where this input-output representation is not necessarily possible.

In the context of this paper, the idea behind Problem 1 is that $G(s)$ characterises the dynamics of an electrical network, w a set of disturbance currents and voltages, and z a set of driving point currents and voltages that can be constrained by another electrical network:

$$w = \begin{bmatrix} i_{\mathrm{dis}} \\ -v_{\mathrm{dis}} \end{bmatrix} \text{ and } z = \begin{bmatrix} i_{\mathrm{ctl}} \\ v_{\mathrm{ctl}} \end{bmatrix}.$$

Since Kirchhoff's current and voltage laws at the terminal pairs of the electrical network read as

$$\begin{bmatrix} i \\ v \end{bmatrix} = \begin{bmatrix} i_{\mathrm{ctl}} \\ v_{\mathrm{ctl}} \end{bmatrix} + \begin{bmatrix} i_{\mathrm{dis}} \\ -v_{\mathrm{dis}} \end{bmatrix},$$

the objective is then to design an electrical network that can be connected to the given electrical network to minimise the effect of the disturbance currents and voltages as quantified by (1). This particular performance objective has a wide range of interpretations (see §2 of Vinnicombe (2000) for an extended discussion), including maximising robustness to normalised coprime factor perturbations of the process dynamics.

The rest of the paper is structured as follows. We begin by demonstrating that whenever the process to be controlled corresponds to an LCTG network, the optimal solution to Problem 1 is given by

$$K(s) \equiv [I \ I].$$

This control law can be implemented by connecting a unit resistor across each of the open terminal pairs of the perturbed electrical network, as depicted in Fig. 1(b). This is the implication (1) ⇒ (2) in Theorem 1. Theorem 1 also demonstrates that the LCTG networks can be characterised in terms of solutions to Problem 1. This is more of a curiosity than anything else, but offers an alternative classification of the LCTG networks to the conditions on p.21 of Hughes and Branford (2021). The paper concludes with an example showing that this optimal control law arises naturally in a simple iterative algorithm for solving constrained least squares problems.

2. RESULTS

Theorem 1. Given $R(s) \in \mathbb{R}^{n\times 2n}[s]$, the following are equivalent:

(1) The behavior

$$\mathfrak{B} = \left\{\begin{bmatrix} i \\ v \end{bmatrix} \in \mathcal{L}_2^{\mathrm{loc},2n} : R\left(\tfrac{d}{dt}\right)\begin{bmatrix} i \\ v \end{bmatrix} = 0\right\}$$

is the driving point behavior of an LCTG network, where i and v denote the driving point currents and voltages, respectively.

(2) The matrix

$$K(s) \equiv [I \ I]$$

minimises the performance objective in Problem 1 when $G(s) \equiv R(s)$, and

$$K(s) \equiv [I \ -I]$$

minimises the performance objective in Problem 1 when $G(s) \equiv R(-s)$. In both cases a value of $\sqrt{2}$ is achieved for the performance objective in (1).

Proof. (1) ⇒ (2): It follows from Theorem 5 of Hughes (2017a) that under the hypothesis that $\mathfrak{B}$ is the driving point behavior of an LCTG network, there exists a permutation matrix $P = [P_1 \ P_2]$, and matrices

$$\begin{bmatrix} -A & -B \\ C & D \end{bmatrix} = -\begin{bmatrix} -A & -B \\ C & D \end{bmatrix}^{\mathsf{T}}, \quad (2)$$

where the pair (C,A) is observable and (A,B) is controllable [2], such that

$$\mathfrak{B} = \left\{\begin{bmatrix} i \\ v \end{bmatrix} : \left[\begin{array}{c} i \\ \hdashline v \end{array}\right] \left[\begin{array}{cc:cc} P_1 & 0 & P_2 & 0 \\ \hdashline 0 & P_2 & 0 & P_1 \end{array}\right] \left[\begin{array}{c} u \\ \hdashline y \end{array}\right], (u,y) \in \mathfrak{B}_{\mathrm{ss}}\right\},$$

where

$$\mathfrak{B}_{\mathrm{ss}} = \left\{(u,y) : \begin{bmatrix} x \\ u \\ y \end{bmatrix} \in \mathcal{L}_2^{\mathrm{loc},2n+m}, \begin{bmatrix} A - I\frac{d}{dt} & B & 0 \\ C & D & -I \end{bmatrix}\begin{bmatrix} x \\ u \\ y \end{bmatrix} = 0\right\}.$$

It then follows that $\mathfrak{B}_{R(s)}$ is given by the set of weak solutions to the equations

$$\begin{aligned} \tfrac{d}{dt}x &= Ax + [B \ 0]\,d + Bu, \\ F^{\mathsf{T}}z &= \left(\begin{bmatrix} C \\ 0 \end{bmatrix}x + \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix}d + \begin{bmatrix} D \\ I \end{bmatrix}u\right), \\ y &= Cx + [0 \ I]\,d + Du, \end{aligned} \quad (3)$$

where

$$F = \begin{bmatrix} P_1 & 0 & P_2 & 0 \\ 0 & P_2 & 0 & P_1 \end{bmatrix} \text{ and } w = Fd.$$

Since $FF^{\mathsf{T}} = F^{\mathsf{T}}F = I$ and the realisation in (3) is minimal, Problem 1 with $G(s) \equiv R(s)$ corresponds to minimising the H-infinity norm of the transfer function

[2] The existence of an observabile and controllabile realisation can be deduced from Hughes (2017b), since together Definition 7, Remark 8 and Theorem 9 from that paper imply that the driving point behavior of an LCTG network is always behaviorally controllable. See also the proof of Theorem 2 from Pates (2022) for an approach based on state-space techniques.

from d to $F^{\mathsf{T}}z$ as defined by (3). This is precisely the H-infinity control problem studied in Glover and McFarlane (1989). If we let

$$R = \left(I + DD^{\mathsf{T}}\right) \text{ and } S = \left(I + D^{\mathsf{T}}D\right),$$

the optimal value for this problem is equal to

$$\sqrt{1 + \lambda_{\max}},$$

where $\lambda_{\max}$ is the largest eigenvalue of XY, X is the unique positive semi-definite solution to the generalised control algebraic Riccati equation

$$\begin{aligned}\left(A - BS^{-1}D^{\mathsf{T}}C\right)^{\mathsf{T}} X + X\left(A - BS^{-1}D^{\mathsf{T}}C\right)\\ -XBS^{-1}B^{\mathsf{T}}X + C^{\mathsf{T}}R^{-1}C = 0,\end{aligned}$$

and Z is the unique positive semi-definite solution to the generalised filtering algebraic Riccati equation

$$\begin{aligned}\left(A - BS^{-1}D^{\mathsf{T}}C\right)Z + Z\left(A - BS^{-1}D^{\mathsf{T}}C\right)^{\mathsf{T}}\\ -ZC^{\mathsf{T}}R^{-1}CZ + BS^{-1}B^{\mathsf{T}} = 0.\end{aligned}$$

From (2) we see that $A = -A^{\mathsf{T}}$, $B = C^{\mathsf{T}}$, and $D = -D^{\mathsf{T}}$. Direct substitution then reveals that $X \equiv I$ and $Z \equiv I$ solve the Riccati equations under these constraints. It is easily checked that the optimal value is achieved by the control law $u = -y$, which corresponds to

$$K(s) \equiv [I \ I].$$

A state-space description for $\mathfrak{B}_{R(-s)}$ can be similarly obtained (make the substitutions $A \mapsto -A$ and $B \mapsto -B$ in (3)), leading once more to the Riccati equation solutions $X \equiv I$ and $Z \equiv I$, but this time yielding the optimal control law defined by

$$K(s) \equiv [I \ -I]$$

as required.

(2) $\Rightarrow$ (1): First observe that for any $s \in \mathbb{C}$,

$$\operatorname{rank} R(s)\begin{bmatrix} I \\ -I \end{bmatrix} \leq \min\{\operatorname{rank} R(s), n\}$$

and so there exist no non-zero $v \in \mathcal{L}_2^{\mathrm{loc},n}$ such that

$$R\left(\tfrac{d}{dt}\right)\begin{bmatrix} I \\ -I \end{bmatrix} v = 0$$

only if (Polderman and Willems, 1998, Lemma 5.4.8)

$$\operatorname{rank} R(s) = n \text{ for all } s \in \mathbb{C}. \tag{4}$$

Next observe that if $G(s) \equiv R(s)$ and $K(s) \equiv [I \ I]$, then $\mathfrak{B}_{G(s),K(s)}$ is equal to the set of locally integrable (w, z) such that

$$R\left(\tfrac{d}{dt}\right)\left(w + \begin{bmatrix} I \\ -I \end{bmatrix} v\right) = 0 \text{ and } z = \begin{bmatrix} I \\ -I \end{bmatrix} v.$$

for some $v \in \mathcal{L}_2^{\mathrm{loc},n}$. Therefore under the hypothesis of (2), (4) must hold, otherwise there would exist a v with $\|v\| = 1/\sqrt{2}$ such that for any $\alpha \in \mathbb{R}$

$$\left(-\begin{bmatrix} I \\ -I \end{bmatrix} v, (1+\alpha)\begin{bmatrix} I \\ -I \end{bmatrix} v\right) \in \mathfrak{B}_{R(s),K(s)},$$

which would imply that the performance objective in (1) is infinite. This implies that $\mathfrak{B}$ is behaviorally controllable, from which it follows (Willems, 1991, §8) that there exist matrices of rational functions $\tilde{M}(s)$ and $\tilde{N}(s)$ with no poles in the closed right-half-plane such that

$$\begin{bmatrix} i \\ v \end{bmatrix} \in \mathfrak{B} \quad \Leftrightarrow \quad [-\tilde{M}\left(\tfrac{d}{dt}\right) \ \tilde{N}\left(\tfrac{d}{dt}\right)]\begin{bmatrix} i \\ v \end{bmatrix} = 0.$$

Furthermore it is no loss of generality to assume that this left coprime factorisation is normalised (Vidyasagar (1988)), meaning that for all $\omega \in \mathbb{R}$

$$\tilde{M}(j\omega)\,\tilde{M}(j\omega)^* + \tilde{N}(j\omega)\,\tilde{N}(j\omega)^* = I. \tag{5}$$

From the inequalities on p.70 of Vinnicombe (2000), for this control law to achieve a performance value of $\sqrt{2}$,

$$\sup\left\{\left\|[-\tilde{M}(s) \ \tilde{N}(s)]\begin{bmatrix} \frac{1}{\sqrt{2}}I \\ -\frac{1}{\sqrt{2}}I \end{bmatrix}\right\| : s \in \mathbb{C}, \operatorname{Re}(s) > 0\right\} \geq \frac{1}{\sqrt{2}}.$$

Using (5), the above is equivalent to the inequality

$$\tilde{N}(s)\,\tilde{M}(s)^* + \tilde{M}(s)\,\tilde{N}(s)^* \succeq 0 \tag{6}$$

holding for all $s \in \mathbb{C}$ with $\operatorname{Re}(s) > 0$. Repeating the above steps for $G(s) \equiv R(-s)$ and $K(s) \equiv [I \ -I]$ demonstrates that[3] for all $\omega \in \mathbb{R}$,

$$\tilde{N}(j\omega)\,\tilde{M}(j\omega)^* + \tilde{M}(j\omega)\,\tilde{N}(j\omega)^* \preceq 0. \tag{7}$$

It then follows from (4), (6) and (7) that all the conditions from (Hughes and Branford, 2021, p.21) are satisfied, making $\mathfrak{B}$ the driving point behavior of an LCTG network. □

3. EXAMPLE

The objective of constrained least squares is to find an $\bar{x} \in \mathbb{R}^n$ that satisfies

$$\min_{\bar{x}\in\mathbb{R}^n} \|C\bar{x} - b\|_2, \text{s.t. } A\bar{x} = d, \tag{8}$$

where $C \in \mathbb{R}^{m\times n}$, $A \in \mathbb{R}^{p\times n}$, $b \in \mathbb{R}^m$ and $d \in \mathbb{R}^p$ are the problem data. Constrained least squares encompasses a very broad class of problems including, for example, finite horizon LQR, and includes standard least squares and minimum norm solutions to a set of linear equations as special cases ($p = 0$, and $C = I$ and $b = 0$, respectively). The solution to (8) can be obtained from the Karush-Kuhn-Tucker conditions

$$\begin{bmatrix} -C^{\mathsf{T}}C & -A^{\mathsf{T}} \\ A & 0 \end{bmatrix}\begin{bmatrix} \bar{x} \\ \bar{z} \end{bmatrix} = \begin{bmatrix} -C^{\mathsf{T}}b \\ d \end{bmatrix}, \tag{9}$$

where we assume for simplicity that

i) A is right invertible;
ii) $\begin{bmatrix} C \\ A \end{bmatrix}$ is left invertible;

so that these equations have a unique solution. We will now see that the solution to (9) arises naturally from the solution to Problem 1.

To this end, consider the system

$$\begin{aligned}\tfrac{d}{dt}x &= \begin{bmatrix} 0 & -A^{\mathsf{T}} \\ A & 0 \end{bmatrix}x + \begin{bmatrix} C^{\mathsf{T}} \\ 0 \end{bmatrix}(u + w_1 - r_1) + \begin{bmatrix} 0 \\ I \end{bmatrix}r_2,\\ y &= [C \ 0]x + w_2.\end{aligned} \tag{10}$$

Together (i)-(ii) imply that this realisation is observable and controllable, which implies (Willems, 1972, Theorem 8) that it can be synthesised using p inductors, n capacitors and some transformers. In light of Theorem 1, the control law that minimises (1) (with $r_1 = r_2 = 0$) can be synthesised by connecting unit resistors across each of the external terminal pairs. This maximises robustness with

[3] A small technical point here is that $\tilde{M}(-s)$ and $\tilde{N}(-s)$ do not give a left coprime factorization of $R(-s)$, since the resulting factors have poles in the right-half-plane. Nevertheless it is necessary that the resulting inequalities must still hold on the imaginary axis, which is all that is required to conclude (7).

respect to normalised coprime factor perturbations. We also see from (10) that the closed loop system becomes

$$\frac{d}{dt}x = \begin{bmatrix} -C^{\mathsf{T}}C & -A^{\mathsf{T}} \\ A & 0 \end{bmatrix} x + \begin{bmatrix} C^{\mathsf{T}} \\ 0 \end{bmatrix} (w_1 - r_1) + \begin{bmatrix} 0 \\ I \end{bmatrix} r_2,$$
$$y = [C\ 0]x + w_2.$$

Therefore by applying the step inputs $r_1 = bH(t)$ and $r_2 = dH(t)$, where $H(t)$ denotes the unit step, we see that

$$\lim_{t\to\infty} x(t) = \begin{bmatrix} \bar{x} \\ \bar{z} \end{bmatrix}.$$

This means that for any b and d, the solution to the constrained least squares problem can be obtained by measuring the voltage across the capacitors. Of course it is not necessary to actually use an electrical circuit to implement the optimal control law. These equations could equally well be interpreted as a simple algorithm which can be easily distributed in the case of sparse C and A, and Theorem 1 then shows that this algorithm has excellent robustness properties.

Abstract: We focus on computing certified upper bounds for the positive maximal singular value (PMSV) of a given matrix. The PMSV problem boils down to maximizing a quadratic polynomial on the intersection of the unit sphere and the nonnegative orthant. We provide a hierarchy of tractable semidefinite relaxations to approximate the value of the latter polynomial optimization problem as closely as desired. This hierarchy is based on an extension of Pólya's representation theorem. Doing so, positive polynomials can be decomposed as weighted sums of squares of s-nomials, where s can be a priori fixed ($s = 1$ corresponds to monomials, $s = 2$ corresponds to binomials, etc.). This in turn allows us to control the size of the resulting semidefinite relaxations.

Keywords: Polynomial optimization, Pólya's representation, semidefinite programming, linear programming, second-order conic programming, s-nomials, positive maximal singular value

1. INTRODUCTION

Let $\mathbb{N}$, $\mathbb{R}$, $\mathbb{R}_+$ be the sets of nonnegative integers, real numbers and nonnegative real numbers, respectively. In the present paper, we focus on the problem of computing the positive maximal singular value (PMSV) of a given real matrix $M \in \mathbb{R}^{n\times n}$, denoted by $\sigma_+(M)$. Providing PMSV bounds is crucial for certain induced norm analysis of discrete-time linear time-invariant systems, where the input signals are restricted to be nonnegative; see, e.g., Ebihara et al. (2021). The squared value $\sigma_+(M)^2$ can be obtained by solving the following polynomial maximization problem:

$$\begin{aligned}\sigma_+(M)^2 &= \sup_{x\in\mathbb{R}^n_+}\{x^\top(M^\top M)x \,:\, \|x\|_2^2 = 1\}\,,\\ &= \sup_{x\in\mathbb{R}^n_+}\{x^\top(M^\top M)x \,:\, \|x\|_2^2 \le 1\}\,.\end{aligned} \tag{1}$$

For $m \in \mathbb{N}\backslash\{0\}$, let $[m] := \{1,\dots,m\}$. Note that (1) is a particular instance of a polynomial optimization problem (POP) on the nonnegative orthant:

$$f^\star := \sup_{x\in S} f(x)\,, \tag{2}$$

where f is a polynomial and S is a basic closed semialgebraic set, i.e., the intersection of finitely many polynomial inequalities as follows:

$$S := \{x \in \mathbb{R}^n \,:\, x_i \ge 0\,,\, i \in [n]\,,\, g_j(x) \ge 0\,,\, j \in [m]\}\,, \tag{3}$$

for some $g_j \in \mathbb{R}[x]$, $j \in [m]$ with $g_m := 1$. Letting $x^2 := (x_1^2,\dots,x_n^2)$ and $\check{p}(x) := p(x^2)$ whenever $p \in \mathbb{R}[x]$, it follows that problem (2) is equivalent to solving

$$f^\star = \sup_{x\in\check{S}} \check{f}\,, \tag{4}$$

with

$$\check{S} := \{x \in \mathbb{R}^n \,:\, \check{g}_j(x) \ge 0\,,\, j \in [m]\}\,. \tag{5}$$

In the case of PMSV, one has $m = 2$, $\check{g}_1 = 1 - \sum_{i\in[n]} x_i^4$, $\check{g}_2 = 1$ and $\check{f} = (x^2)^\top M^\top M x^2$.

In Dickinson and Povh (2015), the authors state a specific constrained version of Pólya's Positivstellensatz. Explicitly, if $f, g_1,\dots,g_m$ are homogeneous polynomials, S is defined as in (3), and f is positive on $S\backslash\{0\}$, then

$$(\sum_{j\in[n]} x_j)^k f = \sum_{j\in[m]} \sigma_j g_j\,, \tag{6}$$

for some $k \in \mathbb{N}$ and homogeneous polynomials σ_j with positive coefficients. They also construct a hierarchy of linear relaxations associated with (6) converging from above to $f^\star$.

Contributions. Here, we extend this result to the case where the input polynomials f, g_j are all even, i.e., invariants under any variable sign flip, to get a representation similar to (6), where each multiplier σ_j is a sum of s-nomial squares. The case $s = 1$ corresponds to monomials, yielding a hierarchy of linear programming relaxations similar to Dickinson and Povh (2015), the case $s = 2$ corresponds to binomials, yielding a hierarchy of second-order conic programming relaxations. Fixing $s > 2$ in advance leads to a hierarchy of SDP relaxations with controlled sizes and allows us to overcome the potential ill-conditioning of the linear relaxations. Our optimization framework can be applied in particular to the PMSV problem and we illustrate the related numerical performance at the end of the paper.

Related works. A well-known method to approximate $f^\star$ is to consider the hierarchy of SDP relaxations by Lasserre (2001) based on the representation by Putinar (1993). Namely if f is positive on S and S involves the polynomial $g_1 = L - \|x\|_2^2$ for some $L > 0$, then $f = \sum_{j\in[m]} \sigma_j g_j$ for some SOS polynomials σ_j. The resuling hierarchy of SDP relaxations to approximate $f^\star$ from above is:

$$\inf \left\{ \lambda : \lambda - f = \sum_{j\in[m]} \sigma_j g_j \,, \deg(\sigma_j g_j) \le 2k \right\} . \tag{7}$$

Increasing k imrpoves the accuracy of the resulting upper bounds but the size of the SDP becomes rapidly intractable. To overcome this computational burden, a remedy consists of exploiting sparsity of the input polynomials; see the work by Waki et al. (2006) and Wang et al. (2021a, 2020). Another research direction is to restrict each multiplier σ_j to be a sum of s-nomials. When $s \in \{1, 2\}$, we retrieve the framework by Ahmadi and Majumdar (2019) based on scaled diagonally dominant sums of squares (SDSOS), generalized later on by Gouveia et al. (2022) for arbitrary larger s. However, the resulting hierarchy of linear or second-order conic programming relaxations does not produce a sequence of upper bounds converging to $f^\star$. It turns out that convergence can be obtained by multiplying f by the power of a given positive polynomial, e.g., $1 + \|x\|_2^2$, or equivalently forcing the multipliers σ_j to have denominators. Such representations have been derived in Pólya (1928); Reznick (1995); Putinar and Vasilescu (1999) and the latter led to the optimization framework presented in Mai et al. (2021).

2. EXTENDING PÓLYA'S REPRESENTATION

We now state our main result, which extends Pólya's representation to even input polynomials. In addition, we provide a degree bound for the multipliers.

Theorem 1. Let $g_1, \dots, g_m$ be even polynomials such that $g_1 = L - \|x\|_2^2$ for some $L > 0$ and $g_m = 1$. Let S be the semialgebraic set defined by

$$S := \{x \in \mathbb{R}^n \,:\, g_1(x) \ge 0 \dots, g_m(x) \ge 0\} . \tag{8}$$

Let f be an even polynomial and nonnegative on S and $d_f := \lfloor \deg(f)/2 \rfloor + 1$. Then the following statements hold:

(1) For all $\varepsilon > 0$, there exists $K_\varepsilon \in \mathbb{N}$ such that for all $k \ge K_\varepsilon$, there exist sums of monomial squares σ_j with $\deg(\sigma_j g_j) \le 2(k + d_f)$, $j \in [m]$ and

$$(1 + \|x\|_2^2)^k (f + \varepsilon) = \sum_{j\in[m]} \sigma_j g_j \,. \tag{9}$$

(2) If S has nonempty interior, there exist positive constants $\bar{c}$ and c depending on f and S such that for all $\varepsilon > 0$, (9) holds with $K_\epsilon = \bar{c}\varepsilon^{-c}$.

Theorem 1 can be proved in the same way as (Mai and Magron, 2022, Corollary 2). It is important to note that the theorem still holds if we replace the first constraint polynomial $g_1 = L - \|x\|_2^2$ by $L - \sum_{i\in[n]} x_i^4$ and we do so for the PMSV problem. If we remove the multiplier $(1+\|x\|_2^2)^k$ in (9), Theorem 1 is no longer true. Indeed, let $n = 1$, $f := (x^2 - \frac{3}{2})^2$ and assume that $f = \sigma_1(1-x^2)+\sigma_2$ for some SOS of monomials σ_1, σ_2. Note that f is even and positive on $[-1, 1]$. We write $\sigma_i := a_i + b_i x^2 + x^4 r_i(x)$ for some $a_i, b_i \in \mathbb{R}_+$ and $r_i \in \mathbb{R}[x]$. It implies that

$$\begin{aligned} x^4 - 3x^2 + \frac{9}{4} = {} & (a_1 + b_1 x^2 + x^4 r_1(x))(1 - x^2) \\ & + (a_2 + b_2 x^2 + x^4 r_2(x)) \,. \end{aligned} \tag{10}$$

Then we obtain the system of linear equations: $\frac{9}{4} = a_1 + a_2$ and $-3 = b_2 - a_1 + b_1$. Summing gives $-\frac{3}{4} = a_2 + b_2 + b_1$. However, $a_2 + b_2 + b_1 \ge 0$ since $a_i, b_i \in \mathbb{R}_+$, yielding a contradiction. Thus, Putinar's representation with sums of monomial squares does not exist for even input polynomials. With the multiplier $(1+x^2)^2$, we obtain a Pólya's representation:

$$(1 + x^2)^2 f = \bar{\sigma}_1 (1 - x^2) + \bar{\sigma}_2 \,, \tag{11}$$

where $\bar{\sigma}_1 = x^4 + \frac{15}{4} x^2 + \frac{9}{4}$ and $\bar{\sigma}_2 = x^8$ are SOS of monomials.

3. TRACTABLE SEMIDEFINITE RELAXATIONS

Given $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{N}^n$, we write $x^\alpha = x_1^\alpha \cdots x_n^{\alpha_n}$. An s-nomial square is a polynomial which can be written as $(\sum_{i\in[s]} a_i x^{\alpha(i)})^2$, with $a_i \in \mathbb{R}$, $\alpha(i) \in \mathbb{N}^n$, $i \in [s]$. Let us denote by Σ_s the set of sums of s-nomial squares. The set of monomial squares corresponds to Σ_1. For any $s \in \mathbb{N}\backslash\{0\}$, one has the obvious inclusion $\Sigma_1 \subset \Sigma_s$, thus the representation result (9) from Theorem 1 holds with multipliers $\sigma_j \in \Sigma_s$, $j \in [m]$. With f and S as in Theorem 1, we rely on this representation to derive a converging sequence of upper bounds for $f^\star$. Each upper bound is obtained by solving an SDP, indexed by $s \in \mathbb{N}\backslash\{0\}$ and $k \in \mathbb{N}$:

$$\begin{aligned} \rho_{k,s} := \inf_\lambda \; & \lambda \\ \text{s.t. } & (1 + \|x\|_2^2)^k (\lambda - f) = \sum_{j\in[m]} \sigma_j g_j \,, \\ & \deg(\sigma_j g_j) \le 2(k + d_f) \,,\; \sigma_j \in \Sigma_s \,, j \in [m] \,. \end{aligned} \tag{12}$$

As a consequence of Theorem 1, we obtain the following convergence result.

Corollary 2. Let f and S be as in Theorem 1. The following statements hold:

(1) For all $k \in \mathbb{N}$ and for every $s \in \mathbb{N}\backslash\{0\}$, $\rho_{k,1} \geq \rho_{k,s} \geq f^\star$.
(2) For every $s \in \mathbb{N}\backslash\{0\}$, the sequence $(\rho_{k,s})_{k\in\mathbb{N}}$ converges to $f^\star$.
(3) If S has nonempty interior, there exist positive constants $\bar{c}$ and c depending on f and S such that for every $s \in \mathbb{N}\backslash\{0\}$ and for every $k \in \mathbb{N}$,

$$0 \leq \rho_{k,s} - f^\star \leq \left(\frac{k}{\bar{c}}\right)^{-\frac{1}{c}}. \tag{13}$$

Remark 3. We briefly outline the computational cost of SDP (12). In the case without constraints, one can show that the number of decision variables of is $\binom{n+k}{n} \cdot \binom{s}{2}$, to be compared with $\frac{1}{2}\binom{n+k}{n} \cdot \left(\binom{n+k}{n} + 1\right)$ in the dense case. Therefore, one expects a computational benefit when $s \ll \sqrt{\binom{n+k}{n}}$.

4. NUMERICAL EXPERIMENTS

We demonstrate the accuracy and efficiency of our optimization framework, namely the SDP relaxations (12) based on the extension of Pólya's representation theorem. Our framework is implemented in Julia 1.3.1 and available online via the link `https://github.com/maihoanganh/InterRelax`. We compare the upper bounds and runtime with the ones of the standard SDP relaxations (7), based on Putinar's Positivstellensatz. These latter relaxations are modeled by TSSOS Wang et al. (2021b). All SDP relaxations are solved by the solver Mosek 9.1. We use a desktop computer with an Intel(R) Core(TM) i7-8665U CPU @ 1.9GHz × 8 and 31.2 GB of RAM. Our benchmarks come from induced norm analysis of linear time-invariant systems, where the input signals are restricted to be nonnegative; we generate random matrices M as in (Ebihara et al., 2021, (12)), that is

$$M := \begin{bmatrix} D & 0 & 0 & \dots & 0 \\ CB & D & 0 & \dots & 0 \\ CAB & CB & D & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ CA^{r-2}B & CA^{r-3}B & CA^{r-4}B & \dots & D \end{bmatrix}, \tag{14}$$

where A, B, C, D are square matrices of size r, fixed in advance. In our numerical experiments, we choose $r \in \{4, 5, 6, 7\}$ and every entry of A, B, C, D is taken uniformly in $(-1, 1)$. Note that the number of variables of the resulting POP is $n = r^2$. We associate an "Id" to each related SDP relaxation, in which we compute a decomposition into sums of s-nomial squares. For Putinar's representation, we take a small relaxation order $k \in \{1, 2\}$ while for the extension Pólya's representation we let $k = 0$, leading to decompositions without denominators. We indicate the data of each SDP program, namely "nmat" and "msize" correspond to the number of matrix variables and their largest size, "nscal" and "naff" are the number of scalar variables and affine constraints. The symbol "−" means that the corresponding computation aborted due to lack of memory. The most accurate upper bounds are emphasized in bold. The total running time (including modeling and solving time) is indicated in seconds.

The numerical results are displayed in Table 1. The SDP relaxations associated to our extension of Pólya's representation provide more accurate upper bounds and they are computed more efficiently.

Table 1. Upper bounds of PMSV of M.

On Semi-uniform Input-to-state Stability and Polynomial Input-to-state Stability ⋆

Masashi Wakaiki *

* *Graduate School of System Informatics, Kobe University, Nada, Kobe, Hyogo 657-8501, Japan (e-mail: wakaiki@ruby.kobe-u.ac.jp).*

Abstract: We introduce the notions of semi-uniform input-to-state stability and polynomial input-to-state stability for infinite-dimensional systems. A characterization of semi-uniform input-to-state stability is developed based on attractivity properties as in the uniform case. We also provide sufficient conditions for linear systems to be polynomially input-to-state stable.

Keywords: Infinite-dimensional systems, Input-to-state stability, Polynomial stability

AMS subject classifications: 47D06, 93C25, 93D09

1. INTRODUCTION

The concept of input-to-state stability (ISS), introduced by Sontag (1989) for ordinary differential equations, unifies internal stability with respect to initial states and external stability with respect to disturbances. For infinite-dimensional systems, ISS has been also studied intensively in recent years; see, e.g., the survey article of Mironchenko and Prieur (2020) and the book of Karafyllis and Krstic (2019). In this talk, we introduce the notions of semi-uniform ISS and its subclass, polynomial ISS.

Semi-uniform stability of operator semigroups implies the uniform asymptotic behavior of semigroup orbits with respect to initial values from the unit ball of the domain of the generator endowed with the graph norm. In this sense, semi-uniform stability lies between exponential stability and strong stability. We refer the reader to the overview of Chill et al. (2020) for the recent developments of semi-uniform stability. The motivation of introducing semi-uniform ISS is to bridge the gap between uniform ISS and strong ISS as in the semigroup case.

In this talk, we present results recently obtained by Wakaiki (2022). First, we characterize semi-uniform ISS by using attractivity properties. This result is the semi-uniform version of the characterizations of uniform/strong ISS in Theorems 5 and 12 of Mironchenko and Wirth (2018). By this characterization, we show that semi-uniform ISS implies strong ISS for bilinear systems. Next, we provide sufficient conditions for linear systems to be polynomially ISS. Under the sufficient conditions, the range of an input operator is restricted depending on the polynomial decay rate of $\|T(t)A^{-1}\|$, where $(T(t))_{t\geq 0}$ is the polynomially stable semigroup governing the state evolution of the system without inputs and A is its generator.

2. DEFINITIONS

Let X and U be Banach spaces with norm $\|\cdot\|$ and $\|\cdot\|_U$, respectively. Let $\mathcal{U}$ be a normed vector space contained in the space $L^1_{\mathrm{loc}}(\mathbb{R}_+, U)$ of all locally integrable functions from $\mathbb{R}_+$ to U. We denote by $\|\cdot\|_{\mathcal{U}}$ the norm on $\mathcal{U}$. Assume that $u(\cdot+\tau) \in \mathcal{U}$ and $\|u\|_{\mathcal{U}} \geq \|u(\cdot+\tau)\|_{\mathcal{U}}$ for all $u \in \mathcal{U}$ and $\tau \geq 0$.

Consider a semi-linear system with state space X and input space U:

$$\Sigma(A,F) \quad \begin{cases} \dot{x}(t) = Ax(t) + F\big(x(t), u(t)\big), & t \geq 0 \\ x(0) = x_0, \end{cases}$$

where A is the generator of a C_0-semigroup $(T(t))_{t\geq 0}$ on X, $F : X \times U \to X$ is a nonlinear operator, $x_0 \in X$ is an initial state, and $u \in \mathcal{U}$ is an input.

Definition 1. Suppose that for every $\tau > 0$, $f \in C([0,\tau], X)$, and $g \in \mathcal{U}$, the map $t \mapsto F(f(t), g(t))$ is integrable on $[0,\tau]$. For $\tau > 0$, a function $x \in C([0,\tau], X)$ is called *a mild solution of* $\Sigma(A,F)$ *on* $[0,\tau]$ if x satisfies the integral equation

$$x(t) = T(t)x_0 + \int_0^t T(t-s)F\big(x(s), u(s)\big)ds$$

for all $t \in [0,\tau]$. Moreover, we say that $x \in C(\mathbb{R}_+, X)$ is *a mild solution of* $\Sigma(A,F)$ *on* $\mathbb{R}_+$ if $x|_{[0,\tau]}$ is a mild solution of $\Sigma(A,F)$ on $[0,\tau]$ for all $\tau > 0$.

Throughout this talk, we consider only forward complete systems defined as follows.

Definition 2. The semi-linear system $\Sigma(A,F)$ is *forward complete* if there exists a unique mild solution of $\Sigma(A,F)$ on $\mathbb{R}_+$ for all $x_0 \in X$ and $u \in \mathcal{U}$.

We denote by $\phi(t, x_0, u)$ the unique mild solution of the forward complete semi-linear system $\Sigma(A,F)$ with initial state $x_0 \in X$ and input $u \in \mathcal{U}$, i.e.,

$$\phi(t, x_0, u) := T(t)x_0 + \int_0^t T(t-s)F\big(\phi(s, x_0, u), u(s)\big)ds$$

for $t \geq 0$.

Let $\mathcal{K}_\infty$ and $\mathcal{KL}$ be the sets of the classic comparison functions from nonlinear systems theory. For the forward complete semi-linear system $\Sigma(A,F)$, we introduce the no-

⋆ This work was supported by JSPS KAKENHI Grant Number JP20K14362.

tion of semi-uniform input-to-state stability. Before doing so, we recall the definition of uniform global stability.

Definition 3. The semi-linear system $\Sigma(A,F)$ is called *uniformly globally stable (UGS)* if the following two conditions hold:

(1) $\Sigma(A,F)$ is forward complete;
(2) there exist $\gamma,\mu\in\mathcal{K}_\infty$ such that
$$\|\phi(t,x_0,u)\|\le\gamma(\|x_0\|)+\mu(\|u\|_{\mathcal{U}})$$
for all $x_0\in X$, $u\in\mathcal{U}$, and $t\ge 0$.

The graph norm $\|\cdot\|_A$ of a linear operator $A:D(A)\subset X\to X$ is defined by $\|x\|_A:=\|x\|+\|Ax\|$ for $x\in D(A)$.

Definition 4. The semi-linear system $\Sigma(A,F)$ is called *semi-uniformly input-to-state stable (semi-uniformly ISS)* if the following two conditions hold:

(1) $\Sigma(A,F)$ is UGS;
(2) there exist $\kappa\in\mathcal{KL}$ and $\mu\in\mathcal{K}_\infty$ such that
$$\|\phi(t,x_0,u)\|\le\kappa(\|x_0\|_A,t)+\mu(\|u\|_{\mathcal{U}})$$
for all $x_0\in D(A)$, $u\in\mathcal{U}$, and $t\ge 0$.

In particular, if there exists $\alpha>0$ such that for all $r>0$, $\kappa(r,t)=O(t^{-1/\alpha})$ as $t\to\infty$, then $\Sigma(A,F)$ is called *polynomially input-to-state stable (polynomially ISS) with parameter* α.

3. CHARACTERIZATION OF SEMI-UNIFORM ISS

We establish a characterization of semi-uniform ISS. The following two semi-uniform attractivity properties are used for the characterization.

Definition 5. The forward complete semi-linear system $\Sigma(A,F)$ has the *semi-uniform limit property* if there exists $\mu\in\mathcal{K}_\infty$ such that the following statement holds: For all $\varepsilon,r>0$, there is $\tau=\tau(\varepsilon,r)<\infty$ such that for all $x_0\in D(A)$,
$$\|x_0\|_A\le r\ \ \wedge\ \ u\in\mathcal{U}$$
$$\Rightarrow\quad\exists t\le\tau:\|\phi(t,x_0,u)\|\le\varepsilon+\mu(\|u\|_{\mathcal{U}}).$$

Definition 6. The forward complete semi-linear system $\Sigma(A,F)$ has the *semi-uniform asymptotic gain property* if there exists $\mu\in\mathcal{K}_\infty$ such that the following statement holds: For all $\varepsilon,r>0$, there is $\tau=\tau(\varepsilon,r)<\infty$ such that for all $x_0\in X$ with $\|x_0\|_A\le r$ and all $u\in\mathcal{U}$,
$$t\ge\tau\quad\Rightarrow\quad\|\phi(t,x_0,u)\|\le\varepsilon+\mu(\|u\|_{\mathcal{U}}).$$

Theorem 7. The following statements on the semi-linear system $\Sigma(A,F)$ are equivalent:

1. *$\Sigma(A,F)$ is semi-uniformly ISS.*
2. *$\Sigma(A,F)$ is UGS and has the semi-uniform limit property.*
3. *$\Sigma(A,F)$ is UGS and has the semi-uniform asymptotic gain property.*

For linear systems and bilinear systems, semi-uniform ISS implies strong ISS introduced in Definition 13 of Mironchenko and Wirth (2018); see also Nabiullin and Schwenninger (2018) for strong ISS.

Theorem 8. Assume that the operator F of $\Sigma(A,F)$ satisfies one of the following conditions:

1. *There exists $B\in\mathcal{L}(U,X)$ such that $F(\xi,v)=Bv$ for all $\xi\in X$ and $v\in U$.*
2. *For all $\xi,\zeta\in X$ and $v\in U$,*
$$F(\xi-\zeta,v)=F(\xi,v)-F(\zeta,v).$$

Then semi-uniform ISS implies strong ISS for $\Sigma(A,F)$.

4. POLYNOMIAL ISS OF LINEAR SYSTEMS

We recall the definition of polynomially stable semigroups.

Definition 9. A C_0-semigroup $(T(t))_{t\ge0}$ on a Banach space X generated by $A:D(A)\subset X\to X$ is called *polynomially stable with parameter* $\alpha>0$ if $(T(t))_{t\ge0}$ is uniformly bounded, if $\sigma(A)$ is contained in the open left half-plane, and if $\|T(t)A^{-1}\|=O\left(t^{-1/\alpha}\right)$ as $t\to\infty$.

Consider a linear system
$$\Sigma_{\rm lin}(A,B)\quad\begin{cases}\dot x(t)=Ax(t)+Bu(t),\quad t\ge0\\ x(0)=x_0,\end{cases}$$
where A is the generator of a polynomially stable semigroup on X and $B\in\mathcal{L}(U,X)$. We provide a simple sufficient condition for $\Sigma_{\rm lin}(A,B)$ to be polynomially ISS, by restricting the range of the input operator B.

Proposition 10. Let X and U be Banach spaces. Suppose that A generates a polynomially stable semigroup with parameter $\alpha>0$ on X. If $B\in\mathcal{L}(U,X)$ satisfies $\mathrm{ran}(B)\subset D((-A)^\beta)$ for some $\beta>\alpha$, then $\Sigma_{\rm lin}(A,B)$ is polynomially ISS with parameter α for $\mathcal{U}=L^\infty(\mathbb{R}_+,U)$.

We obtain a refined sufficient condition for polynomial ISS when linear systems are consisted of diagonalizable generators and finite-rank input operators; see Section 2.6 of Tucsnak and Weiss (2009) for diagonalizable operators.

Theorem 11. Let X be a Hilbert space and let U be a Banach space. Suppose that A is a diagonalizable operator generating a polynomially stable semigroup with parameter $\alpha>0$ on X. If $B\in\mathcal{L}(U,X)$ is a finite-rank operator and satisfies $\mathrm{ran}(B)\subset D((-A)^\alpha)$, then $\Sigma_{\rm lin}(A,B)$ is polynomially ISS with parameter α for $\mathcal{U}=L^\infty(\mathbb{R}_+,U)$.

Abstract: We describe here a non-intrusive data-driven time-domain formulation of balanced truncation (BT) for bilinear control systems. We build on the recent method of Gosea et al. (2021) that recasts the classic BT method for linear time invariant systems as a data-driven method requiring only evaluations of either transfer function values or impulse responses. We extend the domain of applicability of this non-intrusive data-driven method to bilinear systems, arguably the simplest nontrivial class of weakly nonlinear systems.

Keywords: data-driven modeling, balanced truncation, model reduction, bilinear dynamics

1. INTRODUCTION

Bilinear dynamical systems (BDS) are an important class of weakly nonlinear systems that appear naturally in many applications, see, e.g., Mohler (1970, 1973); Al-Baiyat et al. (1993); Saputra et al. (2019); Qian and Zhang (2014). They may be described through a state-space realization given as

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{b}\,u(t) + \mathbf{M}\mathbf{x}(t)u(t), \quad y(t) = \mathbf{c}^T\mathbf{x}(t), \quad (1)$$

where $\mathbf{x}(t) : \mathbb{R} \to \mathbb{R}^n$ is the system state, $u(t) : \mathbb{R} \to \mathbb{R}$ is a (scalar) control input, and system matrices are given by $\mathbf{A}, \mathbf{M} \in \mathbb{R}^{n\times n}$ and $\mathbf{b}, \mathbf{c} \in \mathbb{R}^n$. For simplicity, we describe only the case of single-input single-output (SISO) BDS's; the analysis can be extended to multi-input multi-output (MIMO) scenarios without difficulty.

In many applications of interest, the BDS represented in (1) has large state-space dimension and one seeks to reduce the model order to mitigate computational burdens arising in subsequent simulation and control. Many systems theoretic model reduction methods have been extended to reducing BDS; see, e.g., Antoulas et al. (2016a); Benner and Breiten (2012); Benner and Damm (2011b); Flagg and Gugercin (2015); Goyal (2018) and references therein. Balanced truncation (BT) in particular Mullis and Roberts (1976); Moore (1981) has long been one of the gold standards of model reduction. Classic BT is an intrusive projection-based method, requiring access to internal realizations of system dynamics. In recent work Gosea et al. (2021), we have developed a data-driven formulation of BT (called QuadBT), that only requires access system response sampling (either through transfer function evaluation or impulse response observation), but requires neither state-space realizations nor observations of the system state. The goal of this note is to extend this data-driven reformulation of BT to BDS.

The extension of BT to bilinear systems is well established, and generally requires the extraction of system Gramians through the solution of generalized ("bilinear") Lyapunov equations (in lieu of the classical Lyapunov equations used for LTI systems). The key to extending both BT, as well as our data-driven reformulation of it, QuadBT, to bilinear systems relies on the *Volterra series* representation of the BDS system response. Under mild assumptions, one may develop the solution of (1) as $\mathbf{x}(t) = \sum_{k=1}^{\infty} \mathbf{x}_k(t)$ (see Rugh (1981)), where

$$\begin{aligned} \dot{\mathbf{x}}_1(t) &= \mathbf{A}\mathbf{x}_1(t) + \mathbf{b}u(t), \text{ and} \\ \dot{\mathbf{x}}_k(t) &= \mathbf{A}\mathbf{x}_k(t) + \mathbf{M}\mathbf{x}_{k-1}(t)u(t), \text{ for } k > 1. \end{aligned} \quad (2)$$

The output is similarly expressed: $y(t) = \sum_{k=1}^{\infty} y_k(t)$, with $y_k(t) = \mathbf{c}^T\mathbf{x}_k(t)$, for $k \geq 1$, and so, the initial BDS may be recast as a cascade of coupled linear subsystems.

2. DATA-DRIVEN BILINEAR BT

The Volterra formalism of (2) may be resolved via variation of parameters and collected into an explicit series representation as in (3). This *Volterra series* comprises an infinite series of multivariate convolution integrals, and the kernel associated with the kth term, $h_k(t, \tau_1, \tau_2, \ldots, \tau_k)$, is called the *$k$th triangular Volterra kernel*.

Assigning $\tau_0 = t$ and introducing the change of variables $t_{k-i} = \tau_i - \tau_{i+1}$, for $i = 0, 1, \ldots, k-1$, one obtains the so-called *kth regular Volterra kernel*, which we write without a change in notation as

$$h_k(t_1, t_2, \ldots, t_k) = \mathbf{c}^T e^{\mathbf{A}t_k}\mathbf{M}e^{\mathbf{A}t_{k-1}} \cdots \mathbf{M}e^{\mathbf{A}t_1}\mathbf{b}, \quad k \geq 1.$$

A multivariate Laplace transform of $h_k(t_1, \ldots, t_k)$ yields the multivariate transfer function:

$$\begin{aligned} H(s_1, \ldots, s_k) = \mathbf{c}^T(s_k\mathbf{I} - \mathbf{A})^{-1}\mathbf{M}(s_{k-1}\mathbf{I} - \mathbf{A})^{-1}\mathbf{M}\cdots \\ \cdots \mathbf{M}(s_2\mathbf{I} - \mathbf{A})^{-1}\mathbf{M}(s_1\mathbf{I} - \mathbf{A})^{-1}\mathbf{b}. \end{aligned}$$

$$y(t) = \sum_{k=1}^{\infty} \int_0^t \int_0^{\tau_1} \cdots \int_0^{\tau_{k-1}} \underbrace{\mathbf{c}^T e^{\mathbf{A}(t-\tau_1)} \mathbf{M} e^{\mathbf{A}(\tau_1-\tau_2)} \cdots \mathbf{M} e^{\mathbf{A}(\tau_{k-1}-\tau_k)} \mathbf{b}}_{h_k(t,\tau_1,\tau_2,\ldots,\tau_k)} u(\tau_k) \cdots u(\tau_1)\, d\tau_k \cdots d\tau_1. \tag{3}$$

Not surprisingly, $h_k(t_1, \ldots, t_k)$ and $H(s_1, \ldots, s_k)$ extend the usual univariate impulse response and associated transfer function from linear problems to nonlinear problems and so form a basic building block for extending linear system-theoretic approaches for data-driven modeling to nonlinear dynamical systems.

In the LTI case (i.e., $\mathbf{M} = \mathbf{0}$ in (1)), the Gramians are defined in the time domain as $\mathbf{P} = \int_0^\infty e^{\mathbf{A}t}\mathbf{b}\mathbf{b}^T e^{\mathbf{A}^T t} dt$ and $\mathbf{Q} = \int_0^\infty e^{\mathbf{A}^T t}\mathbf{c}\mathbf{c}^T e^{\mathbf{A}t} dt$. For bilinear systems, the corresponding algebraic Gramians are based on the Volterra series expansion for $y(t)$ and are naturally defined as (Al-Baiyat and Bettayeb (1993); D'Alessandro et al. (1974))

$$\mathbf{P} = \sum_{k=1}^{\infty} \int_0^\infty \cdots \int_0^\infty \mathbf{z}_k \mathbf{z}_k^T dt_1 \ldots dt_k, \tag{4}$$

where

$$\begin{cases} \mathbf{z}_1(t_1) = e^{\mathbf{A}t_1}\mathbf{b}, & \text{for } k = 1, \\ \mathbf{z}_k(t_1, \ldots, t_k) = e^{\mathbf{A}t_k}\mathbf{M}\mathbf{z}_{k-1}, & \text{for } k \geq 2, \end{cases} \tag{5}$$

with analogous expressions for $\mathbf{Q}$. Under conditions sufficient to guarantee convergence of these infinite sums Zhang and Lam (2002), the Gramians $\mathbf{P}$ and $\mathbf{Q}$ solve the "bilinear Lyapunov equations"

$$\begin{aligned} \mathbf{A}\mathbf{P} + \mathbf{P}\mathbf{A}^T + \mathbf{M}\mathbf{P}\mathbf{M}^T + \mathbf{b}\mathbf{b}^T = \mathbf{0} \qquad \text{and} \\ \mathbf{A}^T\mathbf{Q} + \mathbf{Q}\mathbf{A}^T + \mathbf{M}^T\mathbf{Q}\mathbf{M} + \mathbf{c}\mathbf{c}^T = \mathbf{0}. \end{aligned} \tag{6}$$

Assuming the system (1) is reachable and observable, then $\mathbf{P}$ and $\mathbf{Q}$ are positive definite matrices. See Zhang and Lam (2002) for details. The bilinear extension of the classical BT then proceeds as for the linear case. Let $\mathbf{U}, \mathbf{L} \in \mathbb{R}^{n\times n}$ be the square-root factors, i.e.,

$$\mathbf{P} = \mathbf{U}\mathbf{U}^T \quad \text{and} \quad \mathbf{Q} = \mathbf{L}\mathbf{L}^T. \tag{7}$$

Then, pick a truncation index, $1 \leq r \leq n$ and compute the SVD of the matrix $\mathbb{L} = \mathbf{L}^T\mathbf{U}$, which is then partitioned as

$$\mathbb{L} = \mathbf{L}^T\mathbf{U} = [\mathbf{Z}_1 \ \mathbf{Z}_2] \begin{bmatrix} \mathbf{S}_1 & \\ & \mathbf{S}_2 \end{bmatrix} \begin{bmatrix} \mathbf{Y}_1^T \\ \mathbf{Y}_2^T \end{bmatrix}, \quad \begin{matrix} \mathbf{S}_1 \in \mathbb{R}^{r\times r}, \\ \mathbf{S}_2 \in \mathbb{R}^{(n-r)\times(n-r)}. \end{matrix} \tag{8}$$

The singular values of $\mathbb{L} = \mathbf{L}^T\mathbf{U}$ (i.e., the diagonal entries of $\mathsf{diag}(\mathbf{S}_1, \mathbf{S}_2)$ in (8)) are called the *Hankel singular values* of the underlying bilinear system. These values are system invariants, i.e., they are independent of realization. BT proceeds by truncating system states that correspond to small Hankel singular values in $\mathbf{S}_2$. Model reduction bases are then constructed from $\mathbf{W}_r = \mathbf{L}\mathbf{Z}_1\mathbf{S}_1^{-1/2}$ and $\mathbf{V}_r = \mathbf{U}\mathbf{Y}_1\mathbf{S}_1^{-1/2}$. As a consequence, the reduced order bilinear model can be constructed as

$$\begin{aligned} \hat{\mathbf{A}} &= \mathbf{W}_r^T\mathbf{A}\mathbf{V}_r = \mathbf{S}_1^{-1/2}\mathbf{Z}_1^T(\mathbf{L}^T\mathbf{A}\mathbf{U})\mathbf{Y}_1\mathbf{S}_1^{-1/2}, \\ \hat{\mathbf{M}} &= \mathbf{W}_r^T\mathbf{M}\mathbf{V}_r = \mathbf{S}_1^{-1/2}\mathbf{Z}_1^T(\mathbf{L}^T\mathbf{M}\mathbf{U})\mathbf{Y}_1\mathbf{S}_1^{-1/2} \\ \hat{\mathbf{b}} &= \mathbf{W}_r^T\mathbf{b} = \mathbf{S}_1^{-1/2}\mathbf{Z}_1^T(\mathbf{L}^T\mathbf{b}), \\ \text{and} \quad \hat{\mathbf{c}} &= \mathbf{V}_r^T\mathbf{c} = \mathbf{S}_1^{-1/2}\mathbf{Y}_1^T(\mathbf{U}^T\mathbf{c}). \end{aligned} \tag{9}$$

This provides a high-fidelity, input-independent, reduced-order bilinear model. However, this approach is *projection-based* and hence *intrusive*, a drawback that we intend to improve upon. The key to our approach is the observation is that BT for bilinear systems does not require explicit access either to $\mathbf{U}$ or to $\mathbf{L}$; instead it needs (the SVD of) $\mathbb{L} = \mathbf{L}^T\mathbf{U}$ in (8), and the related expressions $\mathbf{L}^T\mathbf{A}\mathbf{U}$, $\mathbf{L}^T\mathbf{M}\mathbf{U}$, $\mathbf{L}^T\mathbf{b}$, and $\mathbf{U}^T\mathbf{c}$ in (9). We describe below how all these quantities can be approximated using only input/output data, without access to internal variables.

Even though the bilinear Lyapunov equations of (6) are linear in the unknowns, $\mathbf{P}$ and $\mathbf{Q}$, the terms $\mathbf{M}\mathbf{P}\mathbf{M}^T$ and $\mathbf{M}^T\mathbf{Q}\mathbf{M}$ create significant computational bottlenecks for large-scale problems. We refer the reader to, e.g., Kürschner (2016); Benner and Damm (2011a); Benner and Breiten (2013) and the references therein for some solution techniques.

One way of addressing this computational cost is to note that the terms in the infinite series (4) often decay rapidly and the whole series can be well approximated using only the leading two or three terms. This motivates the definition of truncated Gramians, $\mathbf{P}_T$ and $\mathbf{Q}_T$, which are obtained by truncating the series (4) after T terms. For example, if we pick a truncation index of $T = 2$, the corresponding truncated Gramian, $\mathbf{P}_T$, is

$$\begin{aligned} \mathbf{P}_T = &\int_0^\infty e^{\mathbf{A}t_1}\mathbf{b}\mathbf{b}^T e^{\mathbf{A}^T t_1} dt_1 \\ &+ \int_0^\infty \int_0^\infty e^{\mathbf{A}t_2}\mathbf{M}e^{\mathbf{A}t_1}\mathbf{b}\mathbf{b}^T e^{\mathbf{A}^T t_1}\mathbf{M}^T e^{\mathbf{A}^T t_2} dt_1 dt_2, \end{aligned}$$

with a similar expression for $\mathbf{Q}_T$. $\mathbf{P}_T$ and $\mathbf{Q}_T$ can be computed recursively in the following way: Notice that $\mathbf{P}_T$ can be written as $\mathbf{P}_T = \mathbf{P}_1 + \mathbf{P}_2$, where $\mathbf{P}_1$ and $\mathbf{P}_2$ solve

$$\begin{aligned} \mathbf{A}\mathbf{P}_1 + \mathbf{P}_1\mathbf{A}^T + \mathbf{b}\mathbf{b}^T = \mathbf{0} \quad &\Longrightarrow \quad \mathbf{P}_1 = \mathbf{U}_1\mathbf{U}_1^T \\ \mathbf{A}\mathbf{P}_2 + \mathbf{P}_2\mathbf{A}^T + \mathbf{M}\mathbf{U}_1(\mathbf{M}\mathbf{U}_1)^T = \mathbf{0} \quad &\Longrightarrow \quad \mathbf{P}_2 = \mathbf{U}_2\mathbf{U}_2^T, \end{aligned} \tag{10}$$

where $\mathbf{U}_1$ and $\mathbf{U}_2$ are the square-root factors of $\mathbf{P}_1$ and $\mathbf{P}_2$. Note $\mathbf{P}_1$ and $\mathbf{P}_2$ can be written in time domain as

$$\mathbf{P}_1 = \int_0^\infty e^{\mathbf{A}t}\mathbf{b}\mathbf{b}^T e^{\mathbf{A}^T t} dt \quad \text{and} \tag{11}$$

$$\mathbf{P}_2 = \int_0^\infty e^{\mathbf{A}t}(\mathbf{M}\mathbf{U}_1)(\mathbf{M}\mathbf{U}_1)^T e^{\mathbf{A}^T t} dt. \tag{12}$$

This provides a direct path forward for us, since we can use numerical quadratures on (11) and (12) to approximate the square-roots factors $\mathbf{U}_1$ and $\mathbf{U}_2$. Let $\widetilde{\mathbf{U}}_1$ and $\widetilde{\mathbf{U}}_2$ be the approximate square roots obtained via numerical quadrature on (11) and (12), respectively. Then, an approximate square-root factor $\widetilde{\mathbf{U}}$ for $\mathbf{P}_T$ can be represented in terms of $\widetilde{\mathbf{U}}_1$ and $\widetilde{\mathbf{U}}_2$:

$$\begin{aligned} \mathbf{P}_T = \mathbf{P}_1 + \mathbf{P}_2 &\approx \widetilde{\mathbf{U}}_1\widetilde{\mathbf{U}}_1^T + \widetilde{\mathbf{U}}_2\widetilde{\mathbf{U}}_2^T \\ &= \begin{bmatrix} \widetilde{\mathbf{U}}_1 & \widetilde{\mathbf{U}}_2 \end{bmatrix} \begin{bmatrix} \widetilde{\mathbf{U}}_1 & \widetilde{\mathbf{U}}_2 \end{bmatrix}^T = \widetilde{\mathbf{U}}\widetilde{\mathbf{U}}^T. \end{aligned} \tag{13}$$

One can similarly define a truncated observability Gramian $\mathbf{Q}_T$, which can be written as $\mathbf{Q}_T = \mathbf{Q}_1 + \mathbf{Q}_2$ (analogous to (10)) with the corresponding time-domain formula (analogous to (11) and (12)). Let $\widetilde{\mathbf{L}}_1$ and $\widetilde{\mathbf{L}}_2$ be the approximate square factors for $\mathbf{Q}_1$ and $\mathbf{Q}_2$, respectively, obtained via a numerical quadrature. Then

$$\begin{aligned}\mathbf{Q}_T = \mathbf{Q}_1 + \mathbf{Q}_2 &\approx \widetilde{\mathbf{L}}_1\widetilde{\mathbf{L}}_1^T + \widetilde{\mathbf{L}}_2\widetilde{\mathbf{L}}_2^T \\ &= \begin{bmatrix}\widetilde{\mathbf{L}}_1 & \widetilde{\mathbf{L}}_2\end{bmatrix}\begin{bmatrix}\widetilde{\mathbf{L}}_1 & \widetilde{\mathbf{L}}_2\end{bmatrix}^T = \widetilde{\mathbf{L}}\widetilde{\mathbf{L}}^T,\end{aligned} \tag{14}$$

thus given an approximate square-root factor $\widetilde{\mathbf{L}}$ for $\mathbf{Q}_T$.

Recall (8): BT requires forming the SVD of $\mathbb{L} = \mathbf{L}^T\mathbf{U}$. Approximate $\mathbb{L}$ using the approximate square-roots $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{L}}$; i.e.,

$$\widetilde{\mathbb{L}} = \widetilde{\mathbf{L}}^T\widetilde{\mathbf{U}} = \begin{bmatrix}\widetilde{\mathbf{L}}_1^T\widetilde{\mathbf{U}}_1 & \widetilde{\mathbf{L}}_1^T\widetilde{\mathbf{U}}_2 \\ \widetilde{\mathbf{L}}_2^T\widetilde{\mathbf{U}}_1 & \widetilde{\mathbf{L}}_2^T\widetilde{\mathbf{U}}_2\end{bmatrix}.$$

Our preliminary analysis below shows that as in data-driven BT for the LTI case Gosea et al. (2021), we will be able to evaluate $\widetilde{\mathbb{L}}$ (and thus its SVD) directly from input-output data.

To briefly illustrate this, apply a rectangular quadrature scheme to approximate the Gramians in (11) and (12) with two nodes in time, say τ_1 and τ_2. Then, we obtain,

$$\widetilde{\mathbf{U}_1} = [\mathbf{z}_1(\tau_1)\ \mathbf{z}_1(\tau_2)],$$
$$\widetilde{\mathbf{U}_2} = [\mathbf{z}_2(\tau_1,\tau_1)\ \mathbf{z}_2(\tau_1,\tau_2)\ \mathbf{z}_2(\tau_2,\tau_1)\ \mathbf{z}_2(\tau_2,\tau_2)],$$

where $\mathbf{z}_1(t_1) = e^{\mathbf{A}t_1}\mathbf{b}$ and $\mathbf{z}_2(t_1,t_2) = e^{\mathbf{A}t_1}\mathbf{M}e^{\mathbf{A}t_2}\mathbf{b}$, (with the goal of $\mathbf{P}_1 \approx \widetilde{\mathbf{U}}_1\widetilde{\mathbf{U}}_1^T$ and $\mathbf{P}_2 \approx \widetilde{\mathbf{U}}_2\widetilde{\mathbf{U}}_2^T$). Similarly,

$$\widetilde{\mathbf{L}_1} = [\mathbf{w}_1(\tau_1)\ \mathbf{w}_1(\tau_2)],$$
$$\widetilde{\mathbf{L}_2} = [\mathbf{w}_2(t_1,t_1)\ \mathbf{w}_2(\tau_1,\tau_2)\ \mathbf{w}_2(\tau_2,\tau_1)\ \mathbf{w}_2(\tau_2,\tau_2)],$$

where $\mathbf{w}_1(t_1) = e^{\mathbf{A}^Tt_1}\mathbf{c}^T$ and $\mathbf{w}_2(t_1,t_2) = e^{\mathbf{A}^Tt_1}\mathbf{M}^Te^{\mathbf{A}^Tt_2}\mathbf{c}^T$ (with the goal of $\mathbf{Q}_1 \approx \widetilde{\mathbf{L}}_1\widetilde{\mathbf{L}}_1^T$ and $\mathbf{Q}_2 \approx \widetilde{\mathbf{L}}_2\widetilde{\mathbf{L}}_2^T$). Hence, for this simple set-up, one can show that

$$\widetilde{\mathbf{L}_1}^T\widetilde{\mathbf{U}_1} = \begin{bmatrix}h_1(2\tau_1) & h_1(\tau_1+\tau_2) \\ h_1(\tau_1+\tau_2) & h_2(2\tau_2)\end{bmatrix},$$
$$\widetilde{\mathbf{L}_1}^T\widetilde{\mathbf{U}_2} = \begin{bmatrix}h_2(2\tau_1,\tau_1) & \dots & h_2(\tau_1+\tau_2,\tau_2) \\ h_2(\tau_1+\tau_2,\tau_1) & \dots & h_2(2\tau_2,\tau_2)\end{bmatrix},$$
$$\widetilde{\mathbf{L}_2}^T\widetilde{\mathbf{U}_1} = \begin{bmatrix}h_2(\tau_1,2\tau_1) & h_2(\tau_1,\tau_1+\tau_2) \\ \vdots & \vdots \\ h_2(\tau_2,\tau_1+\tau_2) & h_2(\tau_2,2\tau_2)\end{bmatrix},$$
$$\widetilde{\mathbf{L}_2}^T\widetilde{\mathbf{U}_2} = \begin{bmatrix}h_3(\tau_1,2\tau_1,\tau_1) & \dots & h_3(\tau_1,2\tau_2,\tau_2) \\ \vdots & \ddots & \vdots \\ h_3(\tau_2,\tau_2+\tau_1,\tau_2) & \dots & h_3(\tau_2,2\tau_2,\tau_2)\end{bmatrix}$$
